z/OS Communications Server

IP Configuration Guide

Version 1 Release 12

SC31-8775-18

z/OS Communications Server

IP Configuration Guide

Version 1 Release 12

SC31-8775-18

Note:
Before using this information and the product it supports, be sure to read the general information under "Notices" on page 1575.

Nineteenth Edition (April 2011)

This edition applies to Version 1 Release 12 of z/OS (5694-A01) and to all subsequent releases and modifications until otherwise indicated in new editions.

IBM welcomes your comments. You may send your comments to the following address.

International Business Machines Corporation
Attn: z/OS Communications Server Information Development
Department AKCA, Building 501
P.O. Box 12195, 3039 Cornwallis Road
Research Triangle Park, North Carolina 27709-2195

You can send us comments electronically by using one of the following methods:

Fax (USA and Canada):

1+919-254-1258

Send the fax to "Attn: z/OS Communications Server Information Development"

Internet e-mail:

comsvrcf@us.ibm.com

World Wide Web:

http://www.ibm.com/systems/z/os/zos/webqs.html

If you would like a reply, be sure to include your name, address, telephone number, or FAX number. Make sure to include the following in your comment or note:

- Title and order number of this document
- Page number or topic related to your comment

When you send information to IBM, you grant IBM a nonexclusive right to use or distribute the information in any way it believes appropriate without incurring any obligation to you.

About this document

This document contains guidance material to enable you to configure IP address spaces, servers, and applications for z/OS® Communications Server. This volume is part of a two-volume set:

- *z/OS Communications Server: IP Configuration Guide*, which contains concepts and guidance, explaining an overall approach to IP configuration.
- *z/OS Communications Server: IP Configuration Reference*, which describes parameters, options, and syntax of statements.

The information in this document includes descriptions of support for both IPv4 and IPv6 networking protocols. Unless explicitly noted, descriptions of IP protocol support concern IPv4. IPv6 support is qualified within the text.

For detailed information about configuration-related data sets and statements, see *z/OS Communications Server: IP Configuration Reference*.

For detailed information about commands used during configuration, see *z/OS Communications Server: IP System Administrator's Commands*.

This document refers to Communications Server data sets by their default SMP/E distribution library name. Your installation might, however, have different names for these data sets where allowed by SMP/E, your installation personnel, or administration staff. For instance, this document refers to the *hlq*.SEZAINST samples data set simply as SEZAINST. Your installation might choose a data set name of SYS1.SEZAINST, CS390.SEZAINST, or other high level qualifiers for the data set name.

Who should read this document

This document is intended for programmers and system administrators who are familiar with TCP/IP, MVS™, z/OS UNIX, and the Time Sharing Option Extensions (TSO/E).

How this document is organized

This document is divided into the following parts:

Part 1, "Base TCP/IP system," on page 1 contains information on configuring the base TCP/IP stack.

Part 2, "Server applications," on page 511 contains information that explains the server applications for z/OS Communications Server.

Part 3, "Appendixes" provides additional information for this document.

"Notices" contains notices and trademarks used in this document.

"Bibliography" contains descriptions of the documents in the z/OS Communications Server library.

How to use this document

Use this document to perform the following tasks:

- Configure z/OS Communications Server
- Customize and administer z/OS Communications Server

Determining whether a publication is current

As needed, IBM® updates its publications with new and changed information. For a given publication, updates to the hardcopy and associated BookManager® softcopy are usually available at the same time. Sometimes, however, the updates to hardcopy and softcopy are available at different times. The following information describes how to determine if you are looking at the most current copy of a publication:

- At the end of a publication's order number there is a dash followed by two digits, often referred to as the dash level. A publication with a higher dash level is more current than one with a lower dash level. For example, in the publication order number GC28-1747-07, the dash level 07 means that the publication is more current than previous levels, such as 05 or 04.
- If a hardcopy publication and a softcopy publication have the same dash level, it is possible that the softcopy publication is more current than the hardcopy publication. Check the dates shown in the Summary of Changes. The softcopy publication might have a more recently dated Summary of Changes than the hardcopy publication.
- To compare softcopy publications, you can check the last two characters of the publication's file name (also called the book name). The higher the number, the more recent the publication. Also, next to the publication titles in the CD-ROM booklet and the readme files, there is an asterisk (*) that indicates whether a publication is new or changed.

How to contact IBM service

For immediate assistance, visit this Web site: http://www.software.ibm.com/network/commserver/support/

Most problems can be resolved at this Web site, where you can submit questions and problem reports electronically, as well as access a variety of diagnosis information.

For telephone assistance in problem diagnosis and resolution (in the United States or Puerto Rico), call the IBM Software Support Center anytime (1-800-IBM-SERV). You will receive a return call within 8 business hours (Monday – Friday, 8:00 a.m. – 5:00 p.m., local customer time).

Outside the United States or Puerto Rico, contact your local IBM representative or your authorized IBM supplier.

If you would like to provide feedback on this publication, see “Communicating your comments to IBM” on page 1605.

Conventions and terminology that are used in this document

Commands in this book that can be used in both TSO and z/OS UNIX environments use the following conventions:

- When describing how to use the command in a TSO environment, the command is presented in uppercase (for example, NETSTAT).
- When describing how to use the command in a z/OS UNIX environment, the command is presented in bold lowercase (for example, **netstat**).
- When referring to the command in a general way in text, the command is presented with an initial capital letter (for example, Netstat).

All the exit routines described in this document are *installation-wide exit routines*. The installation-wide exit routines also called installation-wide exits, exit routines, and exits throughout this document.

The TPF logon manager, although included with VTAM®, is an application program; therefore, the logon manager is documented separately from VTAM.

Samples used in this book might not be updated for each release. Evaluate a sample carefully before applying it to your system.

For definitions of the terms and abbreviations that are used in this document, you can view the latest IBM terminology at the IBM Terminology Web site.

Clarification of notes

Information traditionally qualified as **Notes** is further qualified as follows:

Note Supplemental detail

Tip Offers shortcuts or alternative ways of performing an action; a hint

Guideline
Customary way to perform a procedure

Rule Something you must do; limitations on your actions

Restriction
Indicates certain conditions are not supported; limitations on a product or facility

Requirement
Dependencies, prerequisites

Result Indicates the outcome

How to read a syntax diagram

This syntax information applies to all commands and statements that do not have their own syntax described elsewhere.

The syntax diagram shows you how to specify a command so that the operating system can correctly interpret what you type. Read the syntax diagram from left to right and from top to bottom, following the horizontal line (the main path).

Symbols and punctuation

The following symbols are used in syntax diagrams:

Symbol
Description

►► Marks the beginning of the command syntax.

► Indicates that the command syntax is continued.

| Marks the beginning and end of a fragment or part of the command syntax.

►◄ Marks the end of the command syntax.

You must include all punctuation such as colons, semicolons, commas, quotation marks, and minus signs that are shown in the syntax diagram.

Commands

Commands that can be used in both TSO and z/OS UNIX environments use the following conventions in syntax diagrams:

- When describing how to use the command in a TSO environment, the command is presented in uppercase (for example, NETSTAT).
- When describing how to use the command in a z/OS UNIX environment, the command is presented in bold lowercase (for example, **netstat**).

Parameters

The following types of parameters are used in syntax diagrams.

Required
Required parameters are displayed on the main path.

Optional
Optional parameters are displayed below the main path.

Default
Default parameters are displayed above the main path.

Parameters are classified as keywords or variables. For the TSO and MVS console commands, the keywords are not case sensitive. You can code them in uppercase or lowercase. If the keyword appears in the syntax diagram in both uppercase and lowercase, the uppercase portion is the abbreviation for the keyword (for example, OPERand).

For the z/OS UNIX commands, the keywords must be entered in the case indicated in the syntax diagram.

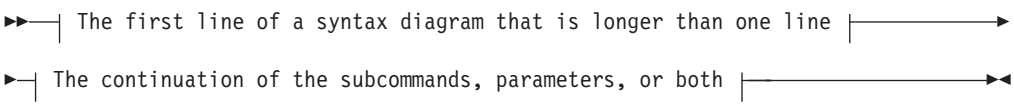
Variables are italicized, appear in lowercase letters, and represent names or values you supply. For example, a data set is a variable.

Syntax examples

In the following example, the USER command is a keyword. The required variable parameter is *user_id*, and the optional variable parameter is *password*. Replace the variable parameters with your own values.

Longer than one line

If a diagram is longer than one line, the first line ends with a single arrowhead and the second line begins with a single arrowhead.



Required operands

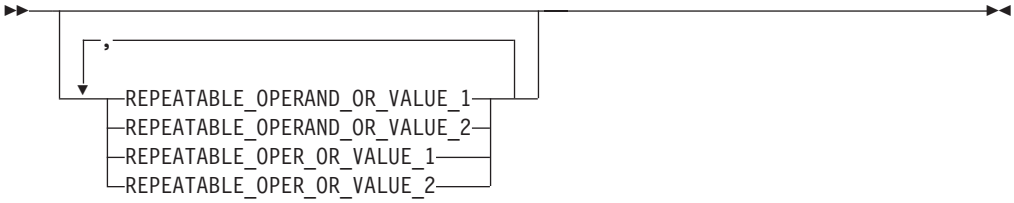
Required operands and values appear on the main path line. You must code required operands and values.

Optional values

Optional operands and values appear below the main path line. You do not have to code optional operands and values.

Selecting more than one operand

An arrow returning to the left above a group of operands or values means more than one can be selected, or a single one can be repeated.



Nonalphanumeric characters

If a diagram shows a character that is not alphanumeric (such as parentheses, periods, commas, and equal signs), you must code the character as part of the syntax. In this example, you must code OPERAND=(001,0.001).

Blank spaces in syntax diagrams

If a diagram shows a blank space, you must code the blank space as part of the syntax. In this example, you must code OPERAND=(001 FIXED).

Default operands

Default operands and values appear above the main path line. TCP/IP uses the default if you omit the operand entirely.

Variables

A word in all lowercase italics is a *variable*. Where you see a variable in the syntax, you must replace it with one of its allowable names or values, as defined in the text.

Syntax fragments

Some diagrams contain syntax fragments, which serve to break up diagrams that are too long, too complex, or too repetitious. Syntax fragment names are in mixed case and are shown in the diagram and in the heading of the fragment. The fragment is placed below the main diagram.

Syntax fragment:

Prerequisite and related information

z/OS Communications Server function is described in the z/OS Communications Server library. Descriptions of those documents are listed in “Bibliography” on page 1585, in the back of this document.

Required information

Before using this product, you should be familiar with TCP/IP, VTAM, MVS, and UNIX System Services.

Softcopy information

Softcopy publications are available in the following collections.

Titles	Order Number	Description
z/OS V1R12 Collection	SK3T-4269	This CD collection is shipped with the z/OS product. It includes the libraries for z/OS V1R12, in both BookManager and PDF formats.
z/OS Software Products Collection	SK3T-4270	This CD includes, in both BookManager and PDF formats, the libraries of z/OS software products that run on z/OS but are not elements and features, as well as the *Getting Started with Parallel Sysplex®* bookshelf.
z/OS V1R12 and Software Products DVD Collection	SK3T-4271	This collection includes the libraries of z/OS (the element and feature libraries) and the libraries for z/OS software products in both BookManager and PDF format. This collection combines SK3T-4269 and SK3T-4270.
z/OS Licensed Product Library	SK3T-4307	This CD includes the licensed documents in both BookManager and PDF format.
IBM System z Redbooks Collection	SK3T-7876	The Redbooks® selected for this CD series are taken from the IBM Redbooks inventory of over 800 books. All the Redbooks that are of interest to the zSeries® platform professional are identified by their authors and are included in this collection. The zSeries subject areas range from e-business application development and enablement to hardware, networking, Linux, solutions, security, parallel sysplex, and many others.

Other documents

For information about z/OS products, refer to *z/OS Information Roadmap* (SA22-7500). The Roadmap describes what level of documents are supplied with each release of z/OS Communications Server, as well as describing each z/OS publication.

Relevant RFCs are listed in an appendix of the IP documents. Architectural specifications for the SNA protocol are listed in an appendix of the SNA documents.

The following table lists documents that might be helpful to readers.

Title	Number
DNS and BIND, Fifth Edition, O'Reilly Media, 2006	ISBN 13: 978-0596100575
Routing in the Internet , Second Edition, Christian Huitema (Prentice Hall 1999)	ISBN 13: 978-0130226471
sendmail, Fourth Edition, Bryan Costales, Claus Assmann, George Jansen, and Gregory Shapiro, O'Reilly Media, 2007	ISBN 13: 978-0596510299
SNA Formats	GA27-3136
TCP/IP Illustrated, Volume 1: The Protocols, W. Richard Stevens, Addison-Wesley Professional, 1994	ISBN 13: 978-0201633467
TCP/IP Illustrated, Volume 2: The Implementation, Gary R. Wright and W. Richard Stevens, Addison-Wesley Professional, 1995	ISBN 13: 978-0201633542
TCP/IP Illustrated, Volume 3: TCP for Transactions, HTTP, NNTP, and the UNIX Domain Protocols, W. Richard Stevens, Addison-Wesley Professional, 1996	ISBN 13: 978-0201634952
TCP/IP Tutorial and Technical Overview	GG24-3376

Redbooks

The following Redbooks might help you as you implement z/OS Communications Server.

Title	Number
IBM z/OS V1R11 Communications Server TCP/IP Implementation, Volume 1: Base Functions, Connectivity, and Routing	SG24-7798
IBM z/OS V1R11 Communications Server TCP/IP Implementation, Volume 2: Standard Applications	SG24-7799
IBM z/OS V1R11 Communications Server TCP/IP Implementation, Volume 3: High Availability, Scalability, and Performance	SG24-7800
IBM z/OS V1R11 Communications Server TCP/IP Implementation, Volume 4: Security and Policy-Based Networking	SG24-7801
IBM Communication Controller Migration Guide	SG24-6298
IP Network Design Guide	SG24-2580
Managing OS/390 TCP/IP with SNMP	SG24-5866
Migrating Subarea Networks to an IP Infrastructure Using Enterprise Extender	SG24-5957
SecureWay™ Communications Server for OS/390 V2R8 TCP/IP: Guide to Enhancements	SG24–5631
SNA and TCP/IP Integration	SG24-5291
TCP/IP in a Sysplex	SG24-5235
TCP/IP Tutorial and Technical Overview	GG24-3376
Threadsafe Considerations for CICS	SG24-6351

The z/OS Basic Skills Information Center

The z/OS Basic Skills Information Center is a Web-based information resource intended to help users learn the basic concepts of z/OS, the operating system that runs most of the IBM mainframe computers in use today. The Information Center is designed to introduce a new generation of Information Technology professionals to basic concepts and help them prepare for a career as a z/OS professional, such as a z/OS system programmer.

Specifically, the z/OS Basic Skills Information Center is intended to achieve the following objectives:

- Provide basic education and information about z/OS without charge
- Shorten the time it takes for people to become productive on the mainframe
- Make it easier for new people to learn z/OS

To access the z/OS Basic Skills Information Center, open your Web browser to the following Web site, which is available to all users (no login required):
http://publib.boulder.ibm.com/infocenter/zoslnctr/v1r7/index.jsp

How to send your comments

Your feedback is important in helping to provide the most accurate and high-quality information. If you have any comments about this document or any other z/OS Communications Server documentation, do one of the following:

- Go to the z/OS contact page at http://www.ibm.com/systems/z/os/zos/webqs.html. You can enter and submit your comments in the form provided at this Web site.
- Send your comments by e-mail to comsvrcf@us.ibm.com. Be sure to include the name of the document, the part number of the document, the version of z/OS

Communications Server, and, if applicable, the specific location of the text that you are commenting on (for example, a section number, a page number or a table number).

Summary of changes

Summary of changes
for SC31-8775-18
z/OS Version 1 Release 12

This document contains information previously presented in SC31-8775-17, which supports z/OS Version 1 Release 12.

This document contains minor maintenance updates. This document also contains the revision bars from SC31-8775-17 for reference purposes.

Summary of changes
for SC31-8775-17
z/OS Version 1 Release 12

This document contains information previously presented in SC31-8775-15 and SC31–8775–16, which support z/OS Version 1 Release 11.

New information

- SMF event records for sysplex events, see "Accounting - SMF records" on page 36.
- Performance improvements for sysplex distributor connection routing, see the following topics:
  - "Steps for converting from IPv4 IPAQENET DEVICE, LINK, and HOME definitions to the IPv4 IPAQENET INTERFACE statement" on page 64
  - "Dynamic LAN idle timer" on page 77
  - "QDIO inbound workload queueing" on page 79
- Performance improvements for streaming bulk data, see "QDIO inbound workload queueing" on page 79.
- Operator command to query and display OSA information, see the following topics:
  - "Displaying OSA-Express QDIO interface information" on page 81
  - "Verifying PROFILE.TCPIP" on page 245
- IKE version 2 support, see the following topics:
  - Chapter 3, "Security," on page 109
  - Chapter 19, "IP security," on page 923
  - Chapter 20, "Network security services," on page 1149
  - Appendix E, "Steps for preparing to run IP security," on page 1505
- Trusted TCP connections, see the following topics:
  - Table 9 on page 112
  - "Sysplex distributor optimization with the OPTLOCAL keyword" on page 486
- Configurable default address selection policy table, see "Source IP address selection" on page 218.
- Verify Netstat message catalog synchronization, see "Customizing TCP/IP messages" on page 248.
- IBM Health Checker for z/OS OMPROUTE checks, see Chapter 6, "Routing," on page 255.

- Enhancements to IPv6 router advertisement, see “IPv6 dynamic routing using router discovery” on page 270.
- Sysplex distributor support for hot-standby server, see the following topics:
  - “Configuring distributed DVIPAs — sysplex distributor” on page 371
  - “Hot standby distribution” on page 477
- Sysplex autonomics monitoring TCP/IP abends, see “Sysplex problem detection and recovery” on page 449.
- Extend sysplex distributor support for DataPower® for IPv6, see “Sysplex distribution with DataPower” on page 491.
- z/OS Communications Server in an ensemble, see Chapter 9, “TCP/IP in an ensemble,” on page 505.
- Common storage reduction for TN3270E server, see “Reducing demand for ECSA storage” on page 649.
- Resolver support for IPv6 connections to DNS name servers, see Chapter 14, “The resolver,” on page 731.
- Improved resolver reaction to unresponsive DNS name servers, see the following topics:
  - “The resolver setup file” on page 733
  - “Monitoring the responsiveness of Domain Name System name servers” on page 752
- IPSec support for certificate trust chains and certificate revocation lists, see the following topics:
  - Chapter 19, “IP security,” on page 923
  - Chapter 20, “Network security services,” on page 1149
  - Appendix E, “Steps for preparing to run IP security,” on page 1505
- IPSec support for FIPS 140 cryptographic mode, see the following topics:
  - Chapter 19, “IP security,” on page 923
  - Appendix E, “Steps for preparing to run IP security,” on page 1505
- Management data for CSSMTP, see “Steps for configuring SMF records for CSSMTP (optional)” on page 1388.

Moved information

- Information about resolvers, resolver caching, and resolver configuration files has been moved to a new chapter, Chapter 14, “The resolver,” on page 731.

This document contains terminology, maintenance, and editorial changes. Technical changes or additions to the text and illustrations are indicated by a vertical line to the left of the change.

You might notice changes in the style and structure of some content in this document–for example, headings that use uppercase for the first letter of initial words only, and procedures that have a different look and format. The changes are ongoing improvements to the consistency and retrievability of information in our documents.

Summary of changes
for SC31-8775-16
z/OS Version 1 Release 11

This document contains information previously presented in SC31-8775-15, which supports z/OS Version 1 Release 11.

This document contains minor maintenance updates. This document also contains the revision bars from SC31-8775-15 for reference purposes.

Summary of changes
for SC31-8775-15
z/OS Version 1 Release 11

This document contains information previously presented in SC31-8775-13 and SC31–8775–14, which support z/OS Version 1 Release 10.

New information

- Resolver DNS cache, see "Resolver caching" on page 744.
- Network management interface enhancements – stack configuration data, see "Accounting - SMF records" on page 36.
- FTP large-volume access, see "Considerations for extended address volumes" on page 63.
- QDIO support for OSA interface isolation, see:
  - "OSA-Express port sharing" on page 75
  - "OSA-Express connection isolation" on page 75
- OSA-Express3 optimized latency mode, see "Optimized latency mode" on page 77.
- QDIO routing accelerator, see "QDIO Accelerator" on page 91.
- QDIO enhancements for WLM IO priority, see "Prioritizing outbound OSA-Express data using the Workload Manager service class" on page 94.
- Network management interface enhancements – OSA network traffic analyzer data, see "TCP/IP OSAENTA trace service access control" on page 127.
- Syslogd enhancements, see:
  - "Configuring syslogd for automatic archiving" on page 204
  - "Step 7: Configuring Policy Agent to automatically monitor applications" on page 861
- IPv6 stateless address autoconfiguration enhancements, see "Source IP address selection" on page 218.
- Support for enhanced WLM routing algorithms, see:
  - "Configuring distributed DVIPAs — sysplex distributor" on page 371
  - "Sysplex distributor" on page 469
- Sysplex autonomics improvements for FRCA, see "Target server connection setup responsiveness monitoring" on page 461.
- Sysplex distributor optimization for multi-tier z/OS workloads, see "Sysplex distribution optimizations for multi-tier z/OS workloads" on page 485.
- Sysplex distributor support for DataPower, see "Sysplex distribution with DataPower" on page 491.
- Customizable pre-logon banner for otelnetd, see "Configuring the z/OS UNIX Telnet server" on page 649.
- FTP access to UNIX named pipes, see "z/OS UNIX named pipes" on page 675.
- Policy infrastructure management, see "Configuration files and policy definition files" on page 831.
- IPSec enhancements, see:
  - "Configuration scenarios supported for NAT traversal" on page 1095
  - "Sysplex-wide Security Associations and IP security" on page 1144

- FTP passive mode enhancements, see "Considerations for IPSec-encapsulated FTP traffic when traversing a NAT" on page 1098.
- NSS private key and certificate services for XML appliances, see Chapter 20, "Network security services," on page 1149.
- Configuration Assistant – Policy infrastructure simplification, see "Steps for configuring the DMD" on page 1187.
- AT-TLS enhancements, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.
- New SMTP client for sending Internet mail, see "Configuring the CSSMTP application" on page 1375.

Changed information

- LDAP server information has been moved to an appendix. See Appendix F, "Using an LDAP server for policy definitions," on page 1519.

Deleted information

- Support for NDB, the DHCP server, BINL, and BIND 4.9.3 is removed from the z/OS V1R11 Communications Server product; information describing this support has been deleted.

This document contains terminology, maintenance, and editorial changes.

Summary of changes
for SC31-8775-14
z/OS Version 1 Release 10

This document contains information previously presented in SC31-8775-13, which supports z/OS Version 1 Release 10.

This document contains minor maintenance updates. This document also contains the revision bars from SC31-8775-13 for reference purposes.

Summary of changes
for SC31-8775-13
z/OS Version 1 Release 10

This document contains information previously presented in SC31-8775-11 and SC31-8775-12, which support z/OS Version 1 Release 9.

New information

- Resolver support for EDNS0, see "Extension Mechanisms for DNS standards and the resolver" on page 758.
- Network Management Interface (NMI) enhancements, see "Accounting - SMF records" on page 36.
- ASID reuse for TCP/IP, TN3270E, and resolver, see "Nonreusable ASIDs" on page 40.
- Allow DNS BIND 9 server to run with BPX.SUPERUSER authorization, see:
  - "Other user IDs requiring z/OS UNIX superuser authority" on page 42
  - "Setting up and running the name server" on page 784
- IBM Health Checker for z/OS enhancements, see "Specifying BPXPRMxx values for a CINET configuration" on page 59.

- Allow multiple sockets to share the same FRCA cache, see “Considerations for Fast Response Cache Accelerator” on page 62.
- Multiple VLAN support and INTERFACE statement support for QDIO, see:
  - “Considerations for networking hardware attachment” on page 63
  - “Configuring PROFILE.TCPIP” on page 211
- HiperSockets™ multiple write, see:
  - “HiperSockets multiple write” on page 90
  - “HiperSockets multiple write assist with IBM zIIP” on page 90
- Enhanced port access control, see:
  - “Port access control” on page 116
  - “Setting up reserved port number definitions in PROFILE.TCPIP” on page 234
- DataPower integration: SAF access services, see:
  - “Network security services for the XMLAppliance discipline” on page 149

Deleted information

- Support for traffic regulation policy in Policy Agent is removed from the z/OS V1R10 Communications Server product; information describing this support has been deleted.

This document contains terminology, maintenance, and editorial changes.

Part 1. Base TCP/IP system

Chapter 1. Overview of z/OS Communications Server

z/OS Communications Server provides a set of communications protocols that support peer-to-peer connectivity functions for both local and wide-area networks, including the most popular wide-area network, the Internet. z/OS Communications Server also provides performance enhancements that can benefit a variety of TCP/IP applications.

z/OS Communications Server provides both SNA and TCP/IP networking protocols for z/OS. The SNA protocols are provided by VTAM and include Subarea, Advanced Peer-to-Peer Networking, and High Performance Routing protocols. For more information on z/OS Communications Server SNA protocols, see *z/OS Communications Server: SNA Network Implementation Guide*.

Figure 1 on page 4 shows the z/OS Communications Server TCP/IP protocol suite (also called stack), whose functions include associated applications, transport- and network-protocol layers, and connectivity and gateway functions. z/OS Communications Server contains IPv6 support. See *z/OS Communications Server: IPv6 Network and Application Design Guide* for more detailed information.

The z/OS Communications Server protocol suite supports two TCP/IP environments:

- A native MVS environment in which users can exploit the popular TCP/IP protocols in MVS application environments such as batch jobs, started tasks, TSO, CICS® applications, and IMS™ applications.
- A z/OS UNIX System Services environment that lets you create and use applications that conform to the POSIX or XPG4 standard (a UNIX specification).

Note: z/OS Communications Server exploits z/OS UNIX services even for traditional MVS environments and applications. Prior to utilizing TCP/IP services, therefore, a full-function mode z/OS UNIX environment—including a Data Facility Storage Management Subsystem (DFSMSdfp), a z/OS UNIX file system, and a security product (such as Resource Access Control Facility, or RACF®)—needs to be defined and active before z/OS Communications Server can be started successfully.

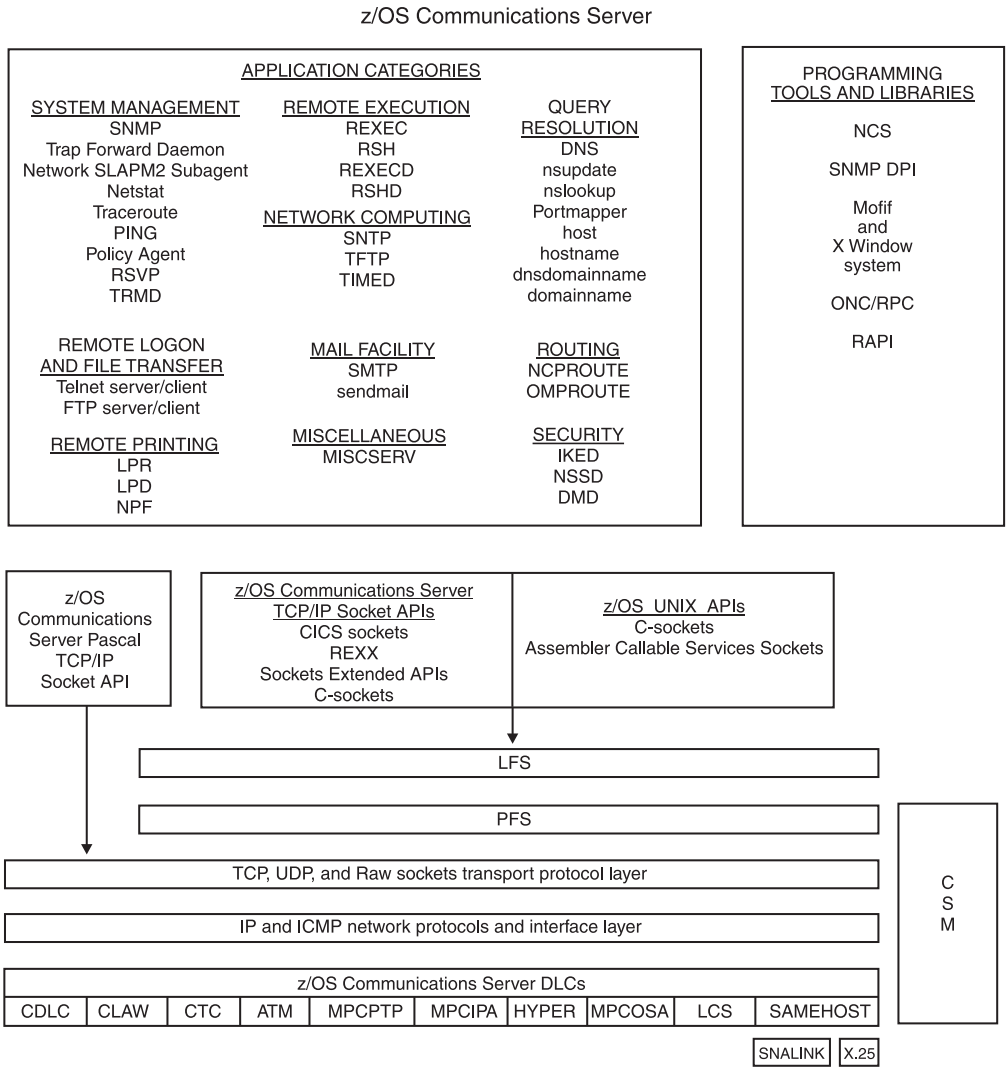

Figure 1. z/OS Communications Server TCP/IP protocol suite

The application categories in Figure 1 do not list every application of the TCP/IP protocol suite.

z/OS Communications Server TCP/IP protocol-suite functions include the following categories:

- "TCP/IP protocol stack"
- "Connectivity and gateway functions" on page 5
- "Network protocol layer" on page 7
- "Transport layer" on page 7
- "File systems" on page 7
- "Application Programming Interfaces" on page 8

TCP/IP protocol stack

The Transmission Control Protocol (TCP) and the Internet Protocol (IP) refer to a non-proprietary protocol suite that enables different packet-switched networks to function as a single entity regardless of underlying network topology.

z/OS Communications Server provides robustness and high performance with the following features:

- A fully multiprocessor capable stack
- Exploitation of MVS Reliability, Availability, and Serviceability (RAS) services
- Exploitation of the z/OS architecture to optimize performance, CPU utilization, and throughput
- Exploitation of the z/OS Sysplex functions to maximize availability and scalability of TCP/IP workloads

In addition, z/OS Communications Server design includes a tightly integrated storage and I/O model. I/O is provided by multipath channel (MPC) for network communication; storage management is provided by Communications Storage Manager (CSM).

Multipath channel I/O process

The term multipath channel (MPC) describes all z/OS Communications Server I/O driver support. There are specific I/O drivers under this support that are also referred to as MPC (such as MPCPTP).

MPC is a component of the I/O process model. MPC handles protocol headers and data separately and executes multiple I/O dispatchable units of work. MPC provides support for all devices supported by z/OS Communications Server. The MPC I/O process and the CSM facilities that TCP/IP exploits are part of the VTAM component of z/OS Communications Server. As a result, VTAM must be configured and active when starting devices on the TCP/IP stack.

Communications Storage Manager

The Communications Storage Manager (CSM) facility is used by authorized programs to manage subsystem storage pools. CSM reduces data moves by providing a flat storage model that is accessible at multiple layers of the process model and across MVS address space boundaries. In addition, CSM provides the following technical advantages:

- MVS cellpool-like services
- Automatic handling of the contraction and expansion of storage resources
- Handling of different types and sizes of storage requests (for example, pageable and fixed)

Connectivity and gateway functions

TCP/IP connectivity and gateway functions handle the physical interfaces and the routing of IP data packets called datagrams. The following communication interfaces are supported by z/OS Communications Server:

ATM Enables TCP/IP to send data to an asynchronous transfer mode (ATM) network using an OSA-2 or OSA-Express ATM adapter over an ATM virtual circuit.

CDLC Provides connectivity to a Network Control Program (NCP) through 3745/3746 network Front End Processor (FEP) controllers.

CLAW Provides access from IBM RS/6000® workstations directly to TCP/IP hosts over a channel. The CLAW (common link access to workstation) interface can also be used to provide connectivity to the original equipment manufacturer (OEM), such as the Cisco Channel Interface Processor (CIP).

CTC Provides access to TCP/IP hosts by way of a channel-to-channel (CTC) connection established over a zSeries ESCON® channel.

HYPERchannel
Provides access to TCP/IP hosts by way of HYPERchannel series A devices and series DX devices that function as series A devices.

LCS Provides access to TCP/IP hosts using the following devices or features:

- An IBM 3172 Interconnect Controller, which connects to a token ring, an Ethernet, or Fiber Distributed Data Interface (FDDI) local area network
- An IBM 8232
- An IBM 2216 Multiaccess Connector Model 400
- An OSA-2 feature: FDDI, Ethernet/Token Ring (EN/TR), or ATM in LAN emulation mode
- An OSA-Express feature: 1000BASE-T Ethernet, Fast Ethernet, ATM in LAN emulation mode, or High Speed Token Ring (HSTR)
- An OSA-Express2 feature: 1000BASE-T Ethernet

MPCIPA
Provides access to:

- TCP/IP hosts using the following:
  - OSA-Express feature: Gigabit Ethernet (GbE), 1000BASE-T Ethernet, Fast Ethernet, HSTR, or ATM in LAN emulation mode
  - OSA-Express2 feature: GbE, 10 GbE, or 1000BASE-T Ethernet
  - OSA-Express3 feature: GbE or 10 GbE
  - HiperSockets using the Internal Queued Direct I/O (iQDIO). HiperSockets provides high-speed, low-latency IP message passing between logical partitions (LPARs) within a single IBM eServer™ zSeries z800, z890, z900, z990, z9®, or z10™ server.

  The OSA-Express features support the Queued Direct I/O (QDIO) architecture. IPv6 is supported on all Ethernet features in QDIO mode.
- An ensemble using the following:
  - OSA-Express3 feature configured as CHPID type OSX
  - OSA-Express3 feature configured as CHPID type OSM

MPCOSA
Provides access to TCP/IP hosts by way of an OSA-2 adapter configured in HPDT MPC mode for Fast Ethernet or FDDI.

MPCPTP
Provides access to TCP/IP hosts through multipath channel point-to-point (MPCPTP) links. MPCPTP supports IPv4 and IPv6 protocols. MPCPTP can be used in two ways to provide direct connectivity to other mainframe hosts running z/OS Communications Server:

- By using a set of two or more zSeries channels
- By configuring to utilize XCF services, if the zSeries hosts are part of the same sysplex

MPCPTP can also be used to provide the following connectivity options:

- Direct communication between two z/OS Communications Server TCP/IP Services protocol stacks running on the same MVS host without requiring any network attachments
- Connectivity to network attachments such as the IBM 2216 Multiaccess Controller Model 400 or the IBM RS/6000

SAMEHOST
Provides connectivity between the TCP/IP address space and other program address spaces within the same MVS host. The SAMEHOST Data Link Control (DLC) provides support for the SNA backbone network (SNALINK LU0 and SNALINK LU6.2) and the X.25 network.

The VTAM component of z/OS Communications Server provides the I/O support for each of these communication interfaces, and requires the creation (dynamically or through definition) of Transport Resource List entries (TRLEs) to represent each interface.

- TRLEs must be defined for the following communication interfaces:
  - ATM
  - MPCOSA
  - MPCIPA devices not connected to an ensemble
  - MPCPTP

  For information about how to define these TRLEs, see *z/OS Communications Server: SNA Resource Definition Reference*.
- For all other communication interfaces, VTAM dynamically creates TRLEs. For information about dynamically created TRLEs for TCP/IP, see *z/OS Communications Server: SNA Network Implementation Guide*.

Network protocol layer

The network protocol layer provides the support for the IP protocol. All TCP and User Datagram Protocol (UDP) data goes through the IP layer when entering and leaving the host. TCP and UDP will use the IPv4 routing layer or the IPv6 routing layer.

The network layer also provides support for the Internet Control Message Protocol (ICMP) and ICMPv6. This is used by the IP layer to exchange information and error messages with IP layers on other hosts and routers. ICMP is used for the IPv4 protocol and ICMPv6 is used for the IPv6 protocol.

Transport layer

The transport layer provides the support for the TCP, UDP, and RAW protocols. All three protocols use IPv4 or IPv6 as the network layer. The TCP protocol provides a connection-oriented, reliable transport layer, whereas UDP provides a simpler, connectionless and unreliable transport layer. The RAW transport layer provides for a more direct interface to the IP layer, which is primarily used by system-management type applications.

File systems

The file system layer provides the main interface between the application programming interfaces (APIs) and the transport layers. The first component of the file system layer is the z/OS UNIX logical file system (LFS). The LFS provides the API layer with a common interface to access files and sockets. In a POSIX-compliant environment, applications can access both files and sockets in a similar fashion. For example, both files and sockets are represented by a 32-bit integer referred to as a descriptor. Common functions can be used to access both file and socket resources.

The layer beneath the LFS is the physical file system (PFS). The PFS layer is where the distinction between files, sockets, and other resources is made. Based on the resource type, the LFS passes the incoming function requests to the appropriate PFS, which handles requests related to resources in the z/OS UNIX file system. For more information about these physical file systems, see *z/OS UNIX System Services Planning*.

From a TCP/IP perspective, the AF_INET and the AF_INET6 PFS are of main interest. TCP/IP is enabled for IPv6 by defining an AF_INET6 PFS. Defining the file systems is the responsibility of the installation's z/OS UNIX programmer. The definitions are found in the BPXPRMxx member of SYS1.PARMLIB.

For information about defining AF_INET and AF_INET6 physical file systems, and about customizing BPXPRMxx for INET and CINET systems, see *z/OS UNIX System Services Planning*.

The AF_INET and the AF_INET6 PFS can be configured in two ways:

Integrated sockets PFS
The integrated sockets PFS can support the AF_INET PFS alone or AF_INET and AF_INET6 PFS together, but not AF_INET6 PFS alone.

Common INET PFS
This configuration is commonly referred to as the C_INET PFS configuration. It enables multiple AF_INET and AF_INET6 transport providers to be configured and active concurrently. Applications using the z/OS UNIX APIs do not know that multiple transport providers exist. For example, multiple TCP/IP Services components of z/OS Communications Server can be configured at the same time. The C_INET PFS is responsible for selecting the PFS over which to flow the request, based on the IP routing information from each of the AF_INET providers.

Under this configuration, it is also possible for TCP/IP application servers using the z/OS UNIX socket APIs to field incoming client requests from all AF_INET transport providers without knowing the particular transport provider.

Application Programming Interfaces

This information provides a short description of each of the application programming interfaces (APIs) that can be used to interface with the TCP/IP Services protocol stack provided by z/OS Communications Server. All of the APIs, with the exception of the PASCAL API, interface with the LFS layer.

The APIs are divided into the following two categories:

- TCP/IP socket APIs provided by z/OS Communications Server
- z/OS UNIX APIs

TCP/IP socket APIs provided by z/OS Communications Server

z/OS Communications Server provides several APIs to access TCP/IP sockets. These APIs can be used in either or both integrated and common INET PFS configurations. In a common INET PFS configuration, however, they function differently from z/OS UNIX APIs. In this type of configuration, the z/OS Communications Server APIs always bind to a single PFS transport provider, and the transport provider must be the TCP/IP stack provided by z/OS Communications Server.

The following TCP/IP socket APIs are included in z/OS Communications Server:

Pascal API
The Pascal application programming interface enables you to develop TCP/IP applications in Pascal language. Supported environments are normal MVS address spaces. The Pascal programming interface is based on Pascal procedures and functions that implement conceptually the same functions as the C socket interface. The Pascal routines, however, have different names than the C socket calls. Unlike the other APIs, the Pascal API does not interface directly with the LFS. It uses an internal interface to communicate with the TCP/IP protocol stack.

Pascal API only supports AF_INET.

CICS sockets
The CICS socket interface enables you to write CICS applications that act as clients or servers in a TCP/IP-based network. Applications can be written in C language, using the C sockets programming, or they can be written in COBOL, PL/I or assembler, using the Sockets Extended programming interface.

CICS sockets only support AF_INET.

C sockets
The C sockets interface supports socket function calls that can be invoked from C programs. However, note that for C application development, IBM recommends the use of the UNIX C sockets interface. These programs can be ported between MVS and most UNIX environments relatively easily if the program does not use any other MVS specific services.

C sockets only support AF_INET.

IMS sockets
The Information Management System (IMS) IPv4 socket interface supports client/server applications in which one part of the application executes on a TCP/IP-connected host and the other part executes as an IMS application program.

The IMS sockets API supports AF_INET.

Sockets Extended macro API
The Sockets Extended macro API is a generalized assembler macro-based interface to sockets programming. It includes extensions to the socket programming interface, such as support for asynchronous processing on most sockets function calls.

The Sockets Extended macro API supports AF_INET and AF_INET6.

Sockets Extended Call Instruction API
The Sockets Extended Call Instruction API is a generalized call-based, high-level language interface to sockets programming. The functions implemented in this call interface resemble the C-sockets implementation, with some extensions similar to the sockets extended macro interface.

The Sockets Extended Call Instruction API supports AF_INET and AF_INET6.

REXX sockets
The REXX sockets programming interface implements facilities for socket communication directly from REXX programs by using an address rxsocket function. REXX socket programs can execute in TSO, online, or batch.

The REXX sockets programming interface supports AF_INET and AF_INET6.

See *z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference* for complete documentation of the TCP/IP Services APIs.

z/OS UNIX APIs

The following APIs are provided by the z/OS UNIX element of z/OS and are supported by the TCP/IP stack in z/OS Communications Server:

z/OS UNIX sockets

A set of C language functions provides support for the z/OS UNIX sockets, which are used in the z/OS UNIX environment. Programmers use this API to create applications that conform to the POSIX or XPG4 standard (a UNIX specification). Applications built with z/OS UNIX sockets can be ported to and from platforms that support these standards.

The z/OS UNIX sockets support AF_INET and AF_INET6.

z/OS UNIX assembler callable services

z/OS UNIX assembler callable services is a generalized call-based, high-level language interface to z/OS UNIX sockets programming. The functions implemented in this call interface resemble the z/OS UNIX C sockets implementation, with some extensions similar to the sockets extended macro interface.

The z/OS UNIX assembler callable services support AF_INET and AF_INET6.

For complete documentation of z/OS UNIX sockets, see *z/OS XL C/C++ Run-Time Library Reference*. For information about z/OS UNIX callable services, see *z/OS UNIX System Services Programming: Assembler Callable Services Reference*.

Chapter 2. IP configuration overview

The objective of this topic is to help you be better prepared for installation related activities. It is important to understand the terms, relationships, and dependencies presented in this topic as a prerequisite to installation and customization. For additional background information on TCP/IP, see *TCP/IP Tutorial and Technical Overview*, GG24-3376, ISBN 0738421650.

IPv6 support

In this information, there might be no statement of support for a particular function in an IPv6 network. To determine whether a given function is applicable to IPv6, see the IPv6 support tables in *z/OS Communications Server: IPv6 Network and Application Design Guide*.

IBM TCP/IP Configuration Demo for z/OS

z/OS Communications Server provides a Windows GUI application called IBM TCP/IP Configuration Demo for z/OS, which collects TCP/IP customization information and then generates TCP/IP configuration statements for inclusion in the configuration files.

Restriction: The IBM TCP/IP Configuration Demo for z/OS has not been updated since z/OS V1R6 and does not support parameters added in later releases. The files generated by the application are valid in later releases.

You can download the IBM TCP/IP Configuration Demo for z/OS from the z/OS Communications Server Web page.

Only a subset of the total configuration for TCP/IP is supported using the IBM TCP/IP Configuration Demo for z/OS.

Included is support for all network devices, routing selections of OSPF or RIP, or use of default routers and static routes. The TN3270E Telnet server can be configured in a basic setup, or in advanced mode, which supports nearly all Telnet options. Multiple FTP servers and FTP clients are completely configurable. The configuration files created are those typically referred to as TCPIP.DATA, PROFILE.TCPIP, FTP.DATA, and OMPROUTE.CONF, as well as TN3270 and PORTS. Supported configuration statements are as follows:

- For TCPIP.DATA

  DATASETPREFIX
  DOMAINORIGIN
  HOSTNAME
  NSINTERADDR
  TCPIPJOBNAME

  Defaults are used for all other configuration statements.
- For PROFILE.TCPIP

  ATMARPSV

z/OS UNIX System Services concepts

Beginning with MVS/ESA Version 4.3, an application programming interface was added to the MVS platform with the intent of integrating a UNIX operating system into MVS. Both a C programming API and an interactive environment called the shell were defined to interoperate with UNIX-style files. Over time, other organizations developed approaches to working with UNIX on various platforms until an organization named X/Open documented standards of what to implement for UNIX interfaces in a series of guides published as the X/Open Portability Guides (XPG). X/Open now owns the term UNIX and certifies different implementations of UNIX according to the UNIX definitions contained in XPG 4.2.

z/OS UNIX System Services, or z/OS UNIX, is a certified UNIX system as defined by X/Open in XPG 4.2. z/OS UNIX coexists with traditional MVS functions and traditional MVS data set types such as partitioned data sets and sequential data sets. It enables access to z/OS UNIX files and utilities concurrently by means of application programming interfaces (APIs) and the interactive shell environment. Two variants of the z/OS UNIX shell environment are available:

- The z/OS UNIX shell, much like a native UNIX environment
- The ISPF shell, an interface with access to menu-driven command interfaces

With the APIs, programs can run in any environment including batch jobs, in jobs submitted by TSO/E interactive users, and in most other started tasks, or in any other MVS application task environment. The programs can request:

- Only MVS services
- Only z/OS UNIX services
- Both MVS and z/OS UNIX services

The shell interface is an execution environment analogous to TSO/E, with a programming language of shell commands analogous to Restructured eXtended eXecutor (REXX) language. The shell support consists of:

- Programs that are run interactively by shell users
- Shell commands and scripts that are run interactively by shell users
- Shell commands and scripts that are run as batch jobs

Prior to OS/390® V2R5, OS/390 UNIX required APPC/MVS for programs issuing the fork() or spawn() function. APPC/MVS is no longer required for this purpose. Forked and spawned address spaces are implemented in z/OS for UNIX processing by the Work Load Manager (WLM) component of MVS.

- For a fork(), the system copies one process, called the parent process, into a new process, called the child process, and places the child process in a new address space, the forked address space.
- Spawn() also starts a new process in a new address space. Unlike a fork(), in a spawn() call the parent process specifies a name of a program to start the child process.

The types of processes can be:

- User processes, which are associated with a user
- Daemon processes, which perform continuous or periodic functions, such as a Web server

  Daemons are programs that are typically started when the operating system is initialized and remain active to perform standard services. Some programs that initialize processes for users are considered daemons, even though these daemons are not long-running processes. Examples of daemons provided by z/OS UNIX are *cron*, which starts applications at specific times, and *inetd*, which starts applications on demand.

A user or daemon process can have one or more threads. A thread is a single flow of control within a process. Application programmers create multiple threads to structure an application in independent sections that can run in parallel for more efficient use of system resources.

Overview of data sets and UNIX files

Data set and *file* are comparable terms. If you are familiar with MVS, you probably use the term *data set* to describe a unit of data storage. If you are familiar with AIX® or UNIX, you probably use the term *file* to describe a named set of records stored or processed as a unit. In the TCP/IP environment, in addition to the traditional MVS data set organizations (such as sequential and partitioned), UNIX files are arranged in a hierarchical directory structure.

Some MVS data sets and UNIX files have special importance because of their function. For example, certain data sets and files are used when configuring the TCP/IP environment. Other data sets are used by the Telnet server when performing specific communication functions. For descriptions of the MVS data sets and UNIX files necessary for configuring the TCP/IP environment and the search orders used to find them, see Table 1 on page 21. A search order can include both MVS data sets and UNIX files, and these MVS data sets and UNIX files are collectively referred to as the *configuration files* in this information.

Note: Not all applications support UNIX files.

Hierarchical file system concepts

A hierarchical file system consists of the following:

- **Files**, which contain data or programs. A file containing a program object, shell script, or REXX program is called an *executable file*. Files are kept in directories.
- **Directories** that contain files, other directories, or both. Directories are arranged hierarchically, in a structure that resembles an upside down tree, with root

directory at the top and the branches at the bottom. The **root** is the first directory for the file system at the peak of the tree and is designated by a slash (/).
- Named pipes, links, and other UNIX items, such as character special files like /dev/console that are used by applications like syslogd. See *z/OS UNIX System Services Planning* for more information about UNIX items like character special files.

The term *file system* has all of the following meanings:
- A logical collection of files, directories, named pipes, links, and other UNIX items and metadata that are arranged in a hierarchy.
- A particular instance of a logical collection of these items that are arranged in a hierarchy. They might reside on local or remote disks or in computer memory.
- A program that is designed to provide the functions and data of one type of file system.

The context indicates which meaning is intended. Often more than one meaning is intended; this is an industry convention.

To the z/OS system, the file hierarchy is a collection of file systems. Additional instances of local or remote file systems might be mounted (logically connected) on directories of the root file system or of additional file systems.

Several types of file systems are supported by z/OS, including the following:
- zSeries File System

  Each instance of zSeries File System resides in a linear data set.
- HFS (hierarchical file system)

  Each instance of HFS resides in an HFS data set.
- TFS (temporary file system)

  Each instance of TFS resides in computer memory.
- NFS (Network File System)

  NFS server provides access to file systems that reside on other computers.

For most application programs, these types of file systems are interchangeable. The root file system is the first file system that is mounted. Subsequent file systems can be logically mounted on a directory within the root file system or on a directory within any mounted file system.

References to installation data sets

This information refers to Communications Server installation data sets by their default SMP/E distribution library name. Your installation might, however, have different names for these data sets where allowed by SMP/E, your installation personnel, or administration staff. For instance, this information refers to sample members of the *hlq*.SEZAINST library as SEZAINST(*member*), where the *hlq* value is the high-level qualifier specified during TCP/IP installation. Your installation can choose a data set name of SYS1.SEZAINST, CS390.SEZAINST, or other high level qualifiers for the data set name.

Understanding search orders of configuration information

It is important to understand the search order for configuration files used by TCP/IP functions, and when you can override the default search order with environment variables, JCL, or other variables you provide. This knowledge allows you to accommodate your local data set and file naming standards, and it is helpful to know the configuration data set or file in use when diagnosing problems.

It is important to note that the z/OS Communications Server environment consists of the TCP/IP address space, z/OS Communications Server applications, and the TCP/IP MVS applications. The TCP/IP address space functions are also referred to as the *stack*. The z/OS Communications Server applications refer to those applications using the z/OS UNIX socket API. The TCP/IP MVS applications refer to those applications written to the MVS APIs (for example, C, Sockets-Extended, CICS, IMS, and REXX). The TCP/IP stack and both sets of applications have some common (or global) configuration files, but they also use configuration files that are different.

Another important point to note is that when a search order is applied for any configuration file, the search ends with the first file found. Therefore, unexpected results are possible if you place configuration information in a file that never gets found, either because other files exist earlier in the search order, or because the file is not included in the search order chosen by the application.

Configuration data set naming conventions

When searching for configuration files, you can explicitly tell TCP/IP where most configuration files are by using DD statements in the JCL procedures or by setting environment variables. Otherwise, you can let TCP/IP dynamically determine the location of the configuration files, based on search orders shown in Table 1 on page 21.

For example, in Table 1 on page 21, for the FTP server application, if the installation did not code the //SYSFTPD DD statement, the FTP server would search for *jobname*.FTP.DATA, then file /etc/ftp.data, then data set SYS1.TCPPARMS(FTPDATA), and finally *hlq*.FTP.DATA.

Dynamic data set allocation

TCP/IP makes extensive use of dynamically allocated data sets using the MVS dynamic data set allocation function to search for configuration files. Multiple versions of a configuration data set can exist, each having a different high-level qualifier or middle-level qualifier. The search order for any configuration file will determine which data set is found and used.

High-level qualifier: High-level qualifiers (HLQ) permit you to associate an application's configuration data set with a particular jobname or TSO user ID, or permit you to use a default configuration data set for the application. The possible high-level qualifiers are:

- *userid*

  Userid is the TSO user ID which invoked the application.
- *jobname*

  Jobname is the application's batch JCL jobname or the name of the application's started procedure.
- *hlq*

TCP/IP is distributed with a default high-level qualifier (HLQ) of *TCPIP*. To override the default HLQ used by dynamic data set allocation, specify the DATASETPREFIX statement in the TCPIP.DATA configuration file. For most configuration files, the DATASETPREFIX value is used as the high-level qualifier of the data set name in the last step in the search order. Note that the DATASETPREFIX value is not used as the high-level qualifier of the data set name used as the last step in the search order for the PROFILE.TCPIP and TCPIP.DATA configuration files.

Middle-level qualifiers: Multiple middle-level qualifiers (MLQ) permit the isolation of certain profile and translation table data sets. Two of the possible middle-level qualifiers are:

- Node name

  Node name is an MLQ used in the search order for finding the configuration file PROFILE.TCPIP. Node name is determined by the parameters specified during VMCF initialization. For further information on initializing VMCF, see *z/OS Program Directory*.
- Function name

  The TCP/IP implementation of multicultural support and double-byte character set (DBCS) support requires the use of multiple translation tables. To facilitate the concurrent use of multiple languages and code pages, TCP/IP uses a middle-level qualifier to designate which server or client uses a particular translation table. STANDARD, the default MLQ, is available for use if a single translation table can be used by multiple servers or clients. The TCP/IP Telnet client and FTP provide a TRANSLATE parameter that permits you to specify your chosen MLQ to replace the function name for that invocation of the command. For example, SRVRFTP is used as an MLQ by the File Transfer Protocol server.

Following are some of the data sets that are only dynamically allocated by TCP/IP in a configuration file search order (you cannot specify them with DD statements in JCL):

```
ETC.PROTO               ETC.RPC
HOSTS.ADDRINFO          HOSTS.SITEINFO
SRVRFTP.TCPCHBIN        SRVRFTP.TCPHGBIN
SRVRFTP.TCPKJBIN        SRVRFTP.TCPSCBIN
SRVRFTP.TCPXLBIN        STANDARD.TCPCHBIN
STANDARD.TCPHGBIN       STANDARD.TCPKJBIN
STANDARD.TCPSCBIN       STANDARD.TCPXLBIN
```

For each of these data sets, the fully qualified name is established by using one of the following values as the data set HLQ:

- User ID or job name
- DATASETPREFIX value

Naming conventions for dynamically allocated data sets: A data set that you allocate explicitly (with a DD statement in JCL) can have any valid MVS data set name or z/OS UNIX file name. A data set that you create for the purpose of being allocated dynamically by TCP/IP must use the following naming conventions.

Note: In these examples, *xxxx* indicates an appropriate high-level qualifier, *yyyy* indicates an appropriate middle-level qualifier, and *zzzz* indicates an appropriate low-level qualifier.

- *userid.yyyy.zzzz*

  userid is the user ID of the logged on TSO user.

- *TSOprefix.yyyy.zzzz*

  TSOprefix is the data set prefix established by the TSO PROFILE command. *userid* is the default value of *TSOprefix*.
- *jobname.yyyy.zzzz*

  jobname is the job name specified on the JOB statement for a job stream or the procedure name for a started procedure.
- *hlq.yyyy.zzzz*

  hlq is the TCP/IP HLQ distributed as the system default, which can be overridden by the value in the DATASETPREFIX statement.
- *xxxx.nodename.zzzz*

  nodename is an MLQ that is used to define the data set name for the TCP/IP stack profile data set.
- *xxxx.function_name.zzzz*

  function_name denotes an acronym specifying a particular TCP/IP server (for example SRVRFTP for the FTP server) and is used as an MLQ for the translation table data set for that application.
- *xxxx.private_name.zzzz*

  private_name is a user-specified private qualifier that can be specified as an option on some TCP/IP commands.
- SYS1.TCPPARMS(TCPDATA)

  The member of a system data set used to find the *configuration file* TCPIP.DATA.

TCP/IP configuration data sets

Table 1 lists the configuration MVS data sets and z/OS UNIX files used by the TCP/IP servers and functions. The table includes the name of the sample data set or file that is provided by Communications Server, and the way the data set or file is used.

Table 1. TCP/IP configuration data sets

Name (search order)	Copied from	Usage
ADNR.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the automated domain name registration started procedure	SEZAINST(ADNRCNF)	Contains automated domain name registration configuration statements.
CSSMTP.CONF 1. The MVS data set or z/OS UNIX file referenced by the CONFIG DD statement in the CSSMTP application started procedure 2. *jobname*.CSSMTP.CONF	SEZAINST(CSSMTPCF)	Contains CSSMTP application configuration statements.
Defense Manager daemon (DMD) configuration 1. The MVS data set or z/OS UNIX file specified by the DMD_FILE environment variable 2. /etc/security/dmd.conf	/usr/lpp/tcpip/samples/dmd.conf	Contains DMD configuration statements.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
/etc/hosts	No sample provided.	One of the possible local host files used for IPv4 name query. See "Creating /etc/hosts" on page 243.
hlq.ETC.IPNODES	SEZAINST(EZBREIPN)	One of the local host files used for IPv6 name query, or IPv4 and IPv6 name query when COMMONSEARCH is specified in the resolver setup file.
/etc/mail/sendmail.cf	/usr/lpp/tcpip/samples/sendmail/cf/sample.cf	Provides configuration information for the sendmail daemon when being used as a message transfer agent (MTA). If /etc/mail/submit.cf does not exist, this data set also provides configuration information for the end-user sendmail application when being used as a mail user agent (MUA).
/etc/mail/submit.cf	/usr/lpp/tcpip/samples/sendmail/cf/submit.cf	Provides configuration information for the end-user sendmail application when being used as a mail user agent (MUA).
/etc/mail/zOS.cf	/usr/lpp/tcpip/samples/sendmail/cf/zOS.cf	Provides z/OS-specific information for the sendmail daemon when being used as a message transfer agent (MTA). Currently the file consists of Secure Sockets Layer (SSL) information only.
ETC.PROTO	usr/lpp/tcpip/samples/protocol	Used to map types of protocol to integer values to determine the availability of the specified protocol. Required by several z/OS Communications Server components. The search order depends on the type of application (z/OS UNIX or native MVS).
ETC.RPC	SEZAINST(ETCRPC)	Defines RPC applications to the Portmapper function.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
ETC.SERVICES	usr/lpp/tcpip/samples/services	Establishes port numbers for servers using TCP and UDP. Required for z/OS UNIX SNMP and OMPROUTE (if the RIP protocol is used). The search order depends on the type of application (z/OS UNIX or native MVS).
/etc/syslog.conf	/usr/lpp/tcpip/samples/syslog.conf	Configuration file for the syslog daemon (syslogd).
FTP.DATA 1. -f command line parameter (FTP client only) 2. The MVS data set or z/OS UNIX file specified on the SYSFTPD DD statement in the FTP server started procedure 3. *userid/jobname*.FTP.DATA 4. /etc/ftp.data 5. SYS1.TCPPARMS(FTPDATA) 6. *hlq*.FTP.DATA	SEZAINST(FTCDATA) for the client and (FTPSDATA) for the server	Overrides default FTP client and server parameters for the FTP server. For more information about the *hlq*, *jobname*, or *userid* values, see Chapter 12, "Transferring files using FTP," on page 659.
HOSTS.LOCAL	SEZAINST(HOSTS)	Input data set to MAKESITE for generation of HOSTS.ADDRINFO and HOSTS.SITEINFO.
IKE daemon configuration 1. The MVS data set or z/OS UNIX file specified by the IKED_FILE environment variable 2. /etc/security/iked.conf	/usr/lpp/tcpip/samples/iked.conf	Contains IKE configuration statements.
LBADV.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the z/OS Load Balancing Advisor started procedure	SEZAINST(LBADVCNF)	Contains z/OS Load Balancing Advisor configuration statements.
LBAGENT.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the z/OS Load Balancing Agent started procedure.	SEZAINST(LBAGECNF)	Contains z/OS Load Balancing Agent configuration statements.
LPD.CONFIG	SEZAINST(LPDDATA)	Configures the Line Printer Daemon for the Remote Print Server.
LU62CFG	SEZAINST(LU62CFG)	Provides configuration parameters for the SNALINK LU6.2 interface.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
MASTER.DATA	No sample provided	DNS database input required for authoritative name servers.
MIBS.DATA 1. The name of a z/OS UNIX file or an MVS data set specified by the MIBS_DATA environment variable 2. /etc/mibs.data z/OS UNIX file	No sample provided	Defines textual names for MIB objects for the z/OS UNIX snmp command.
Network security services (NSS) server configuration 1. The name of a z/OS UNIX file or MVS data set specified by the NSSD_FILE environment variable. 2. /etc/security/nssd.conf	/usr/lpp/tcpip/samples/nssd.conf	Contains NSS server configuration statements.
NPSIDATE	SEZAINST(NPSIDATE)	• Operates the TCP/IP X.25 NCP Packet Switching Interface. • NCP and X.25 definition statements supplied as input to the NCP/EP Definition Facility (NDF) procedure. See *NCP X.25 Planning and Installation* for details.
NPSIGATE	SEZAINST(NPSIGATE)	• Supports GATE MCHs for X.25 NCP Packet Switching Interface. • NCP and X.25 definition statements supplied as input to the NCP/EP Definition Facility (NDF) procedure. See *Network Control Program X.25 Planning and Installation* for details.
OMPROUTE configuration 1. The MVS data set or z/OS UNIX file specified on the OMPCFG DD statement in the OMPROUTE started procedure. 2. The MVS data set or z/OS UNIX file specified by the OMPROUTE_FILE environment variable 3. /etc/omproute.conf 4. *hlq*.ETC.OMPROUTE.CONF	SEZAINST(EZAORCFG)	Contains OMPROUTE configuration statements.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
OSNMP.CONF 1. /etc/osnmp.conf 2. /etc/snmpv2.conf	/usr/lpp/tcpip/samples/snmpv2.conf	Defines target host security parameters for the osnmp command.
OSNMPD.DATA 1. The MVS data set or z/OS UNIX file specified by the OSNMPD_DATA environment variable 2. /etc/osnmpd.data file system file 3. The MVS data set z/OS UNIX file specified on the OSNMPD DD statement in the agent started procedure 4. *jobname*.OSNMPD.DATA, where *jobname* is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(OSNMPD) 6. *hlq*.OSNMPD.DATA, where *hlq* either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	/usr/lpp/tcpip/samples/osnmpd.data	Used by SNMP for setting values for selected MIB objects.
PAGENT.CONF 1. File or data set specified with -c startup option 2. File or data set specified with PAGENT_CONFIG_FILE environment variable 3. /etc/pagent.conf	/usr/lpp/tcpip/samples/pagent.conf	Defines Policy Agent configuration parameters and optionally defines QoS service policies (rules and actions).
PROFILE.TCPIP 1. The MVS data set specified on the PROFILE DD statement in the TCP/IP stack started procedure. 2. *job_name.node_name*.TCPIP 3. *hlq.node_name*.TCPIP 4. *job_name*.PROFILE.TCPIP 5. *hlq*.PROFILE.TCPIP	SEZAINST(SAMPPROF)	Provides TCP/IP initialization parameters and specifications for network interfaces and routing.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
PW.SRC 1. The MVS data set or z/OS UNIX file specified by the PW_SRC environment variable 2. /etc/pw.src file system file 3. The MVS data set or z/OS UNIX file specified on SYSPWSRC DD statement in the started agent procedure 4. *jobname*.PW.SRC, where *jobname* is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(PWSRC) 6. *hlq*.PW.SRC, where *hlq* either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	No sample provided	Defines a list of community names used when accessing objects on a destination SNMP agent.
Resolver Setup File	SEZAINST (RESSETUP)	Provides configuration statements for the resolver.
RSVPD.CONF 1. File or data set specified with -c startup option 2. File or data set specified with RSVPD_CONFIG_FILE environment variable 3. /etc/rsvpd.conf 4. *hlq*.RSVPD.CONF	/usr/lpp/tcpip/samples/rsvpd.conf	Defines RSVP Agent configuration parameters.
SMTPCONF The MVS data set referenced by CONFIG DD statement in the SMTP started procedure.	SEZAINST(SMTPCONF)	Provides configuration parameters for the Simple Mail Transfer Protocol (SMTP).
SMTPNOTE clist System CLIST data set	SEZAINST(SMTPNOTE)	Defines the *note* parameters for Simple Mail Transfer Protocol (SMTP) and the CSSMTP application.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
SNMPD.BOOTS 1. The name of a z/OS UNIX file system file or an MVS data set specified by the SNMPD_BOOTS environment variable. 2. /etc/snmpd.boots	No sample provided	Defines the SNMP agent security and notification destinations. **Note:** If the SNMPD.BOOTS file is not provided, the SNMP agent creates the file. If multiple SNMPv3 agents are running on the same MVS image, use the environment variable to specify different SNMPD.BOOTS files for the different agents. For security reasons, ensure unique engine IDs are used for different SNMP agents.
SNMPD.CONF 1. The name of a z/OS UNIX file system file or an MVS data set specified by the SNMPD_CONF environment variable. 2. /etc/snmpd.conf **Note:** The first file found in the search order is used.	/usr/lpp/tcpip/samples/snmpd.conf	Defines the SNMP agent security and notification destinations. **Note:** If the SNMPD.CONF file is found, the PW.SRC file and the SNMPTRAP.DEST files are not used.
SNMPTRAP.DEST 1. The MVS data set or z/OS UNIX file specified by the SNMPTRAP_DEST environment variable 2. /etc/snmptrap.dest file system file 3. The MVS data set or z/OS UNIX file specified on SNMPTRAP DD statement in the agent started procedure 4. *jobname*.SNMPTRAP.DEST, where *jobname* is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(SNMPTRAP) 6. *hlq*.SNMPTRAP.DEST, where *hlq* either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	No sample provided	Defines a list of managers to which the SNMP agent sends traps.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
TCPIP.DATA	SEZAINST(TCPDATA)	Provides parameters for TCP/IP client programs. The search order depends on the type of application (z/OS UNIX or native MVS). For more information about TCPIP.DATA, see *z/OS Communications Server: IP Configuration Reference*.
TNDBCSCN The MVS data set specified on the TNDBCSCN DD statement in the TN3270E Telnet server started procedure	SEZAINST(TNDBCSCN)	Provides configuration parameters for Telnet 3270 Transform support.
TRAPFWD.CONF 1. A z/OS UNIX system file or an MVS data set specified by the TRAPFWD_CONF environment variable 2. /etc/trapfwd.conf	No sample provided	Defines addresses to which the Trap Forwarder Daemon forwards traps. **Note:** If the environment variable is set and if the file specified by the environment variable is not found, the Trap Forwarder daemon terminates.
VTAMLST The VTAM definitions added to the ATCCONxx member of the MVS data set specified on the VTAMLST DD statement in the VTAM started procedure	SEZAINST(VTAMLST)	Defines VTAM applications and their characteristics. Entries required for TN3270E Telnet server, SNALINK LU0, SNALINK LU6.2, and X.25 NPSI Server.
X25CONF The MVS data set specified on the X25IPI DD statement in the X25PROC started procedure	SEZAINST(X25CONF)	Provides configuration parameters for the X.25 NCP Packet Switching Interface.
X25VSVC The VTAM switched major node definition, added as a member of the MVS data set specified on the VTAMLST DD statement in the VTAM started procedure	SEZAINST(X25VSVC)	Provides switched virtual circuit configuration for the X.25 NCP Packet Switching Interface.

Configuration files for the TCP/IP stack

Two configuration files are used by the TCP/IP stack, PROFILE.TCPIP and TCPIP.DATA. PROFILE.TCPIP is used only for the configuration of the TCP/IP stack. TCPIP.DATA is used during configuration of both the TCP/IP stack and applications; the search order used to find TCPIP.DATA is the same for both the TCP/IP stack and applications.

PROFILE.TCPIP search order

During initialization of the TCP/IP stack, system operation and configuration parameters for the TCP/IP stack are read from the configuration file PROFILE.TCPIP. As shown in Table 1 on page 21, the search order used by the TCP/IP stack to find PROFILE.TCPIP involves both explicit and dynamic data set allocation as follows:

- //PROFILE DD DSN=*aaa.bbb.ccc(anyname)*
- *jobname.nodename*.TCPIP
- *hlq.nodename*.TCPIP
- *jobname*.PROFILE.TCPIP
- TCPIP.PROFILE.TCPIP

Note: Explicitly specifying the PROFILE DD statement in the TCPIPROC JCL is the recommended way to specify PROFILE.TCPIP. If this DD statement is present, the data set it defines is explicitly allocated by MVS and no dynamic allocation is done. If this statement is not present, the search order continues to use dynamic allocation for the PROFILE.TCPIP.

Examples

These examples show the search order used by TCP/IP to find the configuration file PROFILE.TCPIP. These examples use the sample TCP/IP started procedure, TCPIPROC, installed in the SEZAINST data set.

Example when DD cards are in your TCP/IP startup procedure: In this example, the PROFILE DD cards are specified as follows:

```
//TCPIP  PROC PARMS='CTRACE(CTIEZB00)'
//*
//* z/OS Communications Server
//* SMP/E Distribution Name: EZAEB01G
//*
//*     5694-A01 (C) Copr. IBM Corp. 1991,2001.
//*     All rights reserved.
//*     US Government Users Restricted Rights -
//*     Use, duplication or disclosure restricted
//*     by GSA ADP Schedule Contract with IBM Corp.
//*     See IBM Copyright Instructions
//*
//TCPIP    EXEC PGM=EZBTCPIP,
//             PARM='&PARMS',
//             REGION=0K,TIME=1440
//*
:
//PROFILE DD DISP=SHR,DSN=MVSA.PROD.PARMS(PROFILE)
:
```

Because the PROFILE DD is the first step in the search order, TCP/IP uses the data set MVSA.PROD.PARMS(PROFILE) as the PROFILE.TCPIP configuration file.

Example when no DD cards are in your TCP/IP startup procedure: In this example, the PROFILE DD statement is not specified:

```
//TCPIP  PROC PARMS='CTRACE(CTIEZB00)'
//*
//* z/OS Communications Server
//* SMP/E Distribution Name: EZAEB01G
//*
//*     5694-A01 (C) Copr. IBM Corp. 1991,2001.
//*     All rights reserved.
//*     US Government Users Restricted Rights -
```

```
//*     Use, duplication or disclosure restricted
//*     by GSA ADP Schedule Contract with IBM Corp.
//*     See IBM Copyright Instructions
//*
//TCPIP    EXEC PGM=EZBTCPIP,
//             PARM='&PARMS',
//             REGION=0K,TIME=1440
//*
:
```

For the configuration file PROFILE.TCPIP, the search order used is as follows:

1. PROFILE DD

   No PROFILE DD exists...search continues.
2. *jobname.nodename.*TCPIP

   If *jobname.nodename.*TCPIP is found, the search stops here.
3. *hlq.nodename.*TCPIP

   If *hlq.nodename.*TCPIP is found, the search stops here.
4. *jobname*.PROFILE.TCPIP

   If *jobname*.PROFILE.TCPIP is found, the search stops here.
5. TCPIP.PROFILE.TCPIP

   TCPIP.PROFILE.TCPIP is searched last if necessary.

TCPIP.DATA search order

The TCP/IP stack's configuration component uses the TCPIP.DATA configuration file during TCP/IP stack initialization to determine the stack's host name. To find the TCPIP.DATA information, the z/OS UNIX environment search order is used. For a description of this search order, see “Search orders used in the z/OS UNIX environment” on page 762. This host name value is the value that is returned on gethostname socket function calls processed by this stack.

For details on the z/OS UNIX environment and native MVS environment search orders and the usage of z/OS UNIX environment variables, see “Resolver configuration files” on page 759.

Configuration files for TCP/IP applications

This information describes environment variables, the resolver configuration files that can be used by TCP/IP applications, and the search orders for those files. In addition to resolver files, an application can also have its own configuration files that are specific to that application. For more information about application-specific configuration files, see the descriptions of the individual applications in Part 2, “Server applications,” on page 511.

Environment variables

Environment variables are named variables with assigned values that can be accessed by various processes in the Communications Server configuration. Applications use environment variables to define the characteristics of their specific environment.

Table 2 on page 31 lists where to find more information about the environment variables that are explicitly set or used by z/OS Communications Server and its applications. Language Environment® and UNIX System Services also provide environment variables. For information regarding these other variables, see Understanding Shell Variables in *z/OS UNIX System Services User's Guide*.

Table 2. Environment variables

Application	For environment variable information, see:
Bind 9 - DNS	Bind 9-based DNS environment variables in *z/OS Communications Server: IP Configuration Reference*
Communications Server SMTP (CSSMTP)	CSSMTP application environment variables in *z/OS Communications Server: IP Configuration Reference*

X Window System	X Window System environment variables in *z/OS Communications Server: IP Programmer's Guide and Reference*

MVS-related considerations

This topic includes an overview of MVS-related considerations for configuring z/OS Communications Server.

MVS system symbols

Use of MVS system symbols in the PROFILE.TCPIP data set, and data sets referenced by VARY TCPIP,,OBEYFILE commands, is automatically supported. This automatic support first tries to use hiperspace memory files to perform the symbol translation, but if an error occurs, a temporary file is used. The temporary file is created in either the directory specified by the TMPDIR environment variable or, if the TMPDIR environment variable is not defined, in the /tmp directory.

Use of MVS system symbols in the resolver setup file and the TCPIP.DATA file is also automatically supported. The resolver reads and processes the TCPIP.DATA file on behalf of TCP/IP applications that invoke resolver services. System symbols are resolved as file records are read.

Use of MVS system symbols is also supported in the following cases:

- Values of resolver environment variables, like RESOLVER_CONFIG and RESOLVER_TRACE
- OMPROUTE configuration file
- Communications Server SMTP (CSSMTP) configuration file
- BeginArchiveParms DSNPrefix parameter in the syslogd configuration file

For MVS system symbols in other configuration files, use the symbol translator utility, EZACFSM1, to translate the symbols before the files are read by TCP/IP. EZACFSM1 reads an input file and writes to an output file, translating any symbols in the process. For lists of the static system symbols and dynamic system symbols supported by EZACFSM1, see *z/OS MVS Initialization and Tuning Reference*.

Guideline: The input file and output file can be MVS data sets or z/OS UNIX files; however, do not specify the same file for both the input and output file. If you specify the same file, a return code of 45 is returned and no translation is attempted.

Restriction: The record length of the input file cannot exceed 80 bytes.

For more information about the use of MVS system services, see *z/OS MVS Initialization and Tuning Guide*.

Following is the symbol translator JCL, found in SEZAINST(CONVSYM), which is used to start EZACFSM1:

```
//________ JOB (accounting,information),programmer.name,
//             MSGLEVEL=(1,1),MSGCLASS=A,CLASS=A
//*
//*   CS for z/OS
//*   SMP/E distribution name: EZACFCSY
//*
//*   5694-A01 (C) Copyright IBM Corp. 1998, 2005
//*   Licensed Materials - Property of IBM
//*
//*   Function: System Symbols Translator JCL
//*
//*   This JCL kicks off a utility that will read from
//*   an input file that contains MVS System Symbols
//*   and produce an output file which has those symbols
//*   replaced with their substitution text, as defined
//*   in the appropriate IEASYMxx PARMLIB data set; see MVS
//*   Initializaton and Tuning Reference for rules about symbols.
//*
//*   This JCL can be run against any of the TCP/IP configuration
//*   files that contain MVS System Symbols.  An example of how it
//*   could be used is this; a customer could have one base TCPIP.DATA
//*   file containing MVS System Symbols which they edit and maintain.
//*   They would run this utility against this one file the various
//*   MVS systems to produce the TCPIP.DATA file for each different
//*   system.
//*
//STEP1   EXEC  PGM=EZACFSM1,REGION=0K
//SYSIN   DD DSN=TCP.DATA.INPUT,DISP=SHR
//*SYSIN   DD    PATH='/tmp/tcp.data.input'
//*          The input file can be either an MVS data set or an z/OS
//*            UNIX file.
//*
//*
//SYSOUT  DD DSN=TCP.DATA.OUTPUT,DISP=SHR
//*SYSOUT  DD    PATH='/tmp/tcp.data.output',PATHOPTS=(OWRONLY,OCREAT),
//*              PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
//*          The output file can be either an MVS data set or an z/OS
//*            UNIX file.
//*
//*          The output file cannot be the same file as the input file-
//*          doing so will result in a return code of 45.
//*
//*          You can mix input and output file types (i.e., the input
//*          can be an MVS data set with the output being a z/OS UNIX
//*          file or visa versa).
//*          Note: Other pathmodes for sysout may be used if needed.
```

The symbol translator utility can be used on any of the TCP/IP configuration files, but because the PROFILE.TCPIP file is automatically translated during TCP/IP initialization, there is no need to run the utility against that file.

Automatic restart manager

Automatic restart manager (ARM) is an MVS component that can automatically restart the TCP/IP stack after an abnormal end (ABEND).

During initialization, TCP/IP automatically registers with the automatic restart manager, using the following options:

```
REQUEST=REGISTER
ELEMNAME=EZAsysclonetcpname
```

where:

- *sysclone* is a 1– or 2–character shorthand notation for the name of the MVS system. For a complete description of the SYSCLONE static system symbol, see *z/OS MVS Initialization and Tuning Reference*.
- *tcpname* is a 1– to 8–character name of the TCP/IP stack which registers with the automatic restart manager. For example, if the SYSCLONE value is 02 and the TCP/IP stack name is TCPCS, the resulting ELEMENT value is EZA02TCPCS.

```
ELEMTYPE=SYSTCPIP
TERMTYPE=ELEMTERM
```

For more information about automatic restart manager, see *z/OS MVS Setting Up a Sysplex*.

Logging of system messages

Syslog daemon (syslogd) is a server process that must be started as one of the first processes in your z/OS UNIX environment. TCP/IP server applications and components use syslogd for logging purposes and can also send trace information to syslogd. Servers on the local system use AF_UNIX sockets to communicate with syslogd; remote servers use AF_INET sockets. z/OS Communications Server components use the `local1`, `local4`, `daemon`, `mail`, `user`, and `auth` facilities names.

Note: Each application activates and deactivates traces in a slightly different manner. For details, see the information about the individual application.

The syslog daemon reads and logs system messages to the MVS console, log files, SMF, other machines, the operlog log stream, or users as specified by the configuration file. If syslogd is not started, log data from some applications will be displayed on the MVS console. For more information on syslogd, see Chapter 5, "TCP/IP Customization," on page 185.

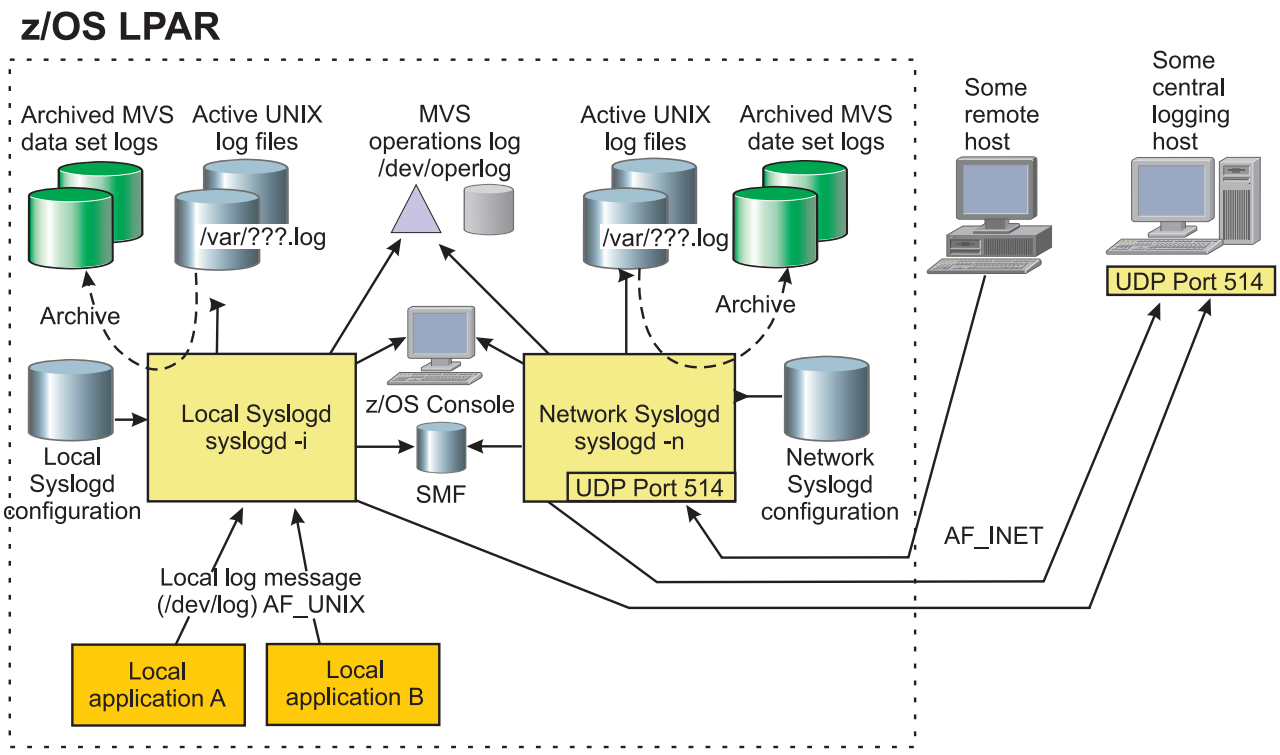

Figure 2. syslogd operation

Note: /var/???.log is the file specified in the syslogd.conf file.

The syslogd facility uses a common mechanism for segregating messages. Table 3 shows the facilities used by z/OS Communications Server functions which write messages to syslogd. The Primary syslog facility column shows the syslog facility used for most messages logged by the application. Some applications use other facilities for certain messages. Table 3 also shows any additional facilities.

Table 3. syslogd facilities

Application	syslogd record identifications	Primary syslog facility	Other syslog facility
Application Transparent Transport Layer Security (AT-TLS)	TTLS	daemon	auth
Automated domain name registration (ADNR)	adnr	daemon	None
Communications Server SMTP (CSSMTP)	CSSMTP	mail	None
Defense Manager daemon (DMD)	DMD	local4	None
FTP server	ftpd, ftps	daemon	None
IKE daemon	IKED	local4	None
NAMED	named	daemon	None
Network security services (NSS) server	NSSD	local4	None

Table 3. syslogd facilities (continued)

Application	syslogd record identifications	Primary syslog facility	Other syslog facility
Network SLAPM2 subagent	NSLAPM2	daemon	None
OMPROUTE	omproute	user	None
OPORTMAP server	oportmap	daemon	None
OREXECD	rexecd	daemon	auth
ORSHD	rshd	daemon	auth
OTELNETD	telnetd	local1	auth
Policy Agent	Pagent	daemon	None
POPPER	popper	mail	None
PWCHANGE command	pwchange	daemon	None
PWTOKEY command	pwtokey	daemon	None
rpcbind	rpcbind	daemon	None
SENDMAIL	sendmail	mail	None
Simple Network Time Protocol daemon	sntpd	daemon	None
SNMP agent (OSNMPD)	snmpagent	daemon	None
syslogd	syslogd	daemon	None
TCP/IP subagent	M2SubA	daemon	None
TFTP server	tftpd	user	None
TIMED daemon	timed	user	None
TN3270E Telnet subagent	TNSubA	daemon	None
Traffic Regulation Management Daemon (TRMD)	TRMD	daemon (used for IDS logging)	local4 (used for IPSEC logging and defensive filter logging)
Trap Forwarder daemon	trapfwd	daemon	None
z/OS Load Balancing Advisor	lbadv	daemon	None
z/OS Load Balancing Agent	lbagent	daemon	None

Accounting - SMF records

Installations use Systems Management Facilities (SMF) records for the following reasons:

Performance management

Performance management includes the tasks that are related to verifying that defined service levels are met, and if not, identifying possible causes.

Aggregated information about delivered service, structured by organizational units (for which service levels have been defined) is needed

to perform these tasks. These reports are typically time series with varying levels of time intervals, ranging from weeks through days to a time interval that matches the SMF interval. Some examples of potential reports related to performance management are:

- TCP connection elapsed time per server port number per time of day (potentially broken down on source IP address, or netmask)
- Number of TCP connections per server port number per time of day (potentially broken down on source IP address, or netmask)
- Number of inbound/outbound bytes transferred in TCP connections per time of day (potentially broken down in various ways: per destination or source port, per destination IP address, netmask, or in total, etc.)
- TCP retransmission activity per time of day (potentially broken down per destination IP address, or netmask)
- Number of outbound TCP connections per time of day (potentially broken down per destination IP address, or netmask)
- Number of inbound/outbound UDP datagrams per time of day (potentially broken down on server port number)
- Number of discards, error packets, and unknown protocol packets inbound and outbound per time of day (potentially broken down per interface)

Capacity planning

Capacity planning includes tasks that are related to forecasting capacity in terms of central processing power, memory, channel-based I/O subsystem, network attachments, and network bandwidth. Such planning tasks are based on analyzing trends for use of capacity during a preceding period (typically one to two years), and applying forecasting metrics, along with knowledge about planned launches of new applications or use of existing applications, to this trend in order to predict capacity needs during the next one to two year period. Some examples of potential reports related to capacity planning are:

- Total number of TCP connections per reserved server port number per day including analysis of average and variations around average during daily peak periods
- Total number of UDP inbound/outbound UDP datagrams per reserved server port number per day including average and variations around average during daily peak periods
- Number of bytes and/or packets transferred inbound and outbound per interface (LINK) per time of day (potentially broken down into unicasts, broadcasts, and multicasts)
- Size of queue length per interface per time of day

Auditing

Auditing involves tasks that are related to identifying and proving that individual events have taken place. Some examples of potential reports related to auditing are:

- Detailed information about specific TCP connections or UDP sockets, IP addresses, server/client identification, duration, number of bytes, and so on
- Details about activity that involves a specific client or server
- Details about a given application session based on server-specific SMF recording, such as individual Telnet sessions or FTP sessions

- Details about changes to the TCP/IP stack profile and the user that requested the change
- Details about changes to the status of dynamic virtual IP addresses (DVIPAs) and sysplex distributor targets

Accounting

Accounting involves tasks that are related to calculating how much each individual user or organizational unit should be charged for use of the shared central IS resources. Input to such calculations vary, but is often based on CPU cycle use, data quantities, bandwidth usage, and memory use. For TCP/IP additional metrics may be defined, such as type of service used (FTP, LPD, Web server, and so on), and TCP connection-related information (number of connections, duration, byte transfer counts, and so on). Some examples of potential reports related to accounting are:

- Aggregated number of connections to a given server from a given source in terms of a specific client IP address, or netmask
- Accumulated connect time to a given server from a given source in terms of a specific client IP address, or netmask.
- Number of bytes transferred to or from a given source in terms of a specific client IP address, or netmask.
- Amount of data protected by specific manual or dynamic tunnels.
- Application-level accounting information specific to each individual server, for example:
  - For CSSMTP: Information about mail message processing
  - For FTP: Number of transfer operations and bytes retrieved or stored per user ID
  - For IKED: Information about IKE tunnels
  - For TN3270: Number of sessions and session type (TN3270/TN3270E/LINEMODE)

In general, SMF records are created for deferred processing and analysis. SMF recording is generally not used for real-time monitoring purposes. In a TCP/IP environment, real-time monitoring is implemented using the SNMP protocol and is based on internal variables that are maintained by SNMP subagents, but on z/OS a lot of the information that is written in SMF records is useful from a real-time monitoring perspective, too.

As can be seen, all disciplines require detailed data as input. Depending on the discipline, certain levels of aggregation is performed on the raw detailed data in order to perform the tasks of that discipline. The objective of the TCP/IP product is to define and generate the lowest level of detail that is needed by all disciplines. How to aggregate and the actual aggregation is performed by other products, such as Performance Reporter for z/OS (PR), MVS Information Control System (MICS), or SAS-based tools or, in many cases, customer-written programs.

TCP/IP– produced SMF records should not be viewed isolated. Other components in MVS produce SMF records for the same purposes as those produced by TCP/IP. An installation is likely to combine information from a series of subsystems in performing detailed performance, or capacity planning. SMF records with information about use of CPU resources and memory resources per address space is, for example, produced by other components in MVS, and TCP/IP produced SMF records should not duplicate that information.

The events that trigger SMF records to be written and the information included in the SMF records must accommodate the intended purposes. There can be multiple purposes for given SMF records.

SMF records can be cut at multiple levels in the TCP/IP protocol stack, and the type of information that can be included depends on where the SMF record is created:

- At the IP and interface layer, there is information about ICMP activity, IP packet fragmentation and reassembly activity, IP checksum errors, IGMP activity, and ARP activity. At this layer, it is difficult to relate the information to specific users (remote clients, local socket address spaces, and so on), so from an accounting point of view, this information is not very interesting. Because you can aggregate network-layer activity to physical interfaces, the information at the IP and interface layer is an important aspect of both performance and capacity management.
- At the transport protocol layer, there is information about IP addresses, port numbers, and host names. For TCP-related workload, there is information about connections and information that is related to TCP connections, such as byte counts, connection times, reliability metrics, and performance metrics. For UDP-related workload, each UDP datagram is a separate entity; the only way to aggregate information for UDP is on a UDP socket level, where SMF records could be created every time a UDP socket is closed.
- At the application layer, there are more details about what goes on, but every application is different and requires separate SMF record definitions and ability to write the SMF records to implement application-layer SMF recording. Currently, application-layer SMF recording is done for the TN3270E Telnet server (Telnet), the FTP server, and the IKE daemon, but not for any other servers.

For more information about the SMF records provided by z/OS Communications Server functions, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Security considerations

Multilevel security is an enhanced security environment that can be configured on a z/OS system. In this environment, the security server and trusted resource managers enforce mandatory access control policies in addition to the usual discretionary access control policies. To participate in a multilevel secure environment, the user IDs associated with z/OS CS tasks and the resource profiles in the SERVAUTH class need to have security labels defined. For more information on the multilevel secure environment and configuring z/OS CS in that environment, see Chapter 4, "Preparing for TCP/IP networking in a multilevel secure environment," on page 153.

z/OS Communications Server relies on a System Authorization Facility (SAF) to protect several resources:

- Started tasks require access to a STARTED resource. This is documented in the server information in the *z/OS Communications Server: IP Configuration Reference*. Also, see SEZAINST(EZARACF) for SAF authorizations required for the TCP/IP stack and servers started tasks.
- Restricting access to a network, subnetwork or particular IP address in the network is provided by resources in the SERVAUTH class. Using NETACCESS statements, z/OS CS can map networks, subnetworks and IP addresses to SAF resource names. Users that are not permitted access to a particular SAF resource are not allowed to communicate with the corresponding network, subnetwork,

or IP address. See the NETACCESS statement in *z/OS Communications Server: IP Configuration Reference* or "Setting up the System Authorization Facility server access authorization class (optional)" on page 240 for more information.

Restricting the ability of the users to run applications that access specific TCP and UDP ports is also provided by resources in the SERVAUTH class. z/OS Communications Server provides a one-to-one mapping between port numbers and SAF resource names. See the PORTACCESS statement in the *z/OS Communications Server: IP Configuration Reference* or "Setting up the System Authorization Facility server access authorization class (optional)" on page 240 for more information.

Similar to the function provided by the PORTACCESS statement, z/OS Communications Server ensures that a user attempting to connect to a TN3270E Telnet server secure port is allowed access to the port. This support is used in conjunction with Telnet client authentication support. See the CLIENTAUTH statement in the *z/OS Communications Server: IP Configuration Reference* or "Setting up the System Authorization Facility server access authorization class (optional)" on page 240 for more information.

Restricting access to the TCPIP stack is also controlled under z/OS CS by defining a resource in the SERVAUTH class. See "Setting up the System Authorization Facility server access authorization class (optional)" on page 240 for more information.

- Restricting access to operator commands is provided through the OPERCMDS resource. z/OS Communications Server verifies that users have access to specific OPERCMDS resources before executing the operator command. See the operator commands information in *z/OS Communications Server: IP System Administrator's Commands* or "Setting up the System Authorization Facility server access authorization class (optional)" on page 240 for more information about limiting access to z/OS Communications Server commands.
- Restricting access to the TSO and UNIX shell Netstat command is provided by SERVAUTH resources. z/OS Communications Server verifies that users have access to specific SERVAUTH resources before executing the Netstat command. See the Netstat command information in the *z/OS Communications Server: IP System Administrator's Commands* for more information about limiting access to Netstat command. The security product resource names in the SERVAUTH class do not apply to DISPLAY TCPIP,,NETSTAT command. If you wish to restrict access to DISPLAY TCPIP,,NETSTAT command, you can do so using standard operator command restriction facility, OPERCMDS class profiles. See *z/OS MVS Planning: Operations* for more information.

Nonreusable ASIDs

The following Communications Server address spaces provide PC-entered services that must be accessible to all address spaces, so a system LX is obtained.

- Resolver
- TCP/IP stack
- TN3270 Telnet server
- VMCF and TNF subsystems

  The following applications use these subsystems:
  - SNMP Query Engine application
  - Pascal Socket Interface
  - SMTP and LPD servers
  - TSO TELNET, HOMETEST, TESTSITE, RSH, REXEC, and LPR commands

Unless you specify REUSASID=YES on the START command, the Address Space Identifiers (ASIDs) associated with these address spaces will be nonreusable when these address spaces are stopped or restarted. If these address spaces are stopped enough times and you do not specify REUSASID=YES when you start the address space, all available ASIDs might be exhausted, which prevents a new address space from being created on the system. In this case, an IPL is required. Specifying REUSASID=YES when starting these address spaces ensures that the ASIDs associated with them can be reused and can help avoid an IPL. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in *z/OS MVS Initialization and Tuning Reference*.

Restriction: Do not specify REUSASID=YES when you are starting the VMCF and TNF subsystems or any applications that use these subsystems.

TSO command authorization

The LPR, MODDVIPA, PING, and TRACERTE commands should be listed in the AUTHCMD NAMES section of your IKJTSO*xx* member of SYS1.PARMLIB.

If a command such as PING or TRACERTE is invoked using another method other than a TSO command, you might have to do additional authorization customization, such as also adding the program names to the AUTHPGM NAMES section of your IKJTSO*xx* SYS1.PARMLIB member.

UNIX System Services security considerations

This information describes some security considerations that have a product-wide effect. Descriptions of security considerations that affect specific servers or components are described with the information for each server and component.

Requirement for an OMVS segment

Many TCP/IP Services components in z/OS Communications Server now exploit z/OS UNIX services in both the native MVS environment and in the z/OS UNIX environment. For example, all TCP/IP socket APIs and TCP/IP applications (whether they are provided by z/OS Communications Server, z/OS, other IBM and non-IBM products, or written by users) now make use of z/OS UNIX services.

Use of z/OS UNIX services requires a z/OS UNIX security context, referred to as an *OMVS segment*, for the user ID associated with any unit of work requesting these services. In other words, most user IDs requiring access to TCP/IP functions now require an OMVS segment to be defined in Resource Access Control Facility (RACF).

Note: The tasks, examples, and references in this information assume that you are using the z/OS Communications Server Security Server (RACF). If you are using a security product from another vendor, read the documentation for that product for instructions on task performance.

To satisfy the requirement for an OMVS segment in RACF, do one of the following:

- Identify all the users in your environment that use TCP/IP services and then define OMVS RACF segments for the associated user IDs.
- Use the unique OMVS segment support provided by RACF and z/OS UNIX for users and groups.

Unique OMVS segment support is enabled when you define the BPX.UNIQUE.USER profile in the FACILITY class. RACF automatically generates unique UIDs and GIDs on demand for users and groups that do not have OMVS segments defined. RACF saves the generated UIDs and GIDs in unique OMVS segments created for user and group profiles in the RACF database.

Guideline: If you currently use default OMVS segment support, switch to unique OMVS segment support to improve security. Default OMVS segment support assigns default OMVS segments that share the same UID and GID, while unique OMVS segment support uses unique IDs.

For more information about unique OMVS segment support, see *z/OS UNIX System Services Planning*. For steps to use unique OMVS segment support, see *z/OS Security Server RACF Security Administrator's Guide*.

Authorization of TCP/IP started task user ID

The TCP/IP address space operates as a transport provider for the INET physical file system. For this to occur, the TCP/IP system address space must connect to z/OS UNIX and become a z/OS UNIX process. Therefore, the started task UID that is assigned to the TCP/IP system address space must have a valid OMVS segment.

As a transport provider, the TCP/IP address space requires superuser privileges in z/OS UNIX. Define the TCP/IP system address space started task UID as UID=0, or define the TCP/IP system address space as a trusted environment in the RACF started class profile for the TCP/IP system address space. Use the following command to assign an OMVS segment to the TCP/IP started task user ID specified as UID=0:

```
ALU tcpip_userid OMVS(UID(0) HOME(/) PGM(/bin/sh))
```

Other user IDs requiring z/OS UNIX superuser authority

When a started procedure is used to start the following servers, daemons, and agents, the user must be a superuser [UID(0)] or permitted to BPX.SUPERUSER class profile.

- Domain Name System (DNS) BIND v9 name server
- Network Print Facility (NPF) queue manager
- OMPROUTE server
- Sendmail Mail Transfer Agent (MTA)
- SNMP agent (OSNMPD)
- TN3270E Telnet server

The File Transfer Protocol (FTP) daemon requires UID(0). For more information, see "Security for the FTP server" on page 663.

The following daemons are managed by the inetd server, and the user specified in file /etc/inetd.conf must be defined to RACF with UID(0). For details on inetd, see *z/OS UNIX System Services Planning*. For details on individual daemons, see *z/OS Communications Server: IP Configuration Reference*.

- z/OS UNIX remote execution daemon (REXECD)
- z/OS UNIX remote shell daemon (RSHD)
- z/OS UNIX Telnet daemon

BPX.DAEMON FACILITY class profile

Certain z/OS Communications Server TCP/IP Services servers need to change the security environment of the process in which they currently execute. For example, the FTPD daemon creates a new z/OS UNIX process for every FTP client connecting to it. After the new process is created, the daemon changes the security environment of the process so that it is associated with the security context of the logged-in user. The RACF FACILITY class resource BPX.DAEMON is used for this purpose. Table 4 contains information about using the BPX.DAEMON resource.

Table 4. BPX.DAEMON

Task	Details
Decide if you want to activate the BPX.DAEMON level of security by reviewing the information about BPX.DAEMON authority in *z/OS UNIX System Services Planning* to determine whether this level of security is appropriate for your installation.	This is not required. It is recommended, however, because it provides additional security in the z/OS UNIX environment. The following TCP/IP Services servers and daemons in z/OS Communications Server change the security environment of their processes: • FTPD • Network security services (NSS) server • Policy Agent • z/OS UNIX REXECD • z/OS UNIX RSHD • z/OS UNIX TELNETD
Plan the time at which you define BPX.DAEMON carefully.	As soon as you define the BPX.DAEMON resource, MVS will not let programs change the security environment unless the programs are retrieved from a program-controlled library and unless the UID under which the program executes has access to BPX.DAEMON.
If you decide *not* to define the BPX.DAEMON FACILITY class profile, assign UID(0) for the UIDs associated with these servers and daemons.	This is sufficient for processing. It is described in "Other user IDs requiring z/OS UNIX superuser authority" on page 42.
If you *do* decide to define the BPX.DAEMON FACILITY class profile, grant READ access to this profile for the UIDs associated with the listed daemons. Also, enable BPX.DAEMON security by defining the BPX.DAEMON FACILITY class profile in RACF.	To define the BPX.DAEMON FACILITY class profile in RACF, use the following command: `RDEFINE FACILITY BPX.DAEMON UACC(NONE)` **Note:** You must specify the name BPX.DAEMON in this command. Substitutions for the name are not allowed.

If all the required conditions are not met, your server programs will fail as soon as you define BPX.DAEMON. If the server programs fail, delete BPX.DAEMON, and the setup reverts to its previous state. Check all your definitions, and make the required corrections before trying to define BPX.DAEMON again.

If this is the first FACILITY class profile that your installation is using, activate the FACILITY class using the following commands:

```
SETROPTS CLASSACT(FACILITY) GENERIC(FACILITY) AUDIT(FACILITY)
SETROPTS RACLIST(FACILITY)
```

If you start server programs using MVS start commands or from shell scripts that execute after startup of z/OS UNIX, you must allow the UIDs access to the BPX.DAEMON FACILITY class resource. The following example shows the UID (ftpd_user_ID) with which you can start the FTPD daemon:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(ftpd_user_ID) ACCESS(READ)
```

Authorization to change the user security environment is granted only if both of the following two conditions are true:

- The server program is executing under a UID that has READ permission to the BPX.DAEMON FACILITY class profile and a UID=0.
- All programs running in the address space have been retrieved from a controlled library.

Program control

There are additional security concerns when you are loading programs that are considered trusted into the z/OS UNIX file system. Program control facilities in RACF and z/OS UNIX provide a mechanism for ensuring that the z/OS UNIX program loading process has the same security features that APF authorization provides in the native MVS environment.

It is recommended that you enable program control in your installation. If you define the BPX.DAEMON FACILITY class profile, you *must* enable program control for certain z/OS Communications Server load libraries. Review the information on program control in *z/OS UNIX System Services Planning* to decide whether program control is appropriate for your installation.

To enable program control, follow the tasks in Table 5.

Table 5. Program control

Task	Details
Activate program control.	Use the following command: `SETROPTS WHEN(PROGRAM)`

Set the universal access for public library data sets (those in LINKLST*xx*) to READ. This allows access to the controlled programs and any other program in those libraries. (MVS opens the LNKLST*xx* libraries during IPL and makes these programs public. However, users cannot make changes.)	Use the following commands to create RACF data set profiles:
	`ADDSD 'cee.version.SCEERUN' UACC(READ)`
	`ADDSD 'SYS1.LINKLIB' UACC(READ)`
	`ADDSD 'TCPIP.SEZALOAD' UACC(READ)`
	`ADDSD 'TCPIP.SEZATCP' UACC(READ)`

Table 5. Program control (continued)

Task	Details

Ensure all load modules that are loaded by the BPX.DAEMON servers into an address space come from controlled libraries.	If the MVS contents supervisor loads a module from a noncontrolled library, the address space becomes *dirty* and loses its authorization. To prevent this from happening, define all the libraries from which load modules can be loaded as program controlled. At a minimum, this should include the C run-time library, the TCP/IP Services SEZALOAD and SEZATCP libraries, SYS1.LINKLIB, and any load libraries containing FTP security exits.
	
	Use the following commands:
	`RDEFINE PROGRAM * ADDMEM('SYS1.LINKLIB'/volser/NOPADCHK) UACC(READ)`
	`RALTER PROGRAM * ADDMEM('SYS1.SIEALNKE'/volser/NOPADCHK)`
	`RALTER PROGRAM * ADDMEM('cee.version.SCEERUN'/volser/NOPADCHK)`
	`RALTER PROGRAM * ADDMEM('TCPIP.SEZALOAD'/volser/NOPADCHK)`
	`RALTER PROGRAM * ADDMEM('TCPIP.SEZATCP'/volser/NOPADCHK)`
	`RALTER PROGRAM * ADDMEM('db2.DSNLOAD'/volser/NOPADCHK)`
	`RALTER PROGRAM * ADDMEM('db2.DSNEXIT'/volser/NPPADCHK)`
	`RALTER PROGRAM * ADDMEM('ftp.userexits'/volser/NOPADCHK)`
	
	Note: If you define the load libraries as controlled, do not specify a universal access of NONE for the PROGRAM resources. If you do so for your SYS1.LINKLIB programs, you cannot IPL your z/OS system. Be aware also that in z/OS, the *volser* specification is optional.

Activate RACF changes.	Use the following command: `SETROPTS WHEN(PROGRAM) REFRESH`

Defining TCP/IP as a UNIX System Services physical file system

The TCP/IP services stack in z/OS Communications Server must be defined as a z/OS Communications Server UNIX System Services physical file system (PFS) before it can be started. This involves updating the BPXPRM*xx* parmlib member. The following sample definition in BPXPRM*xx* defines TCP/IP as a z/OS Communications Server UNIX System Services PFS, where the network layer is IP Version 4 (IPv4) and communication at the sockets layer is through the AF_INET family:

```
FILESYSTYPE TYPE(INET)  ENTRYPOINT(EZBPFINI)

NETWORK DOMAINNAME(AF_INET)
        DOMAINNUMBER(2)
        MAXSOCKETS(60000)
        TYPE(INET)
```

This sample definition shows how to define a single TCP/IP stack as IPv4 only. To define a single TCPIP stack as both IPv4 and IPv6, add an additional NETWORK statement in the BPXPRM*xx* member. The following sample definition in BPXPRM*xx* defines TCP/IP as a z/OS Communications Server UNIX System Services PFS, where the network layer is IP Version 6 (IPv6) and communication at the sockets layer is through the AF_INET6 family:

```
NETWORK DOMAINNAME(AF_INET6)
        DOMAINNUMBER(19)
        MAXSOCKETS(60000)
        TYPE(INET)
```

The BPXPRM*xx* member contains additional parameters that are crucial to the proper operation of TCP/IP. Carefully examine and specify these parameters:

- MAXPROCSYS — Specifies the maximum number of z/OS UNIX processes that the system allows.

- MAXPROCUSER — Specifies the maximum number of processes that a single z/OS UNIX user ID can have concurrently active, regardless of how the processes were created.
- MAXUIDS — Specifies the maximum number of z/OS UNIX user IDs that can operate concurrently.
- MAXFILEPROC — Specifies the maximum number of descriptors for files, sockets, directories, and any other file system objects that a single z/OS UNIX process can have concurrently allocated. This includes access to both z/OS UNIX files and socket descriptors. In z/OS Communications Server, most TCP/IP applications access TCP/IP sockets, either directly or indirectly, using the TCP/IP socket APIs. You should set the MAXFILEPROC value high enough to accommodate the largest number of sockets that a single TCP/IP application (or z/OS UNIX process) can allocate.

  Be aware that the TN3270E Telnet server is exempt from the limit specified in this parameter. The TN3270E Telnet server can obtain the maximum number of socket connections for a single z/OS Communications Server UNIX System Services process.
- MAXPTYS — Specifies the maximum number of pseudo-terminals for the system.
- MAXTHREADTASKS — Specifies the maximum number of MVS tasks that a single process can have concurrently active.
- MAXTHREADS — Specifies the maximum number of threads that a single process can have concurrently active.
- MAXQUEUEDSIGS — The sum of MAXQUEUEDSIGS and MAXFILEPROC multiplied by 2 is the system wide maximum for the total number of asynchronous z/OS UNIX socket calls that can be outstanding. When specifying this number, consider the following:
  - For every TCP/IP connection that the TN3270E Telnet server has, there is an asynchronous z/OS UNIX socket call outstanding. This is true for both TN3270 and TN3270E clients.
  - Any TCP/IP application, IBM or vendor supplied, that uses either the z/OS UNIX asyncio callable service or the TCP/IP-provided Sockets Extended asynchronous API could have one or more outstanding asynchronous socket calls.

The MAXSOCKETS parameter specifies the maximum number of sockets that can be obtained for a given file system type. You must ensure that this specification is large enough to accommodate your installation's workload. For example, each connection to your TN3270E Telnet server or FTP server requires one z/OS Communications Server UNIX System Services socket. Once the maximum number of sockets is allocated, then no more Telnet sessions, FTP sessions, or other applications that require z/OS Communications Server UNIX System Services sockets can be started.

Note: If multiple NETWORK statements are defined, MAXSOCKETS can be specified for each NETWORK statement and will be enforced separately.

For details on the BPXPRM*xx* member, see the following guides:

- *z/OS UNIX System Services Planning*
- *z/OS MVS Initialization and Tuning Reference*

Performance considerations

Follow the guidelines found in the *z/OS MVS Initialization and Tuning Reference*. If your installation is running Workload Manager, follow the guidelines found in *z/OS MVS Planning: Workload Management*.

VTAM, TCP/IP, and some associated server applications must be able to obtain cycles to maintain their network presence. The following dispatching priority guidelines apply for these functions:

- In general, you should set VTAM and TCP/IP to a higher dispatching priority than that of the applications that use their services.
- For server applications such as OMPROUTE, TN3270E Telnet server, IKED, and FTPD, you should set the priority value to the same value to which TCP/IP is set, or to a priority that is just below that value. If you are using WLM, assign these tasks to the SYSSTC service class. Additionally, if you make these tasks non-swappable, they will be available during periods of high CPU usage. The MVS default program property table sets Telnet to be non-swappable and privileged, which automatically assigns the task to the SYSSTC service class.
- Set non-critical applications, such as Policy Agent and TRMD, to a lower priority.
- Set the SNMP agent and all the SNMP subagents to the same WLM service class so that they all have the same dispatching priority. Timeouts can occur if the SNMP subagents are set to a lower dispatching priority than the SNMP agent.

On systems with significant FTP activity, you can improve performance by placing the FTP program objects into the dynamic link pack area (LPA). Putting the FTP program objects into the dynamic LPA eliminates the need to load these program objects from DASD for each FTP session. You can place these program objects into the dynamic LPA using either of the following methods:

- Include the following statement in the PROG*xx* member of SYS1.PARMLIB and then issue a SET PROG=*xx* command:

  ```
  LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
  ```

- Issue the following SETPROG command:

  ```
  SETPROG LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
  ```

Tip: You can also place the SET PROG=*xx* command or the SETPROG command in a COMMND*xx* SYS1.PARMLIB member to have the command issued at IPL time.

Requirement: If maintenance is applied to these program objects, you must update the program objects in storage using one of the following methods:

- Issue an LLA refresh command, and then issue a SET PROG=*xx* command that points to a PROG*xx* member that contains the following command:

  ```
  LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
  ```

- Issue an LLA refresh command, and then issue the following SETPROG command:

  ```
  SETPROG LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
  ```

For more information, see *z/OS MVS System Commands*.

Fast path support

For applications that have extremely strict communications path-length requirements, an optional extension has been provided to further reduce overhead resulting from the z/OS UNIX-to-TCP/IP stack communications. This extension is only available to applications using the UNIX System Services socket API or the z/OS XL C/C++ Run-time Library functions. It is not available to applications using the native MVS socket APIs (such as C/C++, EZASMI macro, EZASOKET, REXX, or CICS socket APIs) provided by the Communications Server. Exploitation of this extension is entirely optional.

This feature can be activated for an entire z/OS UNIX process using the z/OS UNIX environment variable _BPXK_INET_FASTPATH. The value of this variable determines whether a socket application is marked *fast path*. An XL C/C++ application can set the variable by invoking the setenv function, or you can export the variable to the z/OS UNIX shell environment before the socket application is invoked. An application using the z/OS UNIX API can set this variable using the BPX1ENV service.

Note: z/OS UNIX environmental variables have a process-wide scope only—that is, they usually affect a single MVS address space only. It is possible, however, to have multiple UNIX processes within a single address space. In this scenario, the setting of this environmental variable might vary for each process within the address space. It is not a problem if some of your applications exploit fast path services, while others do not. When a socket application is marked as fast path, the communications overhead is reduced on the following socket syscalls:

- - send()
- - recv()
- - sendto()
- - recvfrom()
- - sendmsg()
- - recvmsg()

Although applications are more efficient when using the environmental variable, they are not XPG compliant, and POSIX signals are not supported. Applications can be interrupted only with the SIGKILL terminating signal, and they cannot be debugged using the interactive z/OS UNIX dbx debugger. You can, however, develop and test an application using the dbx debugger without setting the environmental variable, and then execute the application in production with the environmental variable set. Also, note that applications using the z/OS UNIX asynchronous socket interface (BPX1AIO) to invoke synchronous socket operations (that is, setting the AioSync bit in the AIOCB) cannot use the BPX1AIO service to cancel outstanding synchronous calls on sockets that are marked as fast path. Doing so will cause the cancel operation to hang.

For environments that do not use common INET, the value of this variable should be set to the name specified on the TYPE parameter of the FILESYSTYPE statement in the BPXPRMxx parmlib member.

For common INET environments, the value used to set the environmental variable depends on whether the application is using the TCP or UDP protocols. In a common INET environment, the variable should be set as follows:

- For UDP applications, it should be set to the name of the TCP/IP stack as specified on the NAME parameter of the SUBFILESYSTYPE statement in the BPXPRMxx parmlib member. The socket application is explicitly associated with the TCP/IP stack named in the environmental variable (that is, the TCP/IP stack name). This means that the socket application can communicate with partners that are accessible only through the specific TCP/IP stack interfaces. For UDP, the environmental variable effectively overrides the support provided by common INET. You should take this contingency into account before activating fast path for a UDP-based application.

  Note that if the UDP application already establishes affinity to a specific TCP/IP stack using other means, such as setting the _BPXK_SETIBMOPT_TRANSPORT environment variable, using setibmopt(), BPX1PCT, and so on, the setting of the fast path variable is ignored. As a result, UDP applications that require fast path support and affinity to a specific TCP/IP stack must do so using the _BPXK_INET_FASTPATH environmental variable.
- For TCP applications, the variable can be set to an asterisk (*), indicating that any TCP/IP stack in the common INET configuration can be used. This allows all TCP/IP stacks that support the fast path model to obtain the fast path performance benefits automatically. TCP servers are not bound to a specific TCP/IP stack, even if they specify a specific TCP/IP stack name on the environmental variable; instead, they can listen for inbound connections across all TCP/IP stacks. When a connection arrives from the TCP/IP stack named in the environmental variable [at the time of the accept()], it is automatically marked as fast path. Connections that arrive from TCP/IP stacks that are not named by the current environmental variable value are not marked as fast path.

  Note, however, that certain TCP/IP API functions, such as the resolver services [that is, gethostbyname(), gethostbyaddr(), getaddrinfo(), and getnameinfo()] and the network interface identification services [that is, if_nameindex(), if_nametoindex(), and if_indextoname()] use UDP sockets internally to perform their processing. Consequently, if a specific TCP/IP stack name is specified on the environmental variable, these hidden UDP sockets will only be associated with the named TCP/IP stack, which might have undesirable effects. For example, any resolver API queries resulting in communications with a domain name server will occur only over the specified TCP/IP stack. As a result, it is strongly recommended that TCP applications set the environmental variable to the special asterisk (*) value. If the application requires affinity to a specific TCP/IP stack, it should do so using any of the facilities that are provided by z/OS UNIX, such as setibmopt(), BPX1PCT, and so on. For more details on establishing affinity to a specific TCP/IP stack, see *z/OS UNIX System Services Planning*.

Applications can also enable fast path processing for a single socket by issuing the Iocc#FastPath IOCTL for the socket, using the w_ioctl() or the BPX1IOC APIs. Note that this IOCTL is only effective if it is issued against a socket that is already associated with a specific TCP/IP stack. Sockets are considered associated with a specific TCP/IP stack if they meet any of the following conditions:

- The application has explicit process affinity to a specific TCP/IP stack [that is, by setting the _BPXK_SETIBMOPT_TRANSPORT environmental variable, using setibmopt(), BPX1PCT, and so on].
- TCP/IP stack affinity has been explicitly established for this socket (that is, using the SIOCSETRTTD IOCTL).
- A bind() has already been issued for the socket using a specific IP address (that is, not the IPv4 INADDR_ANY address, nor the IPv6 unspecified address, in6addr_any).

- A TCP (that is, streams) socket that is connected. This includes TCP sockets that are returned as a result of accept() or sockets that a connect() was issued for.

The Iocc#FastPath constant is defined in the BPXYIOCC. Note that this IOCTL requires a 4-byte argument as input. This argument should be set to a nonzero value to activate fast path, or a zero value to disable fast path on the specified socket.

Considerations for multiple instances of TCP/IP

The z/OS Communications Server TCP/IP stack is a multiple-processor capable stack, which means that it can concurrently exploit all available processors on a system. Starting multiple stacks will not yield a significant increase in throughput.

In addition, running multiple z/OS Communications Server TCP/IP stacks requires additional system resources, such as storage, CPU cycles, and DASD. It also adds a significant level of complexity to the system administration tasks for TCP/IP.

For these reasons, it is suggested that in most cases you use the INET configuration, which supports a single TCP/IP stack. However, there are some special situations where running multiple stacks can provide a benefit. For example, you might want to run two separate stacks for intranet and Internet traffic.

Common INET PFS

If you wish to run multiple z/OS Communications Server TCP/IP stacks concurrently, you must use the Common INET (CINET) configuration. In this configuration, up to a maximum of eight TCP/IP stacks can be active at any time.

When the CINET configuration is used, the CINET PFS is inserted between the LFS and the TCP/IP PFS for each stack. The CINET PFS maintains an internal copy of each TCP/IP stack's IP configuration, so that it can preroute a socket call to the correct TCP/IP stack. This allows most socket programs to run with multiple stack support with no change to the application. In addition, CINET supports IPv6, and is capable of supporting underlying TCP/IP stacks in IPv4/IPv6 dual mode or in IPv4-only mode.

You can specify your choice of INET (single stack) or CINET (multiple stack) support on the NETWORK, DOMAINNAME, FILESYSTYPE, and SUBFILESYSTYPE statements of SYS1.PARMLIB(BPXPRMxx). For more information about the BPXPRMxx statements, see “Specifying BPXPRMxx values for a CINET configuration” on page 59 and *z/OS UNIX System Services Planning*.

Port management overview

When there is a single transport provider, and the relationship of server to transport provider is 1:1, port management is relatively simple. Using the PORT statement, the port number can be reserved for the server in the PROFILE.TCPIP for that single transport provider.

Port management becomes more complex in a CINET environment where there are multiple transport providers (multiple instances of TCP/IP) and a potential for multiple combinations of the same server (for example, z/OS UNIX and TN3270E Telnet servers).

In a multiple transport provider environment, the following questions need to be answered for each server in an installation:

- Is the server generic so that it can communicate with multiple TCP/IPs or does the server have an affinity for one instance of the transport providers and can only communicate with one TCP/IP?
- How can ports be reserved across multiple transport providers? When is the port reservation determined by MVS rather than by the job name, procedure name, or user ID?
- How can you synchronize between BPXPARMS and PORTRANGE for ephemeral port reservation?
- How can TCP/IP distinguish between two different instances of Telnet (z/OS UNIX Telnet and TN3270E Telnet servers)?

Generic server versus server with affinity for a specific transport provider

This information describes the differences between generic servers and servers with affinities for specific transport providers.

Generic server: A generic server, a server without an affinity for a specific transport provider, provides service to any client on the network. (See Figure 3.) FTP is an example of a generic server. The transport provider is merely a connection linking client and server. The service File Transfer is not related to the internal functioning of the transport provider, and the server can communicate concurrently over any number of transport providers.

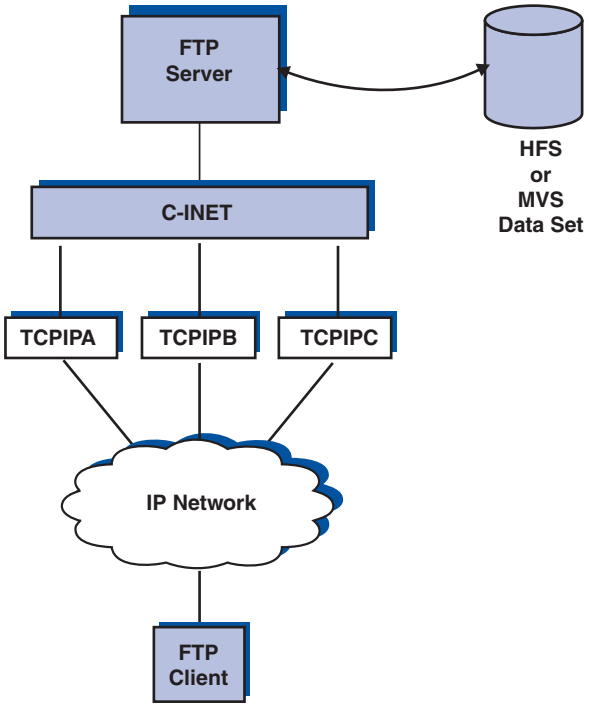

Figure 3. Generic server

Server with an affinity for a specific transport provider: When the service is related to the internal functioning of the transport provider (for example, Telnet, OMPROUTE, OSNMPD, and the Netstat command), there must be an explicit binding of the server application to the chosen transport provider. (See Figure 4 on page 52

page 52.) There must also be a way to specify the single transport to be chosen.

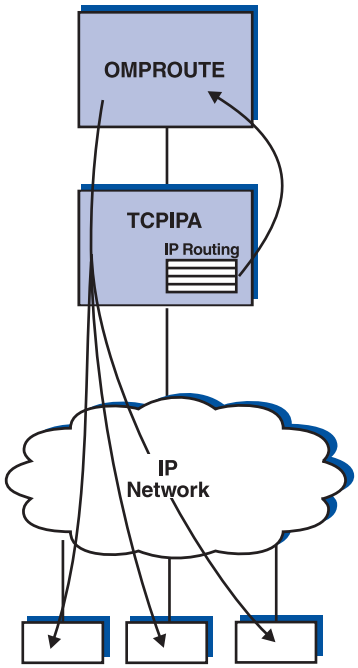

Figure 4. Server with affinity for a specific transport provider

With the exception of applications that use the socket API provided by TCP/IP, other IBM-supplied applications that use the z/OS UNIX socket API and that must bind to a specific transport provider use the z/OS UNIX socket call `setibmopt()` (see *z/OS XL C/C++ Run-Time Library Reference*) to specify which TCP they have chosen. A C function `__iptcpn()`, described in the *z/OS XL C/C++ Run-Time Library Reference*, enables the application to search the TCPIP.DATA file to find the name of the specific TCP/IP. (See Figure 5 on page 53.) An application that uses the z/OS Language Environment runtime can also establish stack affinity by setting the environment variable _BPXK_SETIBMOPT_TRANSPORT.

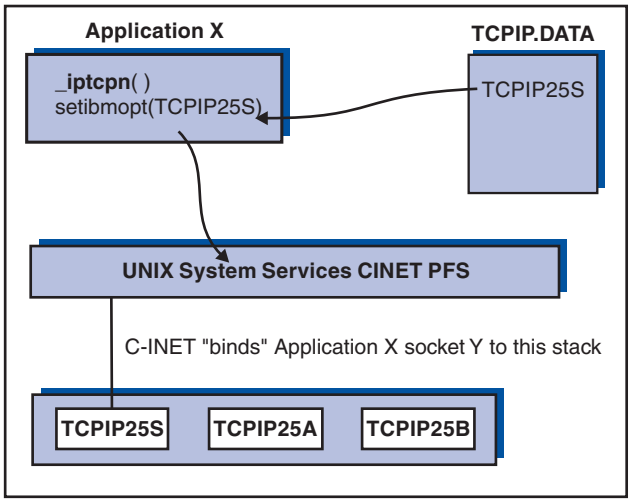

Figure 5. Example of binding an application to a specific transport provider

Generic servers in a CINET environment

In z/OS Communications Server, you can configure multiple TCP/IP stacks in a single MVS image using the CINET feature. In a CINET configuration, an application using the z/OS UNIX socket interface can get transparent access to all the TCP/IP protocol stacks configured under CINET. For example, when an application coded to z/OS UNIX sockets performs a SOCKET/BIND/LISTEN in a CINET environment, the request is propagated by CINET to all the TCP/IP stacks. This application can then service client requests that arrive into any of the configured TCP/IP stacks without having any awareness of this fact. This type of application is often referred to as a *generic server* or *daemon*.

The following servers or daemons shipped by z/OS Communications Server are generic:

- DCAS
- FTPD
- RPCBIND
- SNTPD
- syslogd
- TFTPD
- TIMED
- TN3270E Telnet
- z/OS UNIX POPPER
- z/OS UNIX Portmap
- z/OS UNIX REXECD
- z/OS UNIX RSHD
- z/OS UNIX SENDMAIL
- z/OS UNIX TELNETD

z/OS UNIX RSHD, REXECD and TELNETD are usually started by the INETD daemon, which is shipped as part of the z/OS UNIX. Because INETD is also a generic daemon, any server processes started by INETD inherently become generic servers as well.

If a server started by INETD (a generic server) requires affinity to a specific stack, this affinity can be accomplished by use of the _BPXK_SETIBMOPT_TRANSPORT environment variable. For more information about the _BPXK_SETIBMOPT_TRANSPORT environment variable, see *z/OS UNIX System Services Planning*.

The _BPXK_SETIBMOPT_TRANSPORT environment variable, when set, has an effect similar to the setibmopt() function call provided by the XL C/C++ compiler and described in the *z/OS XL C/C++ Run-Time Library Reference*. This variable can be set in the JCL for a started procedure or batch job that executes a z/OS UNIX C/C++ program to indicate which TCP/IP stack instance the application should bind to. TCP/IP applications that require affinity to a specific TCP/IP stack, like OSNMPD and OMPROUTE, use the setibmopt() function call directly. The _BPXK_SETIBMOPT_TRANSPORT environment variable basically provides the ability to bind a generic server type of application to a specific stack.

For example, if you had two TCP/IP stacks configured under CINET, one named TCPIP and the other TCPIPOE, and you wanted to start an FTPD server instance that was associated with TCPIPOE, you could modify the FTPD procedure as follows:

```
//FTPD   PROC MODULE='FTPD',PARMS='TRACE'
//FTPD   EXEC PGM=&MODULE,REGION=7M,TIME=NOLIMIT,
//       PARM=('POSIX(ON) ALL31(ON)',
//      'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE")',
//      '/&PARMS')
//CEEDUMP  DD SYSOUT=*
//SYSFTSX DD DISP=SHR,DSN=TCPV34.STANDARD.TCPXLBIN
```

All the parameters specified prior to the slash (/) in the parameter statement are processed by the XL C/C++ run-time library. Parameters to be passed to the FTPD program must appear after the slash (/). Also note how the parameters were split over three lines in this example because they could not fit on a single line.

The following example uses JCL for the started procedure for INETD:

```
//INETD  PROC
//*************************************************************
//INETD  EXEC PGM=BPXBATCH,
//*      PARM='PGM /usr/sbin/inetd -d /etc/inetd.conf'
//       PARM='PGM /usr/sbin/inetd    //''USER1.INETD.CONF'''
//*
//STDERR  DD PATH='/tmp/inetd.debug.stderr',
//  PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//  PATHMODE=SIRWXU
//STDOUT  DD PATH='/tmp/inetd.debug.stdout',
//  PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//  PATHMODE=SIRWXU
//STDENV   DD  DISP=SHR,DSN=USER1.INETD.ENVIRON
```

The STDENV data set would contain the _BPX_SETIBMOPT_TRANSPORT variable as follows:

```
_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE
```

In these examples, INETD was also passed its configuration file as a parameter. In our examples, this file is an MVS data set rather than a z/OS UNIX file; therefore, it requires the additional double slash (//) and quotes that the example shows.

Multiple instances of INETD are not allowed, even if each instance is bound to a different TCP/IP stack. This is an INETD restriction, not a TCP/IP restriction. Therefore, if you decide to make INETD have affinity to a specific stack, then that is the only INETD instance that you will be able to have running in that MVS image.

Notes:

1. The _BPXK_SETIBMOPT_TRANSPORT variable should be specified only for a generic server type of application.

   If specified for a non-generic server and/or non-z/OS UNIX application it will not have any effect.
2. The name specified for _BPXK_SETIBMOPT_TRANSPORT must match the job name associated with the TCP/IP stack.

   If the name specified does not match the job name of any TCP/IP stacks defined for CINET, the application will receive a z/OS UNIX return code of X'3F3' and a return value of X'005A' and may be accompanied by the following message:

   ```
   EDC8011I A name of a PFS was specified that either is
   not configured or is not a Sockets PFS.
   ```

   If the name specified does not match the job name of any currently active TCP/IP stack defined under CINET, the application will receive a z/OS UNIX return code of X'70' and a return value of X'0296' and may be accompanied by the following message:

   ```
   EDC5112I Resource temporarily unavailable.
   ```
3. For more detailed information about requesting transport affinity, see *z/OS UNIX System Services Planning*.

Port reservation across multiple transport providers

When there are multiple transport providers, be sure to synchronize the PORT statements in each of the PROFILE.TCPIP files to ensure that the port reservations for each stack match the port definitions for the servers that will be using that stack.

For more information about reserving ports with the PORT statement, see Chapter 5, “TCP/IP Customization,” on page 185.

Ephemeral ports: When running with multiple transport providers, just as it is necessary to synchronize PORT reservations for specific applications across all stacks, it is required to synchronize reservations for port numbers that will be dynamically assigned across all stacks. These are the ephemeral ports above 1023, which are assigned by the stack when none is specified on the application `bind()`. To reserve a group of ports in the PROFILE.TCPIP, use PORTRANGE. For more information about PORTRANGE, see Chapter 5, “TCP/IP Customization,” on page 185. Specify the same PORTRANGE for every stack. In addition, you need to let the z/OS UNIX CINET know which ports are guaranteed to be available on every stack. The following is an example of reserving ports 40000 to 41999 in the two required files:

- PROFILE.TCPIP
  - PORTRANGE 40000 2000 TCP OMVS ; Reserved for OMVS
  - PORTRANGE 40000 2000 UDP OMVS ; Reserved for OMVS

- BPXPRMxx parmlib member
  - NETWORK DOMAINNAME(AF_INET)
  - INADDRANYPORT(40000)
  - INADDRANYCOUNT(2000)

  Notes:

  1. When IPv6 is configured and there are two NETWORK statements, INADDRANYPORT and INADDRANYCOUNT only need to be specified for the NETWORK statement for AF_INET and not for AF_INET6. If they are specified for AF_INET6, they are ignored and the values from the NETWORK statement for AF_INET are used if provided. Otherwise, the default values are used.
  2. In a CINET environment, you can use IBM Health Checker for z/OS to check whether the range of ports specified by the INADDRANYPORT and INADDRANYCOUNT operands of the BPXPRM*xx* parmlib member is reserved for OMVS on the TCP/IP stack. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide*.

Selecting a stack when running multiple instances of TCP/IP

Socket application programs in a multi-stack (CINET) environment must contend with the following:

- How the socket program selects which TCP/IP stack to use for its socket communication
- How the TCP/IP resolver code executing in the socket application address space decides which TCP/IP resolver configuration data sets to allocate

  Note: If a resolver GLOBALTCPIPDATA setup file is used, a local TCPIP.DATA cannot override any explicit statements in the global file and cannot override any resolver statements. Therefore, in a CINET environment, the TCPIPJOBNAME statement should not be specified in the GLOBALTCPIPDATA file. Also, using the GLOBALTCPIPDATA file with CINET requires that the resolver TCPIP.DATA statements are able to be used by all stacks. For example, the IP addresses specified by the NameServer statement must be accessible from all stacks. If they are not, then the GLOBALTCPIPDATA file should not be used and you should continue with multiple TCPIP.DATA data sets. For details, see Chapter 14, "The resolver," on page 731.

To answer these questions, a distinction must be made between standard servers and clients (those that come with the z/OS Communications Server product), and other socket application programs, including those you might have written yourself.

Standard servers and clients

The anchor configuration data set is the TCPIP.DATA data set. This is the base resolver configuration data set with information on host name, domain origin, and so on. It holds the TCPIPJOBNAME statement, which identifies the TCP/IP stack to use, and the DATASETPREFIX statement, which is used by the resolver code and other services when allocating configuration data sets. For more information on these data sets, see "Configuration files for TCP/IP applications" on page 30.

The key to selecting both a specific stack and resolver configuration data sets is to control which TCPIP.DATA data set a standard server or client address space allocates. Applications that use the z/OS UNIX API can use Common INET to

determine which stack an application will use. But, it is important to ensure that the search order and the contents of the resolver configuration data set are understood.

Native MVS servers and clients search for TCPIP.DATA in sequences as described in "Search orders used in the native MVS environment" on page 769.

z/OS UNIX servers and clients will search for TCPIP.DATA in sequences as described in "Search orders used in the z/OS UNIX environment" on page 762.

Nonstandard servers and clients

Nonstandard servers and clients (those that do not come with the z/OS CS product) also use TCPIP.DATA to decide which resolver configuration data sets to allocate. Depending on the socket API used, they might or might not use the TCPIPJOBNAME parameter to select a stack.

If you run sockets programs from other products or vendors, you may want to know which sockets API was used to develop the program, and which techniques, if any, the program uses to specify the name of the TCP/IP system address space. As long as application programs that use a TCP/IP socket library do not specify anything specific on calls `setibmopt()`, `Initialize`, or `INITAPI`, the TCPIPJOBNAME from a TCPIP.DATA data set will be used for finding a TCP/IP system address space name.

Table 6 depicts the differences that prevail in stack selection depending on the TCP/IP socket API under which you are running the socket program.

Table 6. How your own socket programs select a stack

C sockets	Callable and Macro	Pascal sockets	REXX sockets
SETIBMOPT or TCPIPJOBNAME from TCPIP.DATA	TCPNAME on INITAPI or TCPIPJOBNAME from TCPIP.DATA	TCPIPJOBNAME from TCPIP.DATA	Service on Initialize or TCPIPJOBNAME from TCPIP.DATA
Callable and Macro programs might have a configuration option to specify the TCP/IP system address space name, or might interrogate the available stacks via the getibmopt() call.			

A Callable or Macro program does not have to call INITAPI. If INITAPI is not called, an implicit INITAPI is performed with the value taken from TCPIPJOBNAME in a TCPIP.DATA data set. If INITAPI is called with the TCPNAME parameter specified as a space, the TCP/IP system address space name results in the TCPIPJOBNAME keyword value.

In a z/OS UNIX INET (single stack) environment, the socket application program is always associated with the single TCP/IP stack. In the z/OS UNIX Common INET (CINET) environment, your application will be associated with multiple TCP/IP stacks unless the application specifically associates with a particular stack using the z/OS UNIX socket call setibmopt(). For other ways of requesting stack affinity in a CINET environment, see *z/OS UNIX System Services Planning*.

TCP/IP TSO clients

TSO client functions can be directed against any of a number of TCP/IP stacks. Obviously, the client function must be able to find the TCPIP.DATA appropriate to the stack of interest at any one time. Some TSO client commands provide a

parameter to specify the stack to be used. For those that do not, the following methods are available for finding the relevant TCPIP.DATA:

- Add a SYSTCPD DD statement to your TSO logon procedure. The issue with this approach is that a separate TSO logon procedure per stack is required, and users have to log off TSO and log on again using another TSO logon procedure in order to switch from one stack to another.
- Use one common TSO logon procedure without a SYSTCPD DD statement. Before a TSO user starts any TCP/IP client programs, the user has to issue a TSO ALLOC command wherein the user allocates a TCPIP.DATA data set to DD name SYSTCPD. To switch from one stack to another, the user simply has to deallocate the current SYSTCPD allocation (for example, TSO FREE command) and allocate another TCPIP.DATA data set.
- Combine the first and second methods. Use one logon procedure to specify a SYSTCPD DD for a default stack. To switch stacks, issue TSO ALLOC to allocate a new SYSTCPD. To switch back, issue TSO ALLOC again with the name that was on the SYSTCPD DD in the logon procedure. The disadvantage to this approach is that the name that was on the SYSTCPD DD is hidden in the logon procedure and needs to be retrieved or remembered.

The last method can be implemented by creating a small REXX program for every TCP/IP stack on your MVS system. For each stack create a REXX program with the name of the stack (for example, T18A or T18B). Whenever TSO users want to use the T18A stack, they run the T18A REXX program. Any TCP/IP functions invoked thereafter will use the T18A stack for socket communication. If users want to switch to the T18B stack, they run the T18B REXX program. See Figure 6 for an example.

```
/* REXX  "T18B" */
/*********************************************************************/
/*                                                                   */
/* Switch TSO Address Space to use the T18B Stack.                   */
/* Subsequent NETSTAT command will be directed toward                 */
/*  the T18BTCP stack.                                               */
/*                                                                   */
/*********************************************************************/
Say 'Switching to T18BTCP stack'

Figure 6. REXX program to switch TSO user to another TCP/IP stack

Selecting configuration data sets

The resolver code and other services that execute as part of the socket program address space to service calls such as `gethostbyname()`, `getservbyname()` and `getprotobyname()` allocate one or more resolver configuration files to service these calls. All socket programs, including standard servers and clients and homegrown socket programs, need access to resolver configuration files. For information on how the resolver configuration files are found and used, see "Configuration files for TCP/IP applications" on page 30.

Sharing resolver configuration data sets

The general recommendation is to use separate DATASETPREFIX values for each stack and create separate copies of the required configuration data sets; at the very least, create separate copies of the resolver configuration data sets. For a test and a production stack, however, you would probably use different DATASETPREFIX values. However, if the stacks are functionally identical, you may share the same DATASETPREFIX values and many of the same configuration data sets. You need separate TCPIP.DATA data sets because of the two different TCPIPJOBNAMEs. On the other hand, you may choose to share the resolver configuration data sets between the stacks by using the same DATASETPREFIX value in each TCPIP.DATA data set.

In addition to separate TCPIP.DATA data sets, separate /etc/resolv.conf files might also be necessary. If this is the case, use the environment variable RESOLVER_CONFIG to point to the appropriate resolver information.

Exercise caution if servers use DATASETPREFIX to allocate server-specific configuration data sets. Try to use explicit allocation as far as possible in your server JCL procedures. Most servers allow you to explicitly allocate their configuration data sets using DD statements.

Some servers may use DATASETPREFIX to create new data sets. Servers that do create new data sets allow you to specify an alternate data set prefix for the data sets that are created. NPF creates new sequential data sets with captured print data. NPF has a special keyword in NPF.DATA for this purpose; it is called NPFPRINTPREFIX. If this keyword is specified, NPF will use that as the high-level qualifier for newly created print data sets instead of taking the DATASETPREFIX value from TCPIP.DATA. Another example of a server that creates new data sets is the SMTP server.

Specifying BPXPRMxx values for a CINET configuration

For a detailed description of parameters in SYS1.PARMLIB(BPXPRMxx), see *z/OS UNIX System Services Planning* and *z/OS MVS Initialization and Tuning Guide*.

```
/* AF_INET file system for sockets      */
/* CINET support - BPXTCINT  */

FILESYSTYPE TYPE(CINET)
            ENTRYPOINT(BPXTCINT)  1
NETWORK DOMAINNAME(AF_INET)
        DOMAINNUMBER(2)
        MAXSOCKETS(10000)  2          TYPE(CINET)
        INADDRANYPORT(40000)  3
        INADDRANYCOUNT(2000)
NETWORK DOMAINNAME(AF_INET6) 4
        DOMAINNUMBER(19)
        MAXSOCKETS(10000)  2          TYPE(CINET)
SUBFILESYSTYPE NAME(TCPIP1A)  5
               TYPE(CINET)
               ENTRYPOINT(EZBPFINI)  6
               DEFAULT  7
SUBFILESYSTYPE NAME(TCPIP1B)  5
               TYPE(CINET)
               ENTRYPOINT(EZBPFINI)
```

Figure 7. SYS1.PARMLIB(BPXPRMxx) for CINET

1 CINET and BPXTCINT specify the use of CINET.

2 The MAXSOCKETS operand specifies the maximum number of sockets that can be obtained for the given file system type. It should be large enough for the number of sockets needed for applications using z/OS Communications Server. MAXSOCKETS is enforced independently for AF_INET (IPv4 sockets) and AF_INET6 (IPv6 sockets).

3 The INADDRANYPORT and INADDRANYCOUNT operands specify the first ephemeral port number and the range of ports to be used by z/OS UNIX CINET. The port range specified should also be reserved for CINET use in the TCP/IP profile using the port reservation statements. For details, see "Port reservation across multiple transport providers" on page 55. You can use IBM Health Checker for z/OS to check whether the range of ports specified is reserved for OMVS on the TCP/IP stack. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide*.

4 This additional NETWORK statement is required if you want a TCP/IP stack to also support IPv6. Omit this statement if you do not want the stack to support IPv6 (that is, the stack will support IPv4 only).

5 A transport provider stack for CINET is specified with a SUBFILESYSTYPE statement. The NAME field must match the address space name for the TCP/IP started task as well as the TCPIPJOBNAME parameter in TCPIP.DATA. In our example, the name of the first stack is TCPIP1A and the name of the second stack is TCPIP1B.

6 EZBPFINI identifies a z/OS Communications Server TCP/IP stack. For a z/OS Communications Server TCP/IP stack, this is the only valid value.

7 Keyword DEFAULT specifies which transport provider stack is to be used as the default stack for z/OS UNIX. If DEFAULT is not specified, the first active stack will be used as the default stack. The sequence of SUBFILESYSTYPE statements is arbitrary if one stack is identified with the keyword DEFAULT. TCPIP1A is the default stack in Figure 7 on page 59.

Considerations for Enterprise Extender

The Enterprise Extender (EE) network connection is a simple set of extensions to the existing open high-performance routing (HPR) technology. It performs an efficient integration of the HPR frames using UDP/IP packets. To the HPR network, the IP backbone is a logical link. To the IP network, the SNA traffic is UDP datagrams that are routed without any hardware or software changes to the IP backbone. Unlike gateways, there is no protocol transformation and unlike common tunneling mechanisms, the integration is performed at the routing layers without the overhead of additional transport functions. The advanced technology enables efficient use of the intranet infrastructure for support of IP-based client accessing SNA-based data (for example, Telnet emulators or Web browsers using services such as IBM's Host On-Demand) as well as SNA clients using any of the SNA LU types.

Enterprise Extender seamlessly routes packets through the network protocol *edges*, eliminating the need to perform costly protocol translation and the store-and-forward associated with transport-layer functions. Unlike Data Link Switching (DLSw), for example, there are no TCP retransmit buffers and timers and no congestion control logic in the router because it uses connectionless UDP and the congestion control is provided end system to end system. Because of these savings, the *edge* routers have less work to do and can perform the job they do

best, which is forwarding packets instead of incurring protocol translation overhead and maintaining many TCP connections. Data center routers can handle larger networks and larger volumes of network traffic, thus providing more capacity.

Enterprise Extender supports both the IPv4 and IPv6 addressing models. For more information about EE, see *z/OS Communications Server: SNA Network Implementation Guide* and the EE information in *Migrating Subarea Networks to an IP Infrastructure Using Enterprise Extender* (IBM Redbooks).

Considerations for VIPA

The Internet Protocol (IP) is a connectionless protocol. IP packets are routed from the originator through a network of routers to the destination. All physical adapter devices in such a network, including those for client and server hosts, are identified by an IP Address which is unique within the network. The important point about IP is that a failure of an intermediate router node or adapter will not prevent a packet from moving from source to destination, as long as there is an alternate path through the network.

TCP sets up a connection between two endpoints, identified by the respective IP addresses and a port number on each. Unlike failures of an adapter in an intermediate node, if one of the endpoint adapters (or the link leading to it) fails, all connections through that adapter fail and must be reestablished. If the failure is on a client workstation host, only the relatively few client connections are disrupted and usually only one person is inconvenienced. However, an adapter failure on a server means that hundreds or thousands of connections may be disrupted. On an S/390® or zSeries server with large capacity, the number may run to tens of thousands.

A Virtual IP Address, or VIPA in TCP/IP for z/OS , alleviates this situation. A VIPA is configured in the same way as a normal IP address for a physical adapter, except that it is not associated with any particular device. To an attached router, the TCP on z/OS simply looks like another router. When the TCP receives a packet destined for one of its VIPAs, the inbound IP function of the stack notes that the IP address of the packet is in the stack's Home list and passes the packet up the stack. Assuming the stack has multiple adapters or paths to it (including XCF from other TCP stacks in a sysplex), if a particular physical adapter fails, the attached routing network will simply route VIPA-targeted packets to the stack via an alternate route.

While this removes hardware and associated transmission media as a single point of failure for large numbers of connections, the connectivity of a server can still be lost through a failure of a single stack or an MVS image. The VIPA can be configured on another stack with a manual process, but this requires the presence of an operator or programmed automation.

Dynamic VIPA Takeover enables Dynamic VIPAs to be moved without human intervention or programmed automation to allow new connections to a server at the same IP address as soon as possible. This can reduce downtime significantly. With Dynamic VIPA Takeover you can configure one or more TCP/IP stacks to be backups (VIPABACKUP statement) for a particular Dynamic VIPA. If the stack or MVS image where the Dynamic VIPA is active is terminated, one of the backup stacks automatically activates that Dynamic VIPA. The existing connections will be terminated but can be quickly reestablished on the stack that is taking over.

Notes:

1. Because a VIPA is associated with a z/OS TCP/IP stack and is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex, or even to a z/OS TCP/IP stack not in the sysplex as long as the address fits into the installation's network configuration.
2. If using VIPA along with an intelligent bridge or switch, ensure that 'Port fast mode' (Cisco) is enabled. This helps to decrease the amount of time the VIPA is unreachable in scenarios where there is dynamic movement of VIPA (dynamic or static). For more information, see your bridge or switch manual.

You may also associate a particular Dynamic VIPA address with an application using the SIOCSVIPA or SIOCSVIPA6 ioctl command or by BINDing explicitly to the Dynamic VIPA address. If the Dynamic VIPA address is within the VIPARANGE profile statement, then this Dynamic VIPA address will be created dynamically. This type of configuration enables a Dynamic VIPA to become an address of an application in a sysplex.

With sysplex distributor you can spread connection requests destined for Dynamic VIPAs to other stacks in the sysplex. You can use the VIPADISTRIBUTE profile statement to designate up to 32 stacks and 64 ports where connections for a particular DVIPA can be distributed, including the stack where the DVIPA is defined.

The distributing stack (the stack where the VIPADISTRIBUTE statement was coded) might use either WLM or a combination of WLM and Quality of Service (QoS) performance information to determine where to forward new connection requests. If the distributing stack/MVS image fails, connections forwarded to target stacks can be preserved by having the Dynamic VIPA address backed up on another stack.

Similarly, a stack can immediately take back a Dynamic VIPA address from another stack. If the original stack used an address specified with VIPADEFINE with the keyword MOVEABLE IMMEDIATE (the default), then the Dynamic VIPA is moved as soon as the second stack requests ownership. The second stack assumes responsibility for forwarding packets for existing connections to the appropriate stack. If MOVEABLE WHENIDLE was specified, ownership does not pass until all existing connections on the current stack are closed.

For detailed information about VIPA, see Chapter 7, “Virtual IP Addressing,” on page 351.

Considerations for Fast Response Cache Accelerator

Fast Response Cache Accelerator (FRCA) is a Communications Server function that can significantly improve the performance of the z/OS HTTP Server and the WebSphere® Application Server on z/OS. Web pages are cached within the operating system kernel and requests are handled without traversing the entire kernel or entering the user space. For more information about configuring the z/OS HTTP Server to use the FRCA function, see *z/OS HTTP Server Planning, Installing, and Using*. For more information about configuring the WebSphere Application Server to use the FRCA function, see the WebSphere Application Server Information Center.

FRCA also provides the ability to perform content-based quality-of-service (QoS) classification by selecting an appropriate QoS policy for each individual URI in the

HTTP request. For more information on specifying individual URIs, see the Policy Agent and policy applications topic in *z/OS Communications Server: IP Configuration Reference*.

Use the Netstat CACHINFO/-C commands to display information about FRCA statistics. Statistics are displayed for each listening socket configured for FRCA support. For more information on the Netstat CACHINFO/-C reports, see *z/OS Communications Server: IP System Administrator's Commands*.

Considerations for extended address volumes

As of Version 1 Release 10, z/OS supports extended address volumes (EAVs). EAVs are volumes greater than 65 520 cylinders. The part of an EAV beyond the first 65 536 cylinders is called the extended address space (EAS). Not all data sets on an EAV can reside in the EAS. A data set that could reside in the EAS, whether it actually resides in the EAS or not, is said to be an EAS-eligible data set.

Rule: Do not allocate data sets that are used by Communications Server as EAS-eligible data sets, except as follows:

- The FTP client and server allow transfer to or from existing non-VSAM, EAS-eligible data sets.
- The following FTP configuration files can be EAS-eligible data sets:
  - ANONYMOUSLOGINMSG
  - ANONYMOUSMVSINFO
  - BANNER
  - FTP.DATA

    Restriction: The TSO HOMETEST command cannot process FTP.DATA when it is an EAS-eligible data set.
  - LOGINMSG
  - MVSINFO
  - NETRC
  - SOCKSCONFIGFILE

For more information about using extended address volumes, see *z/OS DFSMS Using the New Functions*.

Considerations for networking hardware attachment

This information provides general networking hardware attachment information and considerations associated with the IBM zSeries platform. Most of the information included here is associated with the IBM Open Systems Adapter (OSA) and the QDIO system architecture.

OSA-Express feature in QDIO mode

When an OSA is configured with a DEVICE and LINK definition, the z/OS TCP/IP stack has only one connection to the OSA-Express feature. You define this connection with a combination of the DEVICE, LINK, and HOME statements for IPv4, an INTERFACE statement for IPv6, or both. This single connection uses one channel unit address for communication, which is assigned by VTAM from the DATAPATH parameter of the TRLE definition that represents this OSA-Express feature. Both IPv4 and IPv6 traffic share this one connection and channel unit address. For an overview of the OSA-Express feature and QDIO mode, and how to

configure VTAM to use the OSA-Express feature in this mode, see *z/OS Communications Server: SNA Network Implementation Guide*.

When you configure an OSA-Express feature for IPv4 using the INTERFACE statement and also configure the same OSA-Express feature for IPv6, then the z/OS TCP/IP stack has two connections to the OSA-Express feature and requires two DATAPATH devices.

Steps for converting from IPv4 IPAQENET DEVICE, LINK, and HOME definitions to the IPv4 IPAQENET INTERFACE statement

You can use the INTERFACE statement in the TCP/IP profile to configure IPv4 definitions for OSA-Express QDIO rather than using the DEVICE, LINK, and HOME statements. Using the INTERFACE statement improves stack configuration for IPAQENET interfaces. In addition, you can enable some functions, such as multiple VLAN support, only when the QDIO interface is defined by using the INTERFACE statement.

Perform the following steps to convert your TCP/IP profile so that it uses the INTERFACE statement to configure IPv4 definitions for OSA-Express QDIO.

1. Convert the IPv4 IPAQENET DEVICE, LINK, and HOME statements to an IPv4 IPAQENET INTERFACE statement.

   The values used in the following sub-steps are based on the sample profile that appears after the sub-steps.

   a. Copy the LINK name (`QDIO4101L` in the example) and specify this name as the interface name on the INTERFACE statement.

      Tip: When you use the original LINK name as the new INTERFACE name, you do not have to make changes to the static route definitions, OMPROUTE definitions, PKTTRACE statement, and PRIMARYINTERFACE statement.

   b. Copy the IPAQENET parameter from the LINK statement and specify this parameter after the DEFINE parameter of the INTERFACE statement.

   c. Copy the remaining LINK parameters and values (INBPERF DYNAMIC in the example) to the INTERFACE statement.

   d. Copy the DEVICE name (`QDIO4101` in the example) and specify this name on the PORTNAME parameter of the INTERFACE statement. This PORTNAME value must match the corresponding PORTNAME value in the SNA TRLE definition.

   e. Copy the remaining DEVICE parameters (PRIROUTER in the example) to the INTERFACE statement.

   f. Copy the HOME list entry IP address (`172.16.1.1` in the example) and specify this address on the IPADDR parameter of the INTERFACE statement.

   g. Append a value (`/24` in the example) to the end of the IP address to define the subnet mask.

   h. Remove the HOME list entry.

   Example of the profile before conversion:

```
DEVICE QDIO4101  MPCIPA   PRIROUTER
LINK   QDIO4101L IPAQENET      QDIO4101
  INBPERF DYNAMIC
;
HOME
  172.16.1.1     QDIO4101L
```

Example of the profile after conversion:

```
INTERFACE QDIO4101L
  DEFINE IPAQENET
  INBPERF DYNAMIC
  IPADDR 172.16.1.1/24
  PORTNAME QDIO4101
  PRIROUTER
```

Tip: Optionally, take a dump of the TCP/IP address space and use the CONVERT parameter on the TCPIPCS PROFILE subcommand to display the configuration information at the time of the dump. The resulting output will reflect your IPAQENET DEVICE, LINK, and HOME definitions in INTERFACE statement format, so this might be helpful in converting your profile to use INTERFACE statements. You should thoroughly review the output before you implement any changes. For more information about using the CONVERT parameter on the TCPIPCS PROFILE subcommand, see *z/OS Communications Server: IP Diagnosis Guide*.

For more information about the IPv4 IPAQENET INTERFACE statement, see *z/OS Communications Server: IP Configuration Reference*.

2. Remove any BSDROUTINGPARMS entries for the interface.
3. If you are using a virtual IP address as the source address for outbound datagrams that do not have an explicit source address (IPCONFIG SOURCEVIPA is configured), perform the following steps:
   a. Find the IPAQENET LINK in the original HOME list and search backwards to locate the static VIPA (if any) that is located closest to this link in the HOME list.
   b. If you find a static VIPA, add the SOURCEVIPAINTERFACE parameter to the IPv4 INTERFACE statement. Use the static VIPA link name as the SOURCEVIPAINTERFACE value.
4. If you are using the START statement to start the IPv4 device, change the START statement to specify the name of the IPv4 INTERFACE.
5. If you are using the GATEWAY statement to configure any static routes over the interface, convert the GATEWAY statement to a BEGINROUTES block.

   Tip: Optionally, take a dump of the TCP/IP address space and use the CONVERT parameter on the TCPIPCS PROFILE subcommand to display the configuration information at the time of the dump. The resulting output might be helpful in converting your profile to use a BEGINROUTES block rather than the GATEWAY statement. You should thoroughly review the output before you implement any changes. For more information about using the CONVERT parameter on the TCPIPCS PROFILE subcommand, see *z/OS Communications Server: IP Diagnosis Guide*.
6. If you also have an IPAQENET6 definition for the OSA, perform the following steps:
   a. If you configure the same virtual MAC address (VMAC) on both the IPAQENET LINK statement and IPAQENET6 INTERFACE statement, either change one of the VMAC addresses so that they are unique or let OSA generate the VMAC addresses.

b. Ensure that the corresponding TRLE definition has at least two DATAPATH devices available so that one device is available for the IPv4 interface and one device is available for the IPv6 interface.

For information about the TCP/IP profile (PROFILE.TCPIP) and configuration statements, see *z/OS Communications Server: IP Configuration Reference*.

The following examples show some additional changes that you might need to make to the definitions for OSA-Express QDIO.

Example of the profile before conversion:

```
IPCONFIG
  SOURCEVIPA
;
DEVICE VIPA4811  VIRTUAL  0
LINK   VIPA4811L VIRTUAL  0    VIPA4811
;
DEVICE QDIO4101  MPCIPA   PRIROUTER
LINK   QDIO4101L IPAQENET      QDIO4101
  INBPERF DYNAMIC
;
HOME
  10.81.1.1      VIPA4811L
  172.16.1.1     QDIO4101L
;
PRIMARYINTERFACE QDIO4101L
;
BSDROUTINGPARMS TRUE
  VIPA4811L 1492 0 255.255.255.0 0
  QDIO4101L 1492 0 255.255.255.0 0
ENDBSDROUTINGPARMS
;
GATEWAY
  172.16  =  QDIO4101L  1492  0
;
START QDIO4101
```

Example of the profile after conversion:

```
IPCONFIG
  SOURCEVIPA
;
DEVICE VIPA4811  VIRTUAL  0
LINK   VIPA4811L VIRTUAL  0    VIPA4811
;
; Converted INTERFACE statement
;
;   - QDIO4101L is from the LINK statement
;   - DEFINE IPAQENET is from the LINK statement
;   - INBPERF DYNAMIC is from the LINK statement
;   - IPADDR 172.16.1.1 is from the HOME list entry, /24 is from the
;     BSDROUTINGPARMS entry subnet mask
;   - PORTNAME QDIO4101 is from the DEVICE statement
;   - PRIROUTER is from the DEVICE statement
;   - SOURCEVIPAINTERFACE VIPA4811L is from the order of the HOME list

;
START QDIO4101L
```

Virtual LAN

A local area network (LAN) is a broadcast domain. Nodes on a LAN can communicate with each other without a router, and nodes on different LANs need a router to communicate. A virtual LAN (VLAN) is a configured logical grouping of nodes using switches. Nodes on a VLAN can communicate with each other as if they were on the same LAN, and nodes on different VLANs need a router to communicate.

OSA VLAN

The IBM Open Systems Adapter provides support for IEEE standards 802.1p/q, which describes priority tagging and VLAN identifier tagging. Deploying VLAN IDs allows a physical LAN to be partitioned or subdivided into discrete virtual LANs. This support is provided by the z/OS TCP/IP stack and the OSA-Express feature in QDIO mode.

When you use VLAN IDs, the z/OS TCP/IP stack can have multiple connections to the same OSA-Express feature. One connection is allowed for each unique combination of VLAN ID and IP version (IPv4 or IPv6). Each connection is defined by an INTERFACE statement and uses one channel unit address for communication, which is assigned by VTAM from the DATAPATH parameter of the TRLE definition. To configure one or more VLANs for a single OSA-Express feature, do the following:

- Configure each IPv4 interface for this OSA-Express feature in the TCP/IP profile using the INTERFACE statement for IPAQENET, rather than the DEVICE, LINK, and HOME statements. Configure each IPv6 interface for this OSA-Express feature in the TCP/IP profile using the INTERFACE statement for IPAQENET6.
- Configure a VLANID value on each IPv4 INTERFACE statement and each IPv6 INTERFACE statement on this stack for this OSA-Express feature. For each IP version, these VLANID values must be unique.
- Configure the VMAC parameter on each of the INTERFACE statements with the default ROUTEALL attribute. You can specify the VMAC address or OSA can generate it. If you specify a VMAC address, it must be unique for each INTERFACE statement.

- Configure a unique subnet for each IPv4 interface for this OSA-Express feature, using the subnet mask specification on the IPADDR parameter on the INTERFACE statement.
- If you are using OMPROUTE and OMPROUTE is not configured to ignore this interface, ensure that the subnet mask value that you configure on the INTERFACE statement in the TCP/IP profile matches the subnet mask that is used by OMPROUTE for this interface. The subnet mask that OMPROUTE uses is the subnet mask value that is defined on the corresponding OMPROUTE statement (OSPF_INTERFACE, RIP_INTERFACE, or INTERFACE) for this interface. If no OMPROUTE statement is specified for this interface, the subnet mask that OMPROUTE uses is the class mask for the interface IP address.
- Ensure that a DATAPATH device is available in the TRLE definition for each IPv4 interface and for each IPv6 interface for this OSA-Express feature.
- Ensure that you understand the fixed storage requirements for this configuration; each interface requires its own DATAPATH device, and each DATAPATH device requires fixed storage for read processing. For more details, see "Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces" on page 95.

Restrictions:

- The stack supports a maximum of eight VLAN interfaces per IP version to the same OSA-Express feature.
- For a given OSA-Express feature, a device and link definition is precluded in the following scenarios:
  - An IPv4 interface is or was previously defined.
  - Multiple IPv6 definitions are or were previously defined.

OSA routing

For QDIO devices, z/OS Communications Server and the OSA-Express feature provide functions that control how incoming unicast datagrams are routed, especially when the OSA-Express feature is shared by multiple TCP/IP instances.

When TCP/IP activates a QDIO device, each TCP/IP registers each of its home IP addresses with the OSA-Express feature. (TCP/IP also dynamically registers any updates to its set of home IP addresses with the OSA-Express feature.) This enables the OSA-Express feature to route datagrams destined for a registered IP address to the correct TCP/IP instance.

However, when packets are received for IP addresses that are not registered by any TCP/IP stack, the device needs a method for determining which stack, if any, should receive the packet. Two functions are available to accomplish this:

- OSA-Express Virtual MAC (VMAC) routing
- Primary and secondary routing

OSA-Express virtual MAC routing

If multiple TCP/IP instances are sharing an OSA-Express feature, the preferred method of routing is to define or generate a virtual MAC (VMAC) for each stack and for each protocol being used (IPv4 or IPv6). For IPv4, this results in the OSA-Express feature using the VMAC address rather than the physical *burned in* MAC for all ARPs sent for that TCP/IP stack's registered IP addresses, and using the VMAC as the source MAC address for all packets sent from that stack. In this way, all routers on the same LAN as the OSA-Express feature use only the VMAC address as the destination for all packets destined for that specific TCP/IP stack.

From a network routing perspective, the OSA-Express feature with this VMAC appears as a dedicated device to that TCP/IP stack.

This simplifies a shared OSA configuration significantly. The routers on the LAN always send any packets destined for a particular TCP/IP stack to the VMAC defined for that stack. The OSA-Express feature knows by VMAC address exactly which stack should receive a given packet. Even if the IP address is not registered with the OSA-Express feature, if the packet is destined for that VMAC, the router has determined which stack should be the intermediate router, and the OSA can forward the packet directly to that stack. If the stack is not an intermediate router, the capability is provided for a stack to indicate to the OSA that it wants to receive packets to registered IP addresses only.

This simplification is true for IPv6 as well. TCP/IP uses the VMAC address for all neighbor discovery address resolution flows for that stack's IP addresses, and likewise uses the VMAC as the source MAC address for all IPv6 packets sent from that stack. Again, from a network perspective, the OSA-Express feature with this VMAC appears as a dedicated device to that stack.

The VMAC address can be defined in the stack, or it can be generated by the OSA. If generated by the OSA, it is guaranteed to be unique from all other physical MAC addresses and from all other VMAC addresses generated by any OSA-Express feature.

Rule: If VMACs are defined in the stack, they should be defined as locally administered MAC addresses, and should be unique addresses for the local LAN on which they reside.

Guidelines:

- If the OSA is configured for both IPv4 (using DEVICE and LINK) and IPv6 for a stack, then you can define the same VMAC for both the INTERFACE statement and the LINK statement, or you can define one VMAC on the LINK statement for IPv4 usage and a different VMAC on the INTERFACE statement for IPv6 usage. If the OSA is configured for both IPv4 (using the INTERFACE statement) and IPv6 for a stack, then you must define one VMAC on the INTERFACE statement for IPv4 usage, and a different VMAC on the INTERFACE statement for IPv6 usage.
- A VLAN ID can be associated with an OSA-Express link or interface that is defined with a VMAC. For more information about VMAC routing, see *z/OS Communications Server: SNA Network Implementation Guide*.

To enable virtual MAC support, you must be running at least an IBM System z9® Enterprise Class (z9 EC) or z9 Business Class (z9 BC), and an OSA-Express feature with OSA Layer 3 Virtual MAC support. OSA Layer 3 Virtual MAC support is not available for Fast Ethernet. For more information, see the 2094DEVICE Preventive Service Planning (PSP) bucket and the 2096DEVICE Preventive Service Planning (PSP) bucket.

Primary router

If only one TCP/IP instance is using the OSA-Express device, or when multiple TCP/IP instances are using the same OSA-Express device but you want all instances to share the same physical MAC address of the device, you can optionally have the OSA route unicast packets to unregistered IP addresses by using OSA's primary (PRIROUTER) and secondary (SECROUTER) router support. This function enables a single TCP/IP stack, on a per-protocol (IPv4 and IPv6) basis, to register and act as a router stack on a per-OSA basis. Secondary routers

can also be configured to provide for conditions in which the primary router becomes unavailable and the secondary router takes over for the primary router. The primary router stack is the only stack to which OSA forwards packets when the destination IP address has not been previously registered with OSA. If no active TCP/IP instance using this device is defined as the primary router (PRIROUTER) or secondary router (SECROUTER), the device discards the datagram. If the PRIROUTER or SECROUTER value is not specified, the default value is NONROUTER.

Relationship of VLAN and primary router

The OSA primary router support takes into consideration and interacts with the VLAN ID support (VLAN ID registration and tagging). OSA supports a primary and secondary router on a per VLAN basis (per registered VLAN ID). Therefore, if TCP/IP is configured with a specific VLAN ID and also configured as a primary or secondary router, that stack serves as a router for just that specific VLAN. This allows each OSA (CHPID) to have a primary router per VLAN. Configuring multiple primary routers (one per VLAN) has many advantages and preserves traffic isolation for each VLAN.

This support becomes more important when a single OSA is shared by multiple stacks. In this type of configuration, when each stack was configured with a unique VLAN ID, each stack could also be configured as a primary router for its respective VLANs.

OSA also continues to support a primary and secondary router that is not associated with a specific VLAN. This primary router is referred to as the default primary router. It continues to function as the router for inbound packets that are not VLAN ID tagged, or packets that are VLAN ID tagged with a VLAN ID that is not registered to OSA. This is the same primary router support that existed prior to introduction of the VLAN ID support. Therefore, multiple specific VLAN primary routers and a single default primary router can concurrently activate and share a single OSA.

Each VLAN-specific primary and secondary router is subject to the same OSA rules (that is, supporting a single primary router and allowing multiple secondary routers) as the default primary router.

Figure 8 on page 71 shows a configuration where multiple TCP/IP stacks are sharing a single OSA, and multiple VLANs with primary routers are configured.

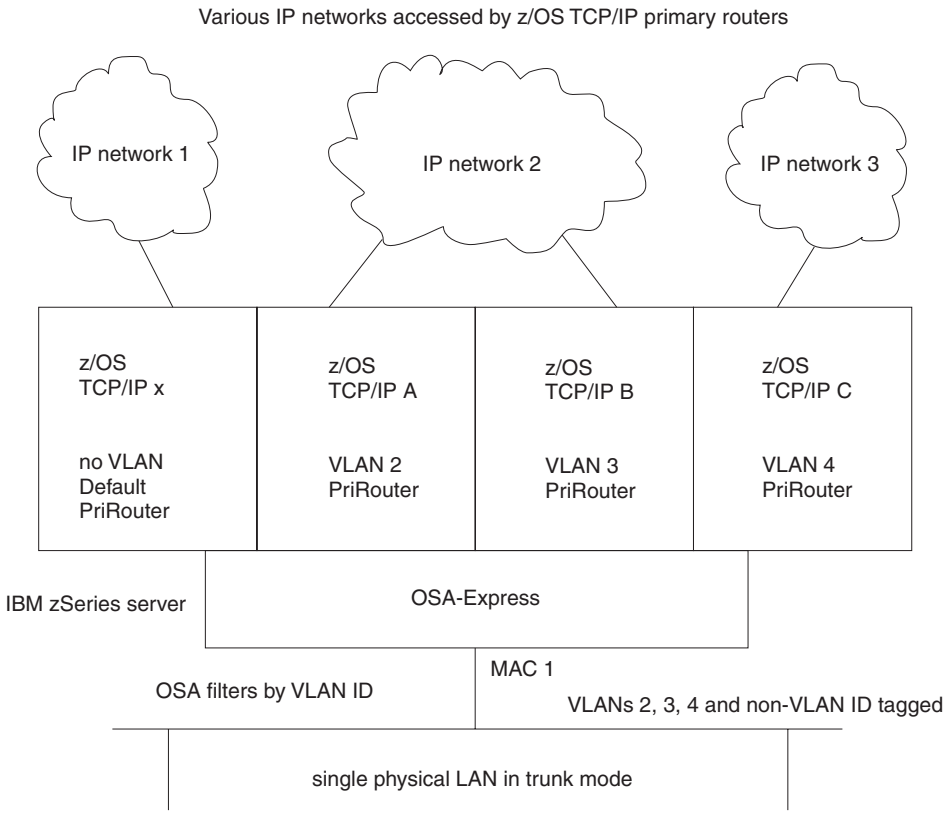

Figure 8. Primary router per VLAN (shared OSA with multiple primary routers)

In this example, TCP/IP x serves as the default primary router (PRIRouter without a VLANID configured). The other three TCP/IP stacks serve as a PRIRouter for just their specific VLANs.

For additional information regarding the details and syntax for configuring a VLAN Identifier (VLANID), and how to configure a TCP/IP stack as a primary or secondary router, see *z/OS Communications Server: IP Configuration Reference*. For IPv4 information on the PRIRouter, SECRouter, NONRouter, and VLANID parameters, see DEVICE and LINK – MPCIPA OSA-Express QDIO devices or INTERFACE - IPAQENET OSA-Express QDIO interfaces. For IPv6 information regarding these parameters, see INTERFACE - IPAQENET6 OSA-Express QDIO interfaces.

Network configuration strategy with VLAN

The IBM OSA-Express VLAN support allows a TCP/IP stack to register a specific VLAN identifier for both IPv4 and IPv6. Note that the VLAN ID for IPv4 can be different than the VLAN ID for IPv6. When a VLAN ID is configured, the following occurs:

1. TCP/IP becomes VLAN aware or enabled, and this TCP/IP (IPv4 or IPv6 connection) is considered to be part of the configured VLAN.
2. During activation, TCP/IP registers the configured VLAN ID value to OSA.
3. A VLAN ID tag is added to all outbound packets.
4. OSA filters inbound VLAN ID tagged packets based on the configured VLAN ID.

5. If this stack is also configured as a router (for example, PRIRouter), the OSA primary router support is extended to this stack, allowing it to serve as the primary router for the configured VLAN ID.

When configuring a z/OS TCP/IP stack with a VLAN ID, consideration must also be given to how the LAN is partitioned and how the VLAN aware switches are configured.

VLAN switch concepts

In conjunction with the IEEE standards, most VLAN aware switches recognize and support at least two modes, referred to as trunk and access modes. This support is provided on a switch port basis. The general concepts of the two modes are as follows:

Trunk mode
Indicates that the switch should allow all VLAN ID tagged packets to pass through the switch port without altering the VLAN ID. Trunk mode is intended for servers that are VLAN capable, and filters and processes all VLAN ID tagged packets. In trunk mode, the switch expects to see VLAN ID tagged packets inbound to the switch port.

Access mode
Indicates that the switch should filter on specific VLAN IDs and only allow packets that match the configured VLAN IDs to pass through the switch port. The VLAN ID is then removed from the packet before it is sent to the server (that is, VLAN ID filtering is controlled by the switch). In access mode, the switch expects to see packets without VLAN ID tags inbound to the switch port.

For the specific details regarding how to configure a VLAN switch, consult the specific product documentation.

VLAN configuration recommendations

When deploying the z/OS TCP/IP VLAN ID support in conjunction with the IBM OSA-Express feature in QDIO mode, it is recommended that deployment be symmetrical with the configuration of the corresponding VLAN switch. Specific recommendations are as follows:

- When using a VLAN ID, configure the switch port in trunk mode.

  When a VLAN ID is configured in any z/OS TCP/IP stack that is sharing an OSA, the corresponding switch port associated with the OSA should be configured in trunk mode. In this mode, OSA performs VLAN ID filtering.

  Conversely, access mode should not be configured on the switch port if a VLAN ID is configured on any stack sharing this OSA.
- When not using a VLAN ID, configure the switch port in access mode.

  When a VLAN ID is not configured on any z/OS TCP/IP stack that is sharing an OSA, access mode should be configured at the switch (if VLAN filtering is desired and therefore required at the switch).

  Conversely, trunk mode should not be configured on the switch port if a VLAN ID is not configured on any stack sharing this OSA.
- Multiple OSAs on the same physical LAN

  When a z/OS TCP/IP stack has access to multiple OSAs that are on the same physical LAN, and a VLAN ID is configured on any of the OSAs, it is recommended that this stack configure a VLAN ID for all OSAs on the same physical LAN. That is, do not mix VLAN and no-VLAN on the same physical network when a stack has access to the same LAN through multiple OSAs.

- VLAN ID 1 considerations

  Some switch vendors use VLAN ID 1 as the default value when a VLAN ID value is not explicitly configured. It is recommended that you avoid the value of 1 when configuring a VLAN ID value.

Figure 9, Figure 10 on page 74, and Figure 11 on page 74 illustrate the preceding recommendations.

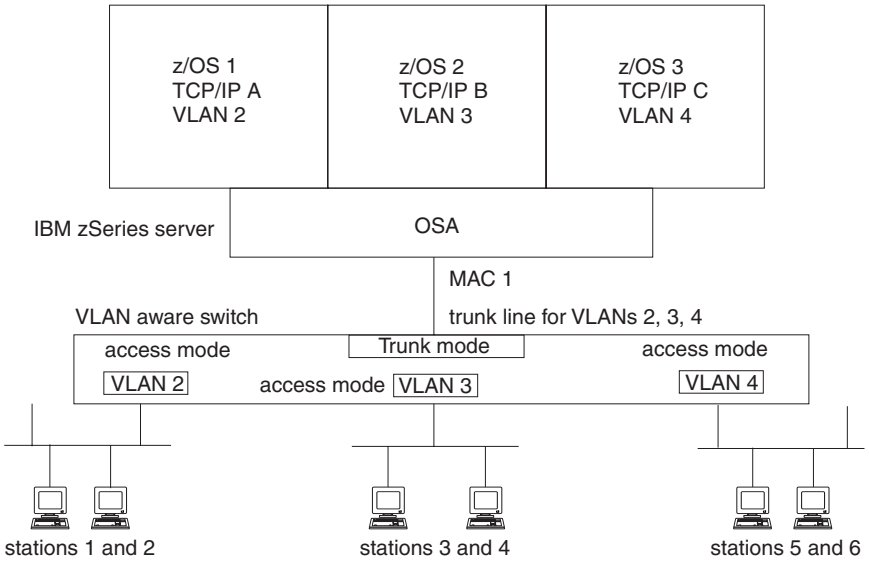

Figure 9. Single OSA and VLAN switch configuration

Figure 9 shows the recommended VLAN switch port configuration when a VLAN ID is configured in the TCP/IP stack. A single physical LAN is divided into three separate virtual LANs (2, 3, and 4), the OSA port is configured as a trunk line, and the other ports on the switch are configured in access mode for their specific VLAN.

In Figure 9 there are three virtual LANs deployed through the same shared OSA, where each TCP/IP stack appears to have a unique and isolated physical network as follows:

- VLAN 2 - TCP/IP A and stations 1 and 2
- VLAN 3 - TCP/IP B and stations 3 and 4
- VLAN 4 - TCP/IP C and stations 5 and 6

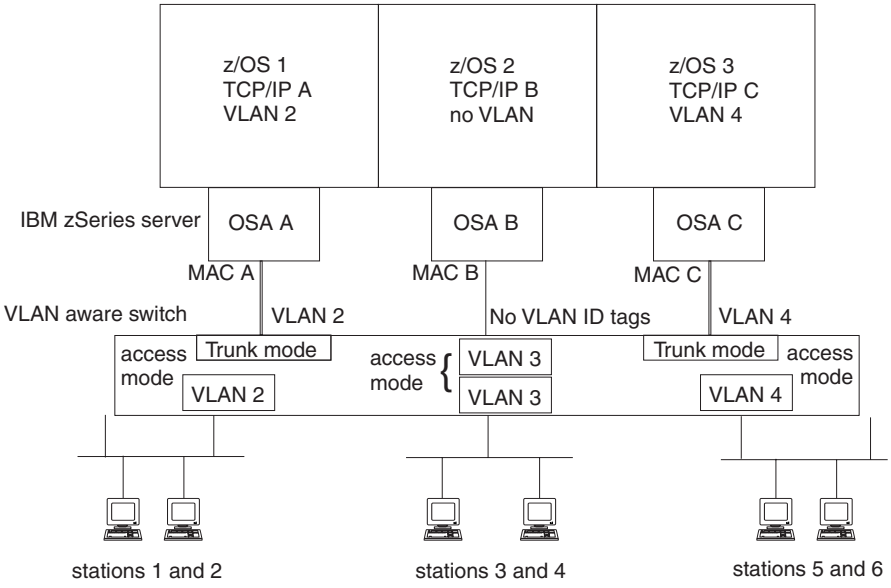

Figure 10. Matching VLAN switch configuration to multiple OSAs (VLAN configuration)

Figure 10 illustrates using multiple OSAs and TCP/IP stacks. Three unique VLANs are created. However, TCP/IP stack B will not deploy a VLAN ID, and the corresponding switch port is configured in access mode. No VLAN ID tags will flow to this OSA port.

In Figure 10 there are also three virtual LANs deployed. Access to each VLAN is provided through separate OSAs, yet the functionality of having three physical networks is still provided. TCP/IP B is not configured with a VLAN ID, and therefore stack B is unaware of the existence of VLAN 3 (although stations 3 and 4 on VLAN 3 have access to stack B through OSA B). Note that the switch port for OSA B is configured in access mode, while the other two switch ports are configured in trunk mode.

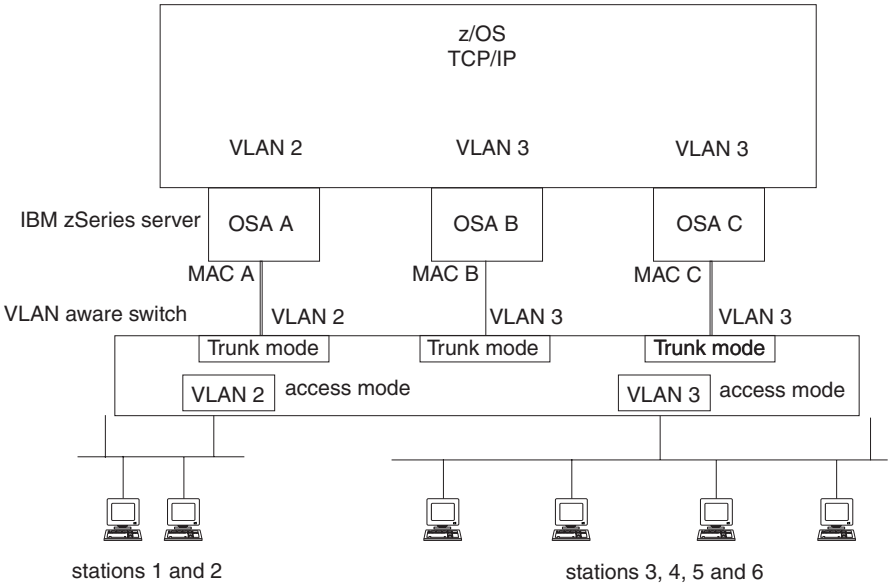

Figure 11. Single stack using multiple OSAs on the same physical network

Figure 11 on page 74 illustrates a single TCP/IP stack using multiple OSAs that are on the same physical network. There are two VLANs deployed, where OSA A is on VLAN 2, and OSA B and OSA C are on VLAN 3.

Configuring OSA B and OSA C with the same VLAN ID has significance for failure or takeover scenarios. The interface takeover (ARP takeover) function, with redundant connectivity onto a LAN, applies within the VLAN. Therefore, if OSA B becomes unavailable, OSA C can take over. Similarly, OSA B can take over if OSA C becomes unavailable. However, OSA A cannot take over for either OSA B or OSA C, because OSA A is on a different VLAN.

In Figure 11 on page 74, a single TCP/IP stack has access to two VLANs through three OSAs, which provides the following network isolation:

- VLAN 2 - through OSA A to stations 1 and 2
- VLAN 3 - through OSA B and OSA C to stations 3, 4, 5 and 6

OSA-Express port sharing

An OSA-Express port can be shared by multiple TCP/IP stacks. In such a configuration, when a unicast packet is sent over the OSA-Express port and the next-hop IP address is registered by another TCP/IP stack on the same LAN or VLAN that shares the OSA-Express port, then the OSA adapter routes the packet directly to the stack that shares the port, bypassing the external LAN. For multicast and broadcast, the OSA adapter also routes the packet directly to the stack that shares the port, in addition to sending the packet onto the LAN.

OSA-Express connection isolation

OSA-Express connection isolation provides a way to prevent the adapter from internally routing packets directly to a stack that shares the same port. When connection isolation is in effect, the OSA-Express feature discards any unicast packets when the next-hop address is registered by a stack sharing the same port, and prevents any multicast or broadcast packets from being internally routed between the stacks sharing the port.

For direct routing to occur, the OSA-Express feature requires that neither of the stacks that are sharing a port can be isolated. Therefore, for traffic between two stacks that are sharing a port, as long as at least one of the stacks is isolated, then connection isolation is in effect for traffic in both directions between these stacks.

OSA-Express connection isolation can be useful when you want to prevent communication between two stacks that share the same OSA-Express port, and it provides extra assurance against a misconfiguration that might otherwise allow such traffic to flow. OSA-Express connection isolation can also be useful if you want to ensure that traffic flowing through the OSA adapter does not bypass any security features implemented on the external LAN.

Dynamic routing is not aware of OSA-Express connection isolation, which is an issue only if static routes are not used and traffic needs to flow between the two hosts that share the OSA adapter using connection isolation. In this case, a dynamic routing protocol might choose a route between the hosts that includes connection isolation, which would make each host unreachable from the other host. If you want dynamic routing to work between hosts that are using OSA-Express connection isolation, you must ensure in your dynamic routing configuration that the path that includes connection isolation is not chosen to route between the hosts.

Guideline: You can ensure that a path that includes OSA-Express connection isolation is not chosen as the route between two hosts by assigning higher routing costs to isolated interfaces than to other network paths between those hosts (for example dynamic XCF or MPC), so that the other network paths between the hosts are chosen. You can also accomplish this by excluding the interfaces with connection isolation from the dynamic routing domain, if it is not necessary for them to be reachable from the wider network (for example, by defining them with INTERFACE statements in OMPROUTE).

Tip: If you want traffic to flow between two stacks that share an OSA-Express port but you also want to ensure that the traffic flows over an external LAN, do one of the following:

- Configure each stack on a separate virtual LAN (VLAN).
- Use a static route with the next-hop address of a router on the LAN.

  Result: Using a static route with the next-hop address of a router on the LAN to route to another host on the same LAN can result in excessive ICMP redirect packets from the router to the originating host.

  Guideline: If you use this technique, turn off receipt of ICMP redirects on the sharing hosts and, if possible, configure the router to not send ICMP redirects.

ARP offload and VIPA ARP processing

In QDIO mode, the OSA performs all Address Resolution Protocol (ARP) processing for IPv4. The z/OS stack informs the OSA of the IP addresses for which it should perform ARP processing. Because the z/OS stack also supports configurations in which ARPs flow for VIPAs (which you might see on some flat network configurations that use static routing), the stack also informs the OSA of the VIPAs for which it should perform ARP processing. OSA sends gratuitous ARPs for these IP addresses during interface takeover scenarios to provide fault tolerance.

If you define the OSA using DEVICE and LINK statements, then the stack informs OSA to perform ARP processing for all VIPAs that are in the home list, which can result in numerous unnecessary gratuitous ARPs for VIPAs in an interface takeover scenario. However, if you use the IPv4 INTERFACE statement for IPAQENET, you can control this VIPA ARP processing by configuring a subnet mask for the OSA. If you specify a nonzero num_mask_bits value on the IPADDR parameter of the INTERFACE statement, then the stack informs OSA to perform ARP processing for a VIPA only if the VIPA is configured in the same subnet as the OSA (as defined by the resulting subnet mask).

Checksum offload

When sending or receiving packets over the OSA-Express feature in QDIO mode with checksum offload support, TCP/IP offloads most IPv4 (outbound and inbound) checksum processing (IP header, TCP, and UDP checksums) to the OSA. The TCP/IP stack performs checksum processing in the following cases where checksum cannot be offloaded:

- Packets that go directly to another stack that shares the same OSA-Express feature
- IPSec-encapsulated packets
- Fragmented and reassembled packets
- Outbound multicast and broadcast packets
- Outbound TCP packets that contain only a TCP header

- When multipath is in effect (unless all interfaces in the multipath group support checksum offload)

TCP segmentation offload

The TCP/IP stack can offload most IPv4 outbound TCP segmentation processing to an OSA-Express feature in QDIO mode using TCP segmentation offload support. You can configure this function by specifying the SEGMENTATIONOFFLOAD parameter on the GLOBALCONFIG profile statement. The TCP/IP stack performs TCP segmentation processing in the following cases in which segmentation cannot be offloaded:

- Packets that go directly to another stack that shares the same OSA-Express feature
- IPSec-encapsulated packets
- When multipath is in effect (unless all interfaces in the multipath group support segmentation offload)
- When the SEGMENTATIONOFFLOAD parameter is not specified on the GLOBALCONFIG statement

Tip: Applications that use large TCP send buffers will obtain the most benefit from TCP segmentation offload. The size of the TCP receive buffer on the other side of the TCP connection also affects the negotiated buffer size. You can control the size of these buffers using the following mechanisms:

- The TCPSENDBFRSIZE parameter on the TCPCONFIG statement sets the default TCP send buffer size for all applications.
- An application can use the SO_SNDBUF socket option to override the default TCP send buffer size.
- The TCPRCVBUFRSIZE parameter on the TCPCONFIG statement sets the default TCP receive buffer size for all applications.
- An application can use the SO_RCVBUF socket option to override the default TCP receive buffer size.

Dynamic LAN idle timer

z/OS Communications Server provides the ability to dynamically adjust how frequently an OSA-Express2 or OSA-Express3 feature should interrupt the host for inbound traffic. By monitoring traffic patterns, the stack can adjust the interrupt-timing values to maximize throughput.

To configure an OSA-Express2 or OSA-Express3 for dynamic LAN idle timer, use the INTERFACE or LINK statement with the dynamic inbound performance setting (INBPERF DYNAMIC). For information about dynamic LAN idle timer and the INBPERF parameter, see DEVICE and LINK – MPCIPA OSA-Express QDIO devices, INTERFACE - IPAQENET OSA-Express QDIO interfaces, and INTERFACE - IPAQENET6 OSA-Express QDIO interfaces in *z/OS Communications Server: IP Configuration Reference*.

Restriction: The OSA-Express2 or OSA-Express3 feature must be configured in QDIO mode.

Optimized latency mode

One way to improve the performance of an OSA-Express3 feature in QDIO mode for processing workloads with demanding latency requirements is to configure the OSA-Express3 feature to operate in optimized latency mode. Optimized latency

mode optimizes interrupt processing for both inbound and outbound data, which decreases latency and can provide significant increases in throughput, particularly for high volume, interactive, non-streaming workloads.

To configure an OSA-Express3 feature to operate in optimized latency mode, use the INTERFACE statement with the OLM parameter. Because optimized latency mode affects both inbound and outbound interrupts, it supersedes other inbound performance settings set by the INBPERF parameter. For more information about optimized latency mode and the OLM and INBPERF parameters on the INTERFACE statement for IPAQENET and IPAQENET6, see *z/OS Communications Server: IP Configuration Reference*.

Because of the operating characteristics of optimized latency mode, two other configuration changes might be required.

- For outbound traffic to gain the benefit of optimized latency mode, direct traffic to priority queues 1, 2, or 3 using the WLMPRIORITYQ parameter on the GLOBALCONFIG statement or using Policy Agent and configuring a policy with the SetSubnetPrioTosMask statement.

  Although an OSA-Express feature supports multiple outbound write priority queues, outbound optimized latency mode is performed only for traffic on priority queue 1 (priority level 1). The TCP/IP stack combines all the traffic directed to priority queues 1, 2, and 3 into priority queue 1 for any OSA-Express3 feature operating in optimized latency mode.

  For more information about directing traffic to outbound OSA-Express priority queues using the WLMPRIORITYQ parameter on the GLOBALCONFIG statement or using the SetSubnetPrioTosMask statement, see *z/OS Communications Server: IP Configuration Reference*.

  Guideline: Configure the WLMPRIORITYQ parameter with no subparameters, which assigns a default mapping of service class importance levels to OSA-Express outbound priority queues. This default mapping directs traffic assigned to the higher priority service class importance levels 1–4 to queues that operate in optimized latency mode, and enables the appropriate types of traffic to benefit from optimized latency mode.

  Result: If neither the WLMPRIORITYQ nor SetSubnetPrioTosMask statements are specified, any packet that has a type of service (ToS) byte with the first three bits being 000 or 001 is directed to queue 4 and does not benefit from optimized latency mode.

- To achieve optimal latency for one or more network interfaces operating in optimized latency mode, limit the number of network interfaces that can concurrently share an OSA-Express3 feature.

  When at least one network interface is operating in optimized latency mode, ensure that there are no more than four concurrent network interfaces sharing an OSA-Express3 port, and no more than eight concurrent network interfaces sharing an OSA-Express3 channel path identifier (CHPID). The following configurations can result in multiple users sharing an OSA-Express3 feature.

  – Multiple LPARs sharing the OSA-Express3 feature
  – Multiple stacks on the same LPAR sharing the OSA-Express3 feature
  – Multiple VLAN interfaces to the OSA-Express3 feature
  – Both an IPv4 and an IPv6 active interface to the OSA-Express3 feature
  – A TCP/IP stack enabling the OSA-Express network traffic analyzer (OSAENTA) for the OSA-Express3 feature

Optimized latency mode is intended for high volume, interactive workloads. Although optimized latency mode can compensate for some mixing of workloads, an excessive amount of high volume, streaming workloads, such as bulk data or file transfer, can result in higher CPU consumption.

Guideline: When enabling multipath routing using the PERPACKET option, do not configure a multipath group that contains an OSA-Express3 feature configured with optimized latency mode and any other type of device.

Restrictions:

- Optimized latency mode is limited to OSA-Express3 Ethernet features in QDIO mode running with an IBM System z10®. For more information, see the 2097DEVICE Preventive Service Planning (PSP) bucket.
- Traffic that is either inbound over or being forwarded to an OSA-Express3 feature configured to operate in optimized latency mode is not eligible for the accelerated routing provided by HiperSockets Accelerator and QDIO Accelerator.
- For an OSA-Express3 interface configured to operate in optimized latency mode, the stack ignores the configured INBPERF setting and uses the value DYNAMIC.

QDIO inbound workload queueing

OSA-Express3 features can perform a degree of traffic sorting by placing inbound packets for differing workload types on separate processing queues. This function is called QDIO inbound workload queueing (IWQ). With the inbound traffic stream already sorted by the OSA-Express3 feature, z/OS Communications Server provides the following performance optimizations:

- Finer tuning of read-side interrupt frequency to match the latency demands of the various workloads that are serviced
- Improved multiprocessor scalability, because the multiple OSA-Express3 input queues are now efficiently serviced in parallel

When QDIO IWQ is enabled, z/OS Communications Server and the OSA-Express3 feature establish a primary input queue and one or more ancillary input queues for inbound traffic. z/OS Communications Server and the OSA-Express3 feature cooperatively use the multiple queues in the following way:

- The OSA-Express3 feature directs an inbound packet (received on this interface) that is to be forwarded by the sysplex distributor to the sysplex distributor ancillary input queue. z/OS Communications Server then tailors its processing for the sysplex distributor queue, notably by using the multiprocessor to service sysplex distributor traffic in parallel with traffic on the other queues.
- The TCP layer automatically detects connections operating in a bulk-data fashion (such as the FTP data connection), and these connections are registered to the receiving OSA-Express3 feature as bulk-mode connections. The OSA-Express3 feature then directs an inbound packet (received on this interface) for any registered bulk-mode connection to the TCP bulk-data ancillary input queue. z/OS Communications Server tailors its processing for the bulk queue, notably by improving in-order packet delivery on multiprocessors, which likely results in improvements to CPU consumption and throughput. Like other ancillary input queues, processing for data on the bulk queue can be in parallel with traffic on the other queues.
- If a packet is not directed to an ancillary input queue, the OSA-Express3 feature directs the packet to the primary input queue.

Requirement: QDIO IWQ is limited to OSA-Express3 Ethernet features in QDIO mode running on an IBM System z10 GA3. For more information, see the 2097DEVICE and 2098DEVICE Preventive Service Planning (PSP) buckets.

Restrictions:

- QDIO IWQ is not supported for IPAQENET interfaces defined with the DEVICE, LINK, and HOME statements. You must convert your IPAQENET definitions to use the INTERFACE statement to enable this support. For more information, see "Steps for converting from IPv4 IPAQENET DEVICE, LINK, and HOME definitions to the IPv4 IPAQENET INTERFACE statement" on page 64.
- QDIO IWQ is not supported for a z/OS guest on z/VM® using simulated (virtual) devices, such as virtual switch (VSWITCH) or guest LAN.
- Bulk-mode TCP connection registration is supported only in configurations in which a single inbound interface is servicing the bulk-mode TCP connection. If a bulk-mode TCP connection detects that it is receiving data over multiple interfaces, QDIO IWQ is disabled for the TCP connection and inbound data from that point forward is delivered to the primary input queue.
- QDIO IWQ does not apply for traffic that is sent over an OSA port that is shared by the receiving TCP/IP stack when an indirect route (where the next hop and destination IP address are different) is being used; this traffic is placed on the primary input queue. QDIO IWQ does apply when traffic on the shared OSA path uses a direct route (where the next hop and destination IP address are the same).

Steps for enabling QDIO inbound workload queueing

Perform the following steps to enable QDIO inbound workload queueing (IWQ):

1. Convert IPAQENET definitions from DEVICE, LINK, and HOME statements to the INTERFACE statement. For more information, see "Steps for converting from IPv4 IPAQENET DEVICE, LINK, and HOME definitions to the IPv4 IPAQENET INTERFACE statement" on page 64.
2. Specify the INBPERF parameter with the DYNAMIC setting on the INTERFACE statement for the IPAQENET or IPAQENET6 interface. In addition, you must specify the WORKLOADQ subparameter and the VMAC parameter.

   Tip: In addition to enabling QDIO IWQ, the INBPERF DYNAMIC setting also dynamically tunes the read-side interrupt frequency for the OSA-Express feature.

You know you are done when the `WorkloadQueueing` field of the Netstat DEvlinks/**-d** report is set to `Yes`, indicating that QDIO IWQ is enabled. You can also obtain this information with a GetIfs request for the TCP/IP callable NMI (EZBNMIFR).

You can use the Netstat ALL/-A report to determine whether any TCP connections are registered to the TCP bulk data ancillary input queue; the `Ancillary Input Queue` field is set to `Yes` and the `BulkDataIntfName` field is set to the interface name. You can also obtain this information with a GetConnectionDetail request for the TCP/IP callable NMI (EZBNMIFR).

You can use the Netstat STATS/-S report to display the total number of TCP segments that are processed on the TCP bulk data ancillary input queue; this number is displayed in the `Segments Received on OSA Bulk Queues` field. You can also obtain this information with a GetGlobalStats request for the TCP/IP callable NMI (EZBNMIFR).

For more information about the Netstat command, see *z/OS Communications Server: IP System Administrator's Commands*. For more information about EZBNMIFR, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Displaying OSA-Express QDIO interface information

You can use the following commands to display information about OSA-Express QDIO interfaces:

- Netstat DEvlinks/**-d**

  This command displays configured and runtime information from the TCP/IP stack for an OSA-Express QDIO interface.
- DISPLAY TCPIP,,OSAINFO

  This command displays configured and runtime information from the OSA-Express QDIO feature for the data subchannel device of the interface.

For information about the syntax and output of these commands, see *z/OS Communications Server: IP System Administrator's Commands*.

HiperSockets concepts and connectivity

HiperSockets is a zSeries hardware feature that provides high performance internal communications between LPARs within the same central processor complex (CPC), without the use of any additional or external hardware equipment (for example, channel adapters, LANs, and so on). When the processor supports HiperSockets and the CHPIDs have been configured in HCD (IOCP), TCP/IP connectivity can occur for two reasons:

- DYNAMICXCF is configured on the IPCONFIG (IPv4) or the IPCONFIG6 (IPv6) statements.
- A user-defined HiperSockets (MPCIPA) DEVICE and LINK (IPv4) or INTERFACE (IPv6) is configured and started.

Therefore, there are two types of HiperSockets devices:

- DYNAMICXCF HiperSockets device or interface (TRLE "IUTIQDIO" and an MPC group of subchannel devices). The PORTNAME will be IUTIQDxx, where xx = the IQD CHPID that VTAM uses (for example, IUTIQDFD when using IQD CHPID x'FD').
- A user-defined HiperSockets device or interface (TRLE "IUTIQDxx" and an MPC group of subchannel devices). The PORTNAME is not applicable for this TRLE.

In both cases, the TRLE is dynamically built by VTAM. For additional details regarding how to configure a user-defined HiperSockets device or interface, see "HiperSockets" on page 446 and *z/OS Communications Server: IP Configuration Reference*.

Concepts and considerations for the IQD CHPID

The HiperSockets hardware device is represented by the IQD CHPID and its associated subchannel devices. All LPARs that are configured (HCD) to use the same IQD CHPID have internal connectivity and therefore have the capability to communicate using HiperSockets. If the system supports multiple channel subsystems, and if HiperSockets connectivity is required across multiple channel subsystems, the IQD CHPID must also be configured (HCD) to span the applicable channel subsystems. The IQD CHPID can be viewed as a logical LAN within the CPC. The HiperSockets hardware allows up to four (16 with systems that support multiple channel subsystems) separate IQD CHPIDs to be defined per CPC, creating the capability of having four (16 with systems that support multiple channel subsystems) separate logical LANs within the same CPC. Figure 12 on page 82

page 82 and Figure 13 illustrate this concept:

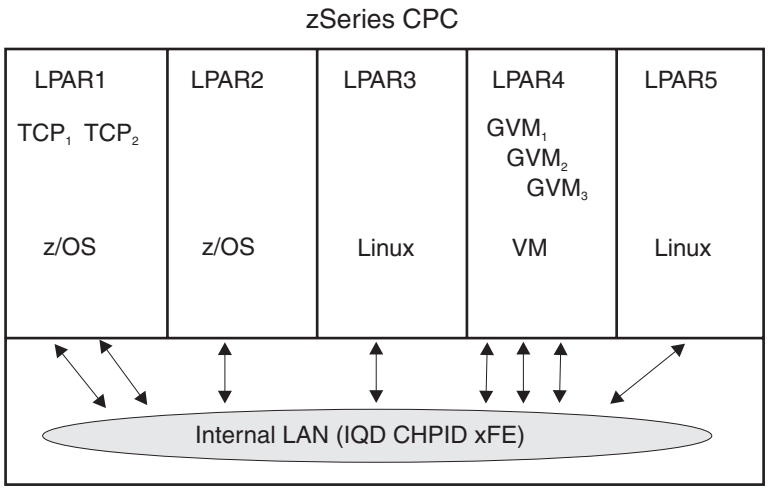

Figure 12. HiperSockets internal LAN

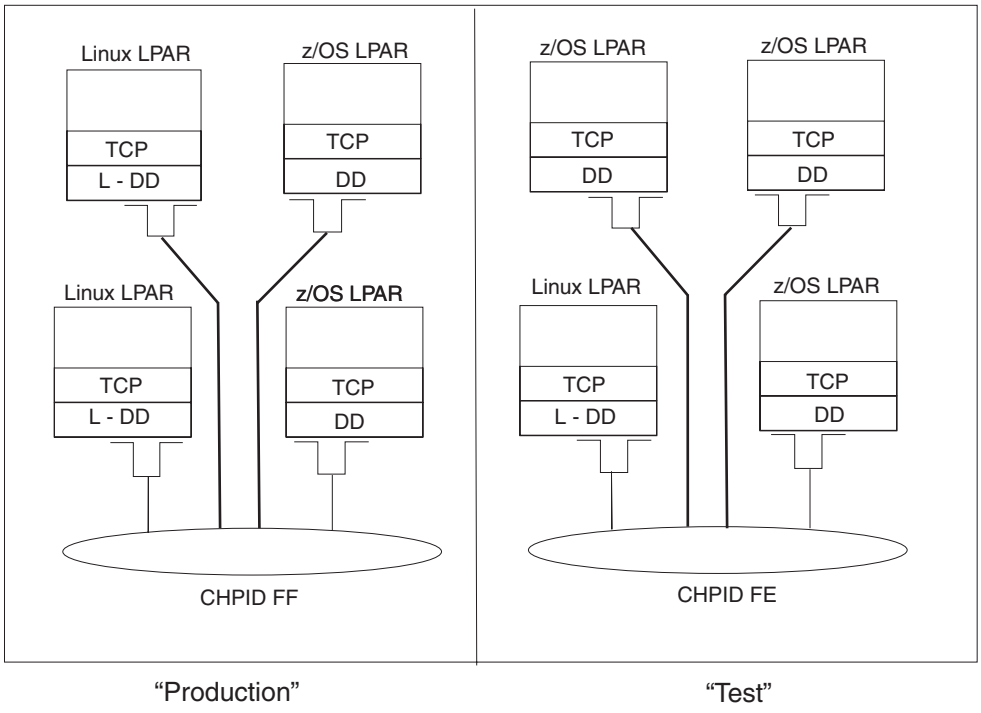

Figure 13. HiperSockets multiple internal LANs

With this capability, the system administrator can logically separate (or control) the internal connectivity. This is accomplished by controlling which specific LPARs are allowed to internally connect using HiperSockets. Further examples of this are as follows:

- SYSPLEX 'A' LPARs running on LPs 1 through 4 could use IQD CHPID x'FC'.
- SYSPLEX 'B' LPARs running on LPs 5 through 8 could use IQD CHPID x'FD'.
- A VM LPAR runs in LP 9 running various second level systems (Linux and z/OS) which use IQD CHPID x'FE'.
- Combinations of these examples could be:

– Another set of LPARs on LPs 10 through 12 which are not using DYNAMICXCF (non SYSPLEX) are connected to IQD CHPIDs x'FE' and x'FF'.
– Subsets of LPARs 1 through 8 are using both the DYNAMICXCF IQD CHPIDs and a non-DYNAMICXCF IQD CHPIDs.
– Some LPARs are connected to all four IQD CHPIDs.

In a HiperSockets CHPID, IP addresses of the HiperSockets interfaces can be in the same subnet or in different subnets. Some applications can detect when HiperSockets IP addresses are in different logical subnets and might issue warning or error messages. For further subdivision of connectivity in the HiperSockets CHPID using virtual LANs, see "HiperSockets and VLAN."

HiperSockets and VLAN

HiperSockets supports VLANs, which means you can logically subdivide the internal LAN for a HiperSockets CHPID into multiple virtual LANs. Therefore, two stacks that configure the same VLAN ID for the same CHPID can communicate over HiperSockets, while two stacks that configure different VLAN IDs cannot. For HiperSockets, the VLAN ID provided applies to both IPv4 and IPv6 connections.

Guideline: If you configure a VLAN ID on a stack using a HiperSockets CHPID, configure a VLAN ID for all other stacks using the same CHPID.

Planning for IQD CHPID spanning

Figure 14 illustrates how an IQD CHPID can span both logical channel subsystem 0 and logical channel subsystem 1.

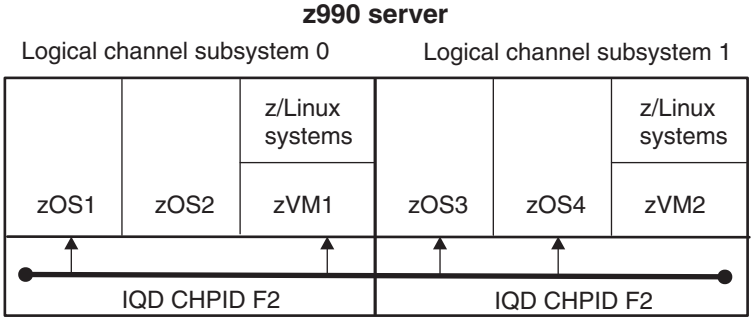

Figure 14. Spanned IQD (HiperSockets) CHPID

In Figure 14, note the following:

- CHPID spanning is applicable to servers that support multiple channel subsystems, such as the IBM z990 server.
- IQD CHPIDs and their spanning attributes are configured using HCD.
- Logical channel subsystem 0 and logical channel subsystem 1 are both using IQD CHPID F2, which was configured (in HCD) to span.
- All images can exploit IQD CHPID spanning.
- Using HiperSockets support along with IQD spanning support, logical partitions in both logical channel subsystem 0 and 1 have internal connectivity.
- Specific logical partitions can be configured to have access to the spanned IQD CHPID. In this example:
  – IQD CHPID F2 is configured to span both logical channel subsystem 0 and logical channel subsystem 1.

  - In logical channel subsystem 0, zOS1 and zVM1 have connectivity (through IQD CHPID F2) to zOS3 and zOS4 in logical channel subsystem 1.
  - zOS2 and zVM2 do not have access to IQD CHPID F2.
- Up to 16 IQD CHPIDs can be configured in HCD.
- There are no TCP/IP or VTAM configuration changes required (spanning support is transparent to z/OS Communications Server).

  Tip: TCP/IP Dynamic XCF support uses HiperSockets connectivity when the remote system is reachable through HiperSockets. This is dynamically determined, and this internal logic also handles a spanned IQD CHPID.

To configure a spanned IQD CHPID, see *z/OS HCD User's Guide*.

The HiperSockets MPC group

For a specific IQD CHPID, VTAM builds a single HiperSockets MPC group, using the subchannel devices associated with that IQD CHPID. VTAM requests up to 10 devices from the I/O subsystem if they are defined to the CHPID being initialized, regardless of how many will be required for the number of TCP/IP stacks to be used in the LPAR. VTAM requires two subchannel devices for the read and write control devices, and 1 to 8 devices for data devices, one device for each of up to 8 TCP/IP stacks.

Therefore, to build the MPC group, there must be a minimum of 3 subchannel devices defined (within HCD) and associated with the same IQD CHPID. The maximum number of subchannel devices that VTAM will use is 10 (supporting 8 data devices or 8 TCP/IP stacks) per LPAR or MVS image. The subchannel devices must be configured for the LPAR and online prior to when the TCP/IP stack is initialized. Generally, the number of HiperSockets subchannel devices you should configure to HCD per LPAR is:

```
     2   (read / write control devices)
   + N   (where N = number of TCP/IP stacks)
   -----------------
     N+2  (total subchannel devices per LPAR)
Example (LPAR 1 starts two TCP/IP stacks and both stacks use HiperSockets):

   -  define 4 subchannel devices on the same IQD CHPID
   -  where 2 are used for read / write control and 2 data devices are available
```

Tip: The HCD configuration is the only way to control the number of devices that VTAM uses for HiperSockets.

The first TCP/IP stack within the LPAR to initialize dynamic XCF support (DYNAMICXCF) causes the IUTIQDIO HiperSockets MPC group to be dynamically created. The first TCP/IP stack within the LPAR to initialize a user-defined HiperSockets device (TRLE IUTIQD*xx*) causes the IUTIQD*nn* HiperSockets MPC group to be dynamically created.

Each TCP/IP stack can then start the HiperSockets device, and each stack is assigned a unique (dedicated) subchannel data device from the IUTIQDIO or IUTIQD*nn* MPC group.

Recommendation: Configure the IQD CHPIDs using CHPIDs x'F0' through x'FF' (but any valid CHPID value x'00' through x'FF' can be configured as TYPE = IQD). See *z/OS HCD Planning* and Appendix D, "Using HCD," on page 1493 for additional details.

HiperSockets maximum frame size

The HiperSockets hardware supports four different frame sizes referred to as the HiperSockets MFS (maximum frame size). Using HCD (or IOCP), the HiperSockets MFS is configured on the IQD CHPID using the 'OS=' parameter. All LPARs communicating over the same IQD CHPID will then use the same IQD MFS. The MFS affects the largest packet that TCP/IP can transmit. TCP/IP will adjust the MTU (Maximum Transmission Unit) based on the MFS, which is discovered during activation.

The following table depicts the four possible TCP/IP MTU sizes resulting from the HiperSockets frame sizes:

OS=*value*	**HiperSockets frame size**	**TCP/IP MTU size**
00 (default)	16 KB	8 KB
40	24 KB	16 KB
80	40 KB	32 KB
C0	64 KB	56 KB

The default HiperSockets MFS is 16 KB. However, in cases in which increased bandwidth is required (such as large file transfers, file backup, and so on), a larger MFS could be used. In most workload environments the default size will result in better storage and CPU utilization.

```

See *z/OS HCD Planning* and Appendix D, “Using HCD,” on page 1493 for additional details.

Modifying HiperSockets connectivity [TCP/IP device and link and the VTAM HiperSockets MPC group (IUTIQDIO)]

Certain modifications can be made to the HiperSockets device (MPC group) without disrupting an active TCP/IP stack.

z/OS supports dynamic I/O for the HiperSockets CHPID and subchannel devices, allowing subchannel devices to be added or removed to or from an LPAR which has already been IPLed.

TCP/IP supports the STOP and START command for the DYNAMICXCF HiperSockets device (IUTIQDIO). However, the commands are only supported when the (internal) start (activation) was successful during stack initialization. TCP/IP also supports the STOP and START command for the user-defined HiperSockets devices (IUTIQDxx). Since a user-defined HiperSockets device is supported as an MPCIPA device, STOP and START function just as they would for other MPCIPA devices.

VTAM supports a MODIFY VTAMOPTS command that you can use to change the initial setting of the IQDCHPID start option.

Therefore, it is possible to make certain changes to the DYNAMICXCF HiperSockets MPC group (IUTIQDIO) without restarting VTAM or an active TCP/IP stack. Examples of changes that can be made are (STOP/START device required):

- Alter which specific IQD CHPID is used for DYNAMICXCF (for example, move from the x'FC' CHPID to the x'FD' CHPID).
- Add or remove subchannel devices (for example, from the current IQD CHPID).
- Alter the IQD MFS which alters the TCP/IP MTU (for example, increase the current IQD CHPID from 16k to 64k).

Although VTAM supports modifications to the start option IQDCHPID (and the modification will be immediately displayed), the effects will vary depending on what the current usage was and the change (from or to) that was made. For example:

- When MODIFIED from ANY (or CHPID) to NONE, there is no effect on current usage but blocks subsequent activations of the DYNAMICXCF HiperSockets device.
- When MODIFIED from NONE to ANY (or CHPID), there is no effect on current usage but allows subsequent activations.
- When MODIFIED from CHPID_X to CHPID_Y, there is no effect on current usage.

  Note: VTAM only uses the CHPID value when building the IUTIQDIO MPC group.

  To change CHPIDs for an active MPC group the following must be done:

  1. TCP/IP IUTIQDIO devices and IQDIOINTF6 interfaces that are changing must be stopped.
  2. Make any necessary HCD/IOCDS changes.
  3. Verify new subchannel devices are varied online.
  4. Verify the MPC group has deactivated (with no usage it times out after approximately 2 minutes).
  5. Modify IQDCHPID = CHPID (to new CHPID).
  6. Restart the TCP/IP IUTIQDIO devices and IQDIOINTF6 interfaces.

To use HiperSockets communications, the processor must have the necessary hardware support. If the processor does not support HiperSockets communications, modifications to this start option will not be accepted, and the IQDCHPID option will not be displayed (displayed as ***NA***) .

HiperSockets connectivity and routing

For each pair of stacks within a sysplex that are not on the same MVS image, if all of the following conditions are true, the stacks will use HiperSockets DYNAMICXCF connectivity (versus standard XCF connectivity):

- The two stacks must be on the same CPC.
- For the DYNAMICXCF HiperSockets device (IUTIQDIO):
  - The two stacks must be using the same IQD CHPID.
  - If running on a system that supports multiple channel subsystems and the two stacks are also in different channel subsystems, the IQD CHPID must be configured (HCD) to span.
- Both stacks must be configured (HCD) to use HiperSockets.
- For IPv4 HiperSockets connectivity, both stacks must be at the z/OS V1R2 level, or a later release. For IPv6 HiperSockets connectivity, both stacks must be at the z/OS V1R7 level.
- The initial HiperSockets activation must complete successfully.

When an IPv4 DYNAMICXCF HiperSockets device and link are created and successfully activated, a subnet route is created across the HiperSockets link. The subnet is created by using the DYNAMICXCF IP address and mask. This allows any LPAR within the same CPC to be reached, even ones that are not within the sysplex. For example, an LPAR that is running z/Linux or z/VM that does not support joining the sysplex can still be reached. The z/Linux or z/VM LPAR must define at least one IP address for the HiperSockets endpoint that is within the subnet defined by the DYNAMICXCF IP address and mask.

Similarly, when an IPv6 DYNAMICXCF HiperSockets interface is created and successfully activated, a prefix route is created across the HiperSockets interface (if prefix_route_len is specified on DYNAMICXCF). This allows any LPAR within the same CPC to be reached, even ones that are not within the sysplex. For example, an LPAR that is running z/Linux or z/VM that does not support joining the sysplex can still be reached. The z/Linux or z/VM LPAR must define at least one IP address for the HiperSockets endpoint that uses the same prefix as the DYNAMICXCF IP address.

Therefore, TCP/IP can communicate with other LPARs within the CPC over the HiperSockets connectivity created by DYNAMICXCF even when the TCP/IP in the other LPAR is not part (joins or supports) of the sysplex. You can also elect to manually configure a HiperSockets device for non-sysplex communications.

When multiple stacks reside within the same LPAR that supports HiperSockets, both IUTSAMEH and HiperSockets links or interfaces will coexist. In this case, it is possible to transfer data across either link or interface. Because IUTSAMEH links or interfaces have better performance, it is better to always use them for intra-stack communication. A host route will be created by DYNAMICXCF processing across the IUTSAMEH link or interface but not across the HiperSockets link or interface. To avoid using the HiperSockets link or interface for communication within the same host, the following rules should be observed:

- Specify DYNAMICXCF IP addresses in a separate subnet than that of VIPA addresses (IPv4) or using a separate prefix than that of VIPA addresses (IPv6).
- Do not specify static IUTSAMEH links or interfaces.

It is also possible with multiple stacks in the same LPAR to end up with both XCF and HiperSockets links or interfaces. This occurs when the availability of the (preferable) HiperSockets link or interface changes as each TCP stack (within the

same LPAR) is started. For example, stack A is started with HiperSockets available and later stack B is started with HiperSockets unavailable. This type of configuration should be avoided.

Efficient routing using HiperSockets Accelerator

Communications Server leverages the technological advances and high performing nature of the I/O processing offered by HiperSockets with the IBM zSeries servers and the IBM OSA-Express feature using QDIO architecture by optimizing IP packet forwarding processing that occurs across these two types of links. This function is referred to as HiperSockets Accelerator. It is a configurable option, and activated by configuring the IQDIORouting option on the IPCONFIG statement.

Restrictions:

- HiperSockets Accelerator is IPv4 only.
- You cannot enable HiperSockets Accelerator if you enable IP security on the stack.
- You cannot enable HiperSockets Accelerator if IP forwarding is disabled on the stack.

When configured, it allows unicast IPv4 packets that are received over a HiperSockets link and are to be forwarded over a QDIO link (or received over QDIO and are to be forwarded over HiperSockets) to be forwarded by the z/OS Communications Server HiperSockets device driver. That is, the IP forwarding function is pushed down as close to the hardware [or to the lowest software DLC (Data Link Control)] layer as possible so that these packets do not have to be processed by the TCP/IP stack or address space. Therefore, valuable TCP/IP resources (storage and machine cycles) are not expended for purposes of routing and forwarding packets. Figure 15 illustrates a configuration before the utilization of HiperSockets Accelerator.

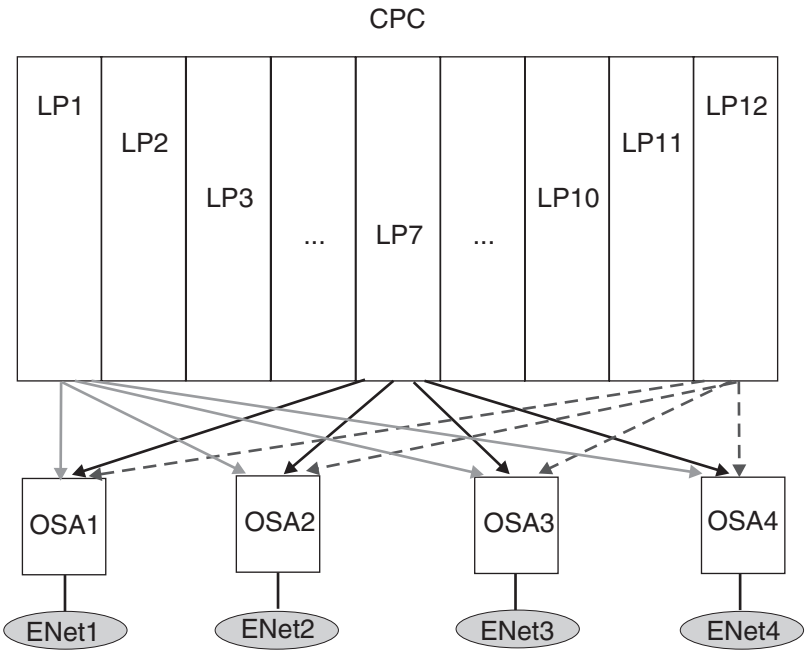

Figure 15. Candidate configuration for HiperSockets Accelerator

HiperSockets Accelerator presents a different configuration and approach to obtain full connectivity, as shown in Figure 16.

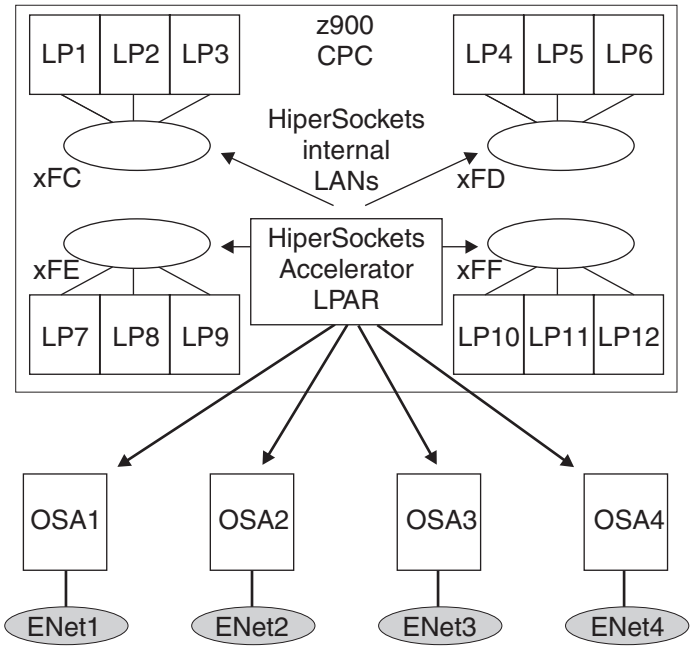

Figure 16. HiperSockets Accelerator configuration

This function allows a user to position a specific or single TCP/IP stack which has direct physical connectivity to the OSAs LANs as the HiperSockets router. This stack can then connect to all remaining TCP/IP stacks in other images (LPARs) within the same CPC that require connectivity to the same OSA LANs using HiperSockets connectivity.

This approach becomes more beneficial as the number of LPARs within a given CPC increase. Instead of attempting to directly attach each LPAR to each physical network attachment using an OSA LAN, a smaller number of OSAs could be concentrated through a single z/OS LPAR. From a performance perspective, HiperSockets Accelerator attempts to make the intermediate (or router) TCP/IP stack appear as if it did not exist in the path. Instead, each LPAR will appear as if each were directly attached to the physical network (for example, packets are forwarded without traversing the router TCP/IP stack). There are no additional routing configuration tasks required by the user. The prerouting occurs automatically. The TCP/IP stack automatically detects IP packet forwarding is occurring across a HiperSockets eligible route (QDIO/HiperSockets or HiperSockets/QDIO), and dynamically creates a HiperSockets Accelerator route entry. All subsequent packets will then take the optimized device driver path, and will not traverse the TCP/IP stack.

The dynamically created HiperSockets Accelerator routing entries can be displayed by the Netstat ROUTE/-r report option with the IQDIO modifier. VTAM tuning statistics are provided to allow the user to monitor or measure prerouting activity.

QDIOPriority (IQDIORouting option) is an optional choice that allows the user to specify which of the four priority queues should be used when prerouting packets from a HiperSockets link outbound to a QDIO link. The default is 1 (highest priority), and in most cases should be sufficient.

For additional details regarding the IQDIORouting configuration option, see the IPCONFIG statement in *z/OS Communications Server: IP Configuration Reference*.

Tips:

- If packet trace is enabled, then packets that are accelerated by HiperSockets Accelerator do not appear in the packet trace (either inbound or outbound). If you want function similar to that of the packet trace in conjunction with HiperSockets Accelerator, you can use the OSA-Express network traffic analyzer (OSAENTA) to trace these packets that are accelerated to or from OSA-Express QDIO. For more details on OSAENTA, see "OSA-Express network traffic analyzer trace" on page 92.
- QDIO Accelerator provides all of the function supported by HiperSockets Accelerator, and provides accelerated forwarding for other combinations of traffic involving QDIO devices, including sysplex distributor. For more information, see "QDIO Accelerator" on page 91.

HiperSockets multiple write

The HiperSockets multiple write facility moves multiple output data buffers in a single write operation. This facility might reduce CPU usage, and might provide a performance improvement for large outbound messages that are typically generated by traditional streaming workloads such as file transfer, and interactive web-based services workloads such as XML or SOAP.

To enable the HiperSockets multiple write facility on all HiperSockets interfaces, including interfaces created for dynamic XCF, add the IQDMULTIWRITE parameter to the GLOBALCONFIG statement. For more information about the GLOBALCONFIG statement and the HiperSockets multiple write facility, see *z/OS Communications Server: IP Configuration Reference*.

Restriction: HiperSockets multiple write is effective only on an IBM System z10 and when z/OS is not running as a guest in a z/VM environment.

HiperSockets multiple write assist with IBM zIIP

When your system is an IBM System z10 and the HiperSockets multiple write facility is enabled, an additional assist for large outbound TCP messages is available through the IBM System z10 Integrated Information Processor and IBM System z9 Integrated Information Processor (zIIP). To enable HiperSockets write processing for large outbound TCP messages on available zIIPs, specify the ZIIP IQDIOMULTIWRITE parameter on the GLOBALCONFIG statement.

When your system is an IBM System z10 that does not have zIIPs configured, you can use the zIIP HiperSockets multiple write facility to project the percentage of existing HiperSockets workload currently running on central processors that would be eligible to run on zIIPs, if zIIPs were available on the z/OS image. To perform such projection analysis, specify the following on the GLOBALCONFIG statement:

- IQDMULTIWRITE parameter
- ZIIP parameter with the value IQDIOMULTIWRITE

In addition, you must also specify PROJECTCPU= YES in the IEAOPT*xx* member of SYS1.PARMLIB. Then run your HiperSockets workload, and SMF provides accounting information regarding zIIP-eligible workload.

Guideline: Remove GLOBALCONFIG ZIIP IQDIOMULTIWRITE from your TCP/IP profile after you have completed your zIIP performance projection runs.

TCP/IP consumes slightly more central processing resources when no zIIPs are online and you have coded GLOBALCONFIG ZIIP IQDIOMULTIWRITE.

For information about configuring the PROJECTCPU parameter in the IEAOPT*xx* member of SYS1.PARMLIB, see *z/OS MVS Initialization and Tuning Reference*. For information about accounting for zIIP eligibility in SMF record types 30 and 7*x*, see *z/OS MVS System Management Facilities (SMF)*. For information about zIIP-related reporting updates, see *z/OS RMF Report Analysis*.

QDIO Accelerator

The QDIO Accelerator function extends the HiperSockets Accelerator function. HiperSockets Accelerator provides accelerated forwarding at the DLC layer for the following types of packets:

- Inbound packets over HiperSockets that are forwarded outbound over OSA-Express QDIO
- Inbound packets over OSA-Express QDIO that are forwarded outbound over HiperSockets

For more information about HiperSockets Accelerator, see "Efficient routing using HiperSockets Accelerator" on page 88.

QDIO Accelerator provides all of the function supported by HiperSockets Accelerator, and also provides accelerated forwarding at the DLC layer for the following types of packets:

- Inbound packets over OSA-Express QDIO that are forwarded outbound over OSA-Express QDIO
- Inbound packets over HiperSockets that are forwarded outbound over HiperSockets
- Sysplex distributor packets that are forwarded to a target stack or that are forwarded to or from a DataPower appliance, when the route involves any of the following inbound and outbound DLC combinations:
  - Inbound over HiperSockets, forwarded outbound over OSA-Express QDIO
  - Inbound over OSA-Express QDIO, forwarded outbound over HiperSockets
  - Inbound over OSA-Express QDIO, forwarded outbound over OSA-Express QDIO
  - Inbound over HiperSockets, forwarded outbound over HiperSockets

  For more information about sysplex distribution with a DataPower appliance, see "Sysplex distribution with DataPower" on page 491.

QDIO Acceleration is supported with or without the VIPAROUTE statement. When QDIO Accelerator is active, the stack dynamically creates QDIO Accelerator routes as it forwards packets in any of the inbound and outbound DLC combinations previously described. The DLC layer can perform accelerated routing for packets across these routes, bypassing the IP forwarding function in the stack. Similarly, the stack dynamically creates QDIO Accelerator routes for packets that would be forwarded by the sysplex distributor in any of the inbound and outbound DLC combinations. The DLC layer can perform accelerated sysplex distributor routing for such packets.

To configure QDIO Accelerator, specify the QDIOACCELERATOR parameter on the IPCONFIG statement. For more information about the IPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

You can display the QDIO Accelerator routing entries that are dynamically created for non-sysplex distributor packets using the Netstat ROUTE/-r report option with the QDIOACCEL modifier. For more information about the Netstat ROUTE/-r report, see *z/OS Communications Server: IP System Administrator's Commands*.

You can use the Netstat VCRT/-V report with the DETAIL modifier to display whether a sysplex distributor connection is eligible for acceleration. For more information about the Netstat VCRT/-V report, see *z/OS Communications Server: IP System Administrator's Commands*.

You can also use VTAM tuning statistics to monitor and measure the accelerated packets. For more information about gathering tuning statistics, see *z/OS Communications Server: SNA Network Implementation Guide*.

Restrictions:

- QDIO Accelerator is supported for IPv4 only.
- You cannot enable QDIO Accelerator support if you enable IP security on the stack.
- If IP forwarding is disabled on the stack, then QDIO Accelerator applies only to packets that are forwarded by the sysplex distributor.
- Packets from the sysplex distributor to the target are not accelerated with the VIPAROUTE destination when the outbound interface is HiperSockets.

Tip: If packet trace is enabled, then packets that are accelerated by QDIO Accelerator do not appear in the packet trace (either inbound or outbound). If you want function similar to that of the packet trace in conjunction with QDIO Accelerator, you can use the OSA-Express network traffic analyzer (OSAENTA) to trace these packets that are accelerated to or from OSA-Express QDIO. For more details on OSAENTA, see "OSA-Express network traffic analyzer trace."

OSA-Express network traffic analyzer trace

When data problems occur in a network with OSA adapters, multiple traces are usually required. A sniffer trace might be required to see the data as it was received from or sent to the network, an OSA hardware trace might be required if the problem is suspected in the OSA, and z/OS Communications Server traces are required to diagnose VTAM or TCP/IP problems.

To assist in problem diagnosis, the OSA-Express network traffic analyzer (OSAENTA) function provides a way to trace inbound and outbound frames for an OSA-Express2 feature in QDIO mode. The OSAENTA trace function is controlled and formatted by z/OS Communications Server, but is collected in the OSA at the network port. You can control the OSAENTA trace function using either the OSAENTA statement in the TCP/IP profile or the VARY TCPIP,,OSAENTA command. The controls provided include the ability to filter what data is collected by parameters such as IP address, TCP/UDP port, or frame type, and to specify how much data is to be collected. They also provide the capability to trace frames discarded by the OSA-Express2 feature. You can display current settings for the OSAENTA trace function using the Netstat DEvlinks/-d command.

Because the data is collected at the Ethernet frame level, this function enables you to trace the MAC headers for packets, a capability not provided by existing packet traces. It also enables the tracing of other types of packets that existing packet traces do not contain, including the following:

- ARP packets

- Packets to and from other users sharing the OSA, including other TCP/IP stacks, z/Linux users, and z/VM users
- SNA packets

There are obvious security considerations for this type of trace. Security control is enabled at the Hardware Management Console (HMC) of the OSA-Express2 feature. To trace packets for stacks or images other than the operating system image where you activate the OSAENTA trace interface, you must use the HMC to configure the OSA to enable this.

The OSAENTA trace function communicates with the OSA-Express feature being traced by using a dynamically defined QDIO interface to the OSA-Express feature. The interface is created when the first VARY TCPIP,,OSAENTA command for that OSA is entered, or the first OSAENTA TCP/IP profile statement is processed. The interface is named EZANTA*xxxxxxxx*, where *xxxxxxxx* is the port name of the OSA specified on the VARY TCPIP,,OSAENTA command, and must match the PORTNAME parameter on the VTAM TRLE representing the traced OSA-Express feature. This also means that a TRLE must be defined in VTAM for this OSA-Express trace interface, though the same TRLE used for MPCIPA devices and interfaces is used for this dynamically defined trace interface. The EZANTA*xxxxxxxx* interface is used exclusively for receiving trace records from that OSA-Express feature. It is started, stopped, and deleted with the ON, OFF, and DEL parameters of the VARY TCPIP,,OSAENTA command.

When the OSAENTA trace is enabled, the received trace records are collected by Component Trace (CTRACE) using the SYSTCPOT component. The traced records can then be formatted using the IPCS CTRACE command, specifying the component name SYSTCPOT. For information about retrieving the OSA-Express network traffic analyzer data in real time, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

The OSAENTA trace can have a negative impact on performance if sufficient trace filters are not specified before you enable the trace. OSAENTA can reduce the amount of traffic that the OSA-Express feature can process and the amount of traffic that can be accelerated through that OSA-Express feature. Also, host processing to collect the OSAENTA trace records can increase host CPU consumption. Specify sufficient filters to limit the amount of traffic that is traced to only what is necessary for problem diagnosis.

For more information about the OSAENTA statement, see *z/OS Communications Server: IP Configuration Reference*. For more information about the VARY TCPIP,,OSAENTA command, see *z/OS Communications Server: IP System Administrator's Commands*. For more information about formatting an OSAENTA trace, see *z/OS Communications Server: IP Diagnosis Guide*. For the level of OSA-Express2 feature that supports OSAENTA, see the 2094DEVICE Preventive Service Planning (PSP) bucket and the 2096DEVICE Preventive Service Planning (PSP) bucket.

Synchronization of OSA-Express2 diagnostic data

VTAM provides the externals that control the QDIOSYNC trace facility, used to synchronize OSA-Express2 diagnostic data with host diagnostic data. For information on the use of the QDIOSYNC trace facility, see *z/OS Communications Server: SNA Diagnosis Vol 1, Techniques and Procedures*.

Prioritizing outbound OSA-Express data using the Workload Manager service class

The z/OS Workload Manager (WLM) provides a priority associated with each unit of work that runs a TCP/IP socket API to send data. The priority provided by WLM is related to the WLM service class associated with the unit of work. The unit of work can derive its priority from the service class associated with the address space in which it is running or from the service class associated with the enclave to which it belongs. The priorities provided by WLM, from highest priority to lowest priority, are as follows:

- System-defined service class (SYSTEM), used for system address spaces
- System-defined service class (SYSSTC), used for high-priority started tasks
- User-defined service classes with importance level 1
- User-defined service classes with importance level 2
- User-defined service classes with importance level 3
- User-defined service classes with importance level 4
- User-defined service classes with importance level 5
- User-defined service classes associated with a discretionary goal

For more information about WLM and the WLM service classes, see *z/OS MVS Planning: Workload Management* and *z/OS MVS Programming: Workload Management Services*.

z/OS Communications Server supports four priority values for outbound QDIO traffic, 1 through 4, with 1 being the highest priority. Priorities with lower numbers are given preferential treatment by the QDIO device driver and the OSA-Express feature.

You can specify the QDIO priority value to be used on the SetSubnetPrioTosMask statement in a Quality of Service (QoS) policy, which provides one way to influence the QDIO traffic priority that is used for outbound packets. The SetSubnetPrioTosMask statement maps the IPv4 type of service (ToS) byte or IPv6 traffic class to these four QDIO traffic priorities. For more information about the SetSubnetPrioTosMask statement, see *z/OS Communications Server: IP Configuration Reference*.

Another way to influence the QDIO traffic priority is to use the WLMPRIORITYQ parameter on the GLOBALCONFIG profile statement. The WLMPRIORITYQ parameter automatically extends the preferential treatment of the most important workloads for a business through the QDIO device driver all the way to the LAN. When the WLMPRIORITYQ parameter is specified and a packet with a ToS or traffic class value 0 is sent over an OSA-Express feature in QDIO mode, Communications Server sets the OSA-Express write priority of the packet based on the priority value provided by the WLM service class. In addition, the WLMPRIORITYQ parameter can be used to influence the QDIO traffic priority of forwarded packets with a ToS or traffic class value 0.

For more information about the GLOBALCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

Restrictions:

- Prioritization using the WLM service class is effective only when enabled and when the ToS or traffic class value is 0.

- Prioritization using the WLM service class is ineffective for interfaces other than OSA-Express features in QDIO mode.
- Prioritization of forwarded packets is ineffective unless DATAGRAMFWD is specified on the IPCONFIG statement, the IPCONFIG6 statement, or both statements.
- The WLMPRIORITYQ setting for forwarded packets has no effect on accelerated packets. To set the write priority for accelerated packets, use QDIOPRIORITY on the IQDIOROUTING parameter or the QDIOACCELERATOR parameter on the IPCONFIG profile statement. For more information about the IPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces

Each OSA-Express QDIO and HiperSockets interface requires fixed storage for read processing (which is allocated by VTAM). If you define a large number of these interfaces (for example, by configuring multiple VLANs to one or more OSA-Express features), then you need to consider how much fixed storage your configuration requires.

For information about how much fixed storage VTAM allocates by default for each OSA-Express QDIO and HiperSockets interface, how to control the amount of this storage allocation using the VTAM QDIOSTG start option (for OSA-Express QDIO) and the VTAM IQDIOSTG start option (for HiperSockets), and considerations for the IVTPRM00 parmlib member, see *z/OS Communications Server: SNA Resource Definition Reference*.

You can also override the global QDIOSTG or IQDIOSTG value and control the amount of fixed storage for a specific OSA-Express QDIO or HiperSockets interface by using the READSTORAGE parameter on the LINK and INTERFACE statements.

Maximum transmission unit considerations

TCP/IP uses the maximum transmission unit (MTU) value to determine the largest sized frame to send. The MTU value that is in effect for a given outbound send is one of the following two values:

- Path MTU value

  TCP/IP automatically enables path MTU discovery for IPv6. If a packet is an IPv6 packet, or if a packet is an IPv4 packet and path MTU discovery is enabled, the path MTU value is used to determine the maximum size of the packet. Path MTU discovery initially sets the path MTU value to the actual route MTU value for the route. If packets require fragmentation to get to the final destination, path MTU discovery determines the path MTU value by repeatedly decreasing the value until it can send packets to the final destination without fragmentation.

  Guideline: You can enable path MTU discovery for IPv4 by configuring IPCONFIG PATHMTUDISCOVERY in the TCP/IP profile.
- Actual route MTU value

  The actual route MTU value is the lesser of the interface MTU value and the configured route MTU value. If path MTU discovery is not enabled, the actual route MTU value is used.

  – Interface MTU value

    The interface MTU value is a characteristic of an interface, and is either learned from the device during activation or is hardcoded based on the type

of the physical device. For information about the interface MTU values that TCP/IP uses for the various network interface types supported by TCP/IP, see the summary of DEVICE and LINK statements and the summary of INTERFACE statements in *z/OS Communications Server: IP Configuration Reference*. For an IPAQENET6 interface, or an IPAQENET interface defined with the INTERFACE statement, you can configure a lower interface MTU value using the MTU keyword on the INTERFACE statement.

Restriction: You cannot modify the interface MTU value for IPAQENET interfaces defined using the DEVICE, LINK, and HOME statements.

Results:

- The TCP/IP stack sets the interface MTU value to the lesser of the learned MTU value and the MTU value configured on the INTERFACE statement.
- For an active link or interface, TCP/IP reports the interface MTU value in the ActMtu field of the Netstat DEVLINKS/**-d** report.

– Configured route MTU value

The configured route MTU value is the MTU size that is configured for a route.

- Static route

  For a static route, you can specify the configured route MTU value in the TCP/IP profile on a ROUTE entry in a BEGINROUTES block or on a GATEWAY statement.

- IPv4 dynamic route

  For IPv4 dynamic routes over an interface that are added by OMPROUTE, the configured route MTU value is the value of the MTU keyword specified on the RIP_INTERFACE, OSPF_INTERFACE or INTERFACE statement in the OMPROUTE configuration file for the outgoing interface of the route.

  Result: If you do not specify an MTU value for an interface in the OMPROUTE configuration file, OMPROUTE uses the value 576.

- IPv6 dynamic route

  For IPv6 dynamic routes added by OMPROUTE, OMPROUTE learns the interface MTU value from TCP/IP; you cannot configure a route MTU value in the OMPROUTE configuration file.

  Result: For IPv6 dynamic routes that are learned by OMPROUTE, the configured route MTU size is the same as the interface MTU size.

These factors comprise a general set of rules for how TCP/IP determines the MTU, but there are some exceptions. For example, if an application uses the IPV6_USE_MIN_MTU socket option, TCP/IP sends outbound packets using the IPv6 minimum MTU value 1280.

Guidelines:

- Enable path MTU discovery in configurations where traffic originating in the z/OS TCP/IP stack will traverse multiple hops with different MTU sizes.
- When you are using OSA-Express Gigabit Ethernet (which supports the interface MTU value 8992), be aware that not all routers and switches support a value this large. If all routers and switches in your configuration do not support the value 8992, specify a lower configured route MTU value or specify a lower MTU value on the INTERFACE statement in the TCP/IP profile.
- When you are using OMPROUTE, specify the MTU keyword for each IPv4 interface.

- When you are using OMPROUTE, configure all nodes on a LAN to use the same MTU value. Otherwise, you might encounter problems, such as OSPF adjacency errors.

Considerations for multiple servers sharing a TCP port

For a TCP server application to support a large number of client connections on a single system while providing good performance for those connections, it might be necessary to run more than one instance of the server application to service the connection requests. For all instances of the server application to receive client connection requests without changing the client applications, the servers must all bind to the same server IP address and port. To enable this in the TCP/IP stack, you must add the SHAREPORT or SHAREPORTWLM keyword to the PORT profile statement that reserves the TCP port for the server instances. For more detailed information on the PORT statement and its keywords, see *z/OS Communications Server: IP Configuration Reference*.

The set of server instances sharing the same TCP port on the same TCP/IP stack is called a shareport group. As incoming client connections arrive for this port and IP address, TCP/IP distributes them across the servers in the shareport group.

If the SHAREPORT keyword was specified, the connections are distributed across the available servers using a weighted round-robin distribution based on the Servers' accept Efficiency Fractions (SEFs).

If the SHAREPORTWLM keyword was specified, the connections are distributed across the available servers using a weighted round-robin distribution based on the WLM server-specific recommendations, modified by the SEFs.

The SEF is a measure, calculated at intervals of approximately 1 minute, of the efficiency of the server application in accepting new connection requests and managing its backlog queue. You can use the Netstat ALL/-A command to obtain the current SEF value for a server. For more detailed information about the Netstat command, see *z/OS Communications Server: IP System Administrator's Commands*.

Configuring a shareport group can also be used to improve the availability of key applications. For example, should an application server instance become inactive (encounters a failure or is stopped for planned maintenance), the other applications in the shareport group can continue to process client requests.

Applications that might be good candidates for being placed in a shareport group must also satisfy the following requirements:

- Multiple instances of the application can be started within a single system.
- Each application instance must provide the same functional capabilities. That is, each must be capable of processing any TCP connection requests to the shared port.

In addition, each TCP connection directed to a shareport group must be eligible for load balancing (it cannot have an affinity to a specific server). If specific client affinities exist to a specific server, you should consider using sysplex distributor, which provides for load balancing of connections while maintaining client affinities to a specific server instance over a period of time (Timed Affinity). While the primary focus of the sysplex distributor is on load balancing across servers on multiple target systems, it also supports multiple servers in a shareport group on

the target systems. For more information on sysplex distributor configuration, see Chapter 8, "TCP/IP in a sysplex," on page 429.

Considerations for Common Information Model providers

The Common Information Model (CIM) provides a model for describing and accessing data across an enterprise. CIM is a standard developed by a consortium of independent hardware and software vendors, including IBM, called the Distributed Management Task Force (DMTF). CIM data is defined by standardized CIM classes. Class definitions define properties for each class. For example, some properties of the CIM_EthernetPort (Ethernet interface) class are interface type, enabled state, and speed. Platforms can extend the standardized CIM classes by defining their own platform-specific classes and their properties.

CIM data instrumentation is supplied by CIM components called providers. The providers gather data on a system in support of the CIM classes. Clients can retrieve the data through the Common Information Model Object Manager. On z/OS, this function is provided by the z/OS CIM server.

Communications Server supplies CIM providers for the CIM classes shown in Table 7. Only IPv4 data is currently supported. To support data from eight TCP/IP stacks on an MVS image, the TCP/IP stack name has been added to the IBMzOS_EthernetPort and IBMzOS_IPProtocolEndpoint classes as a platform-specific property.

For more information about CIM, the z/OS CIM server, the properties support for the Communications Server CIM classes, and other z/OS CIM provider support, see *z/OS Common Information Model User's Guide*.

Table 7. Communications Server CIM providers

CIM base class name	z/OS class name	Description
CIM_EthernetPort	IBMzOS_EthernetPort	IPv4 Ethernet interfaces defined to the TCP/IP stack
CIM_IPProtocolEndpoint	IBMzOS_IPProtocolEndpoint	IPv4 IP addresses defined to the TCP/IP stack
CIM_PortImplementsEndpoint	IBMzOS_NetworkPortImplementsIPEndpoint	IPv4 Ethernet interfaces and their associated IP addresses
CIM_SystemDevice	IBMzOS_CSNetworkPort	MVS system and its associated IPv4 Ethernet interfaces

This CIM provider function resides in the /usr/lpp/tcpip/lib directory. There is no configuration necessary to activate this CIM provider support. The z/OS CIM server must be configured and activated for the data supported by the Communications Server CIM providers to be available to clients. The z/OS Communications Server CIM classes are shipped with the z/OS CIM server. The files that define these classes and any platform specific properties are also installed in the /usr/lpp/tcpip/mof directory.

There are security configuration considerations that govern the ability of providers to gather CIM data. For more information about security configuration, see "CIM provider access control" on page 128.

Required steps before starting TCP/IP

This information describes the steps you must complete before starting TCP/IP.

Planning your installation and migration

It will be to your advantage to have thoroughly studied the following documentation prior to the installation and customization of z/OS Communications Server:

- Program Directory for z/OS for CBPDO Installation and ServerPac Reference, Program Number 5694-A01
- Preventive Service Planning (PSP) bucket
- *z/OS Communications Server: New Function Summary*
- *z/OS UNIX System Services Planning*
- OS390CKL, IBM MKTTOOLS information for the z/OS UNIX System Services implementer

It is also recommended that you attend a z/OS UNIX System Services concepts class and a class in using z/OS UNIX System Services prior to migrating to z/OS Communications Server. If this is not possible, then you will want to ensure that the z/OS UNIX System Services implementer and the RACF administrator work together with you during the installation and customization process.

Planning for and installing z/OS Communications Server requires MVS, UNIX, and networking skill. If your background is in traditional MVS programming or system programming, the z/OS UNIX System Services terminology might at first seem to be somewhat confusing. If your background is in the UNIX environment, the terms should be familiar to you.

In the past, MVS TCP/IP system programmers have needed a working knowledge of the MVS or z/OS system. These programmers have been accustomed to working closely with the RACF administrator and z/OS system programmer for authorizations; the VTAM and NCP system programmers for SNALINK and NCP connections; the IP address administrator for basic name and address assignments; and the administrators of the router network and channel-attached peripherals for connection definition and problem determination.

With the introduction of z/OS Communications Server, the TCP/IP system programmer needs to develop an additional alliance with the z/OS UNIX System Services system programmer. The TSO interfaces that have been traditionally available in the host-based TCP/IP still stand at the system programmer's disposal and additional MVS console commands simplify some TCP/IP operations. However, another user interface provided by the UNIX shell environment, either with the z/OS shell or the ISPF SHELL, is a useful and sometimes necessary tool that the TCP/IP system programmer will need to work with. Additionally, the tight coupling of z/OS Communications Server with z/OS UNIX System Services means that the TCP/IP system programmer needs more than a passing knowledge of UNIX conventions, commands, and hierarchical file system concepts. Even if the system programmer is familiar with other UNIX environments, work with the UNIX shell requires more than basic familiarity.

In the first version of a full TCP/IP stack based on native MVS and on z/OS UNIX System Services, few have all the requisite skills to successfully implement z/OS Communications Server on their own. As more and more system programmers acquire skills in UNIX System Services and in TCP/IP, this will become less and

less the case. Working with the z/OS UNIX System Services implementer when implementing z/OS Communications Server provides the most effective solution to establishing a working z/OS Communications Server environment.

If you are migrating to z/OS Communications Server, establish a migration process to move all your existing applications, and after this, consider the use of new and enhanced functions based on *z/OS Communications Server: New Function Summary*. z/OS Communications Server allows multiple copies of the TCP/IP protocol stack to execute on the same MVS image. However, with all the performance enhancements introduced in z/OS Communications Server, it is probably not necessary to implement a multi-stack system for production purposes unless one is considering building a system programming test stack.

You are now ready to move on to the following steps.

Step 1: Install z/OS Communications Server

Before you begin the installation:

- To help you plan the installation and migration of z/OS Communications Server, see the following:
  - *z/OS Planning for Installation*
  - *z/OS Communications Server: New Function Summary*
  - *z/OS Migration*
- Be sure you understand the data set naming conventions used in TCP/IP. You can find this information in "Configuration data set naming conventions" on page 19.
- Consult the *z/OS Program Directory* (Customization considerations for Wave 1D) for current information about the material, procedures, and storage estimates of the MVS image.

Install z/OS Communications Server with other elements of z/OS. If you use the ServerPac method of installation, see *z/OS Installing Your Order*; if you use the CBPDO method of installation, see *z/OS Program Directory*. When appropriate, that information will direct you back to this information to customize the TCP/IP data sets and procedures and verify their configuration.

Verifying the initial installation

Both the *z/OS Program Directory* and *z/OS Installing Your Order* contain step-by-step instructions that can be used to set up and verify a basic TCP/IP configuration with only the loopback address and a few key servers. For more information regarding these instructions, see the information about Wave 1D customizations in the *z/OS Program Directory* or the information about verifying your installation in *z/OS Installing Your Order*.

Step 2: Customize z/OS Communications Server

To customize TCP/IP you need to update the cataloged procedures and configuration data sets for the TCP/IP address space, its clients, and servers.

z/OS Communications Server runs as a started task in its own address space. Each of the servers runs in its own address space and is started with its own procedure. The TCP/IP address space requires:

- A procedure in a system or recognized PROCLIB.

- A data set that provides configuration definitions for the TCP/IP address space and includes statements affecting many of the servers. This data set is referred to as PROFILE.TCPIP.
- A data set to provide the parameters that are common across all clients. This data set is referred to as TCPIP.DATA.

Many of the servers also require other data sets for their specific functions.

Making SYS1.PARMLIB changes

You need to make certain changes to SYS1.PARMLIB. These changes depend on which of the following installation methods you use:

ServerPac method
After the file system is restored (through the RESTFS job), you will see that ServerPac has changed some of the parmlib members. Follow the instructions to change the BPXPRMxx member of parmlib.

CBPDO method
Change the parmlib members according to the instructions listed in the installation instructions for Wave 1. Tables describing changes to parmlib and changes to the BPXPRMxx member are included.

Note: z/OS Communications Server exploits z/OS UNIX services even for traditional MVS environments and applications. Before using TCP/IP services, the z/OS UNIX environment must be set up in full function mode. For a list of tasks involved in setting up for full function mode, see *z/OS UNIX System Services Planning*. System Managed Storage (SMS, which is part of the DFSMSdfp element of z/OS) must be configured, and you will need to customize SMS, RACF, and the z/OS UNIX file system.

Additional information about required TCP/IP definitions for the UNIX environment can be found in "Defining TCP/IP as a UNIX System Services physical file system" on page 45 and "UNIX System Services security considerations" on page 41.

Common z/OS UNIX configuration problems: Following are some explanations and possible solutions for common problems that you may encounter when configuring the z/OS UNIX environment.

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIP-BPX1SOC,
     00000003,FFFFFFFF,00000070,112B00B6
```

  These messages usually indicate that both INET and CINET FILESYSTYPE have been specified. Only one should be specified; see the FILESYSTYPE information in *z/OS UNIX System Services Planning* for additional information.
- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIP-BPX1SOC,
     00000003,FFFFFFFF,0000006F,112B00B0
```

  These messages indicate that the requester of the service is not privileged. The service requested requires a privileged user. Check the documentation for the service to understand what privilege is required.
- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR
     FOR TCPIPA-BPX1IOC,8008C981,FFFFFFFF,0000009E,12B2005A

EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED
```

These messages usually indicate that an incorrect jobname was specified in the SUBFILESYSTYPE NAME() definition in the BPXPRM*xx* member for a common INET environment. In this scenario, the NAME() must match TCPIPA.

- TCP/IP initialization fails with the following messages:

```
IEA8481 DUMP SUPPRESSED - ABDUMP MAY NOT DUMP STORAG FOR KEY 0-7 JOB TCPV34A
IEF4501 TCPIPA TCPIPA - ABEND=SEC6 U0000 REASON=0F01C008
```

These messages are usually an indicator that an OMVS RACF segment has not been defined for the user ID associated with the TCP/IP started procedure. Define an OMVS segment with a UID of 0 for the user ID associated with the TCP/IP started procedure.

- TCP/IP initialization fails with the following messages:

```
IEF4031 TCPIPA - STARTED - TIME=16.01.25
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIPA-BPX11OC,
     8008139A,FFFFFFFF,00000079,12D2025E
EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED.

==> The 0079 value is EINVAL - The parameter is incorrect
==> The 025E value is JRSocketCallParmError - A socket syscall
    contains incorrect parameters
```

These messages usually indicate that an incorrect entry point name has been specified in the SUBFILESYSTYPE ENTRYPOINT() definition. The correct value is ENTRYPOINT(EZBPFINI).

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIPA-BPX1SOC,
     00000003,FFFFFFFF,0000045A,112B0000
EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED.

==> The 045A value is EAFNOSUPPORT - The address family is not supported
```

These messages indicate that AF_INET was not defined or did not initialize properly. Check for any earlier z/OS UNIX messages and verify that the z/OS UNIX NETWORK DOMAINNAME(AF_INET) statement is in your BPXPRM*xx* member.

- After issuing a NETSTAT command from TSO, the following message is displayed:

```
netstat
CEE5101C During initialization, the z/OS UNIX callable service
     BPX1MSS failed. The system return code was 0000000156,
     the reason code was 0507014D. The application will be
     terminated.
NETSTAT ENDED DUE TO ERROR+
READY
?
USER ABEND CODE 4093 REASON CODE 00000090
READY

==> The 0156 value is EMVSINITIAL - Process initialization error
==> The 014D value is JRFsFailChdir - The dub failed, due to
    an error with the initial home directory
```

These messages indicate that the user ID issuing the NETSTAT command does not have an OMVS RACF segment defined for it. Define an OMVS segment for

this user ID or activate the default OMVS segment support. For details, see "UNIX System Services security considerations" on page 41.

- Socket applications using the z/OS Communications Server TCP/IP Services APIs fail with an ERRNO of 156.

  ERRNO 156 indicates a z/OS UNIX process initialization failure. This is usually an indication that a proper OMVS RACF segment is not defined for the user ID associated with the application. The RACF OMVS segment may not be defined or may contain errors such as an improper HOME() directory specification. If the OMVS segment is not defined, you may also receive the following message:

  ```
  ICH4081 USER(USER8   ) GROUP(SYS1   )   NAME(TSO USERID USER8  )
     CL(PROCESS )
     OMVS SEGMENT NOT DEFINED
  ```

  In this example, USER8 is the user ID associated with the failing application. To correct this problem, define a proper OMVS segment for the user ID associated with the failing application. For details, see "UNIX System Services security considerations" on page 41.

Completion of these steps ensures that the applications and resources on the target system will function correctly at the new level.

Other topics show you how to:

- Configure the TCP/IP address space by updating the samples provided in SEZAINST(SAMPPROF) and SEZAINST(TCPIPROC).
- Configure the universal client parameters provided in SEZAINST(TCPDATA).
- Configure the site table, defined in *hlq*.HOSTS.LOCAL or *hlq*.ETC.IPNODES, to identify the Internet names and addresses of your TCP/IP host.
- Customize the TCP/IP Component Trace parameters by updating the CTRACE parameter in the PARM= field of the EXEC JCL statement in the TCP/IP started procedure.

  You can find a description of the MVS Component Trace support in the *z/OS Communications Server: IP Diagnosis Guide*.
- Specify the ENVAR parameter on the PARM=keyword to override the resolver file. For more information on setting the environment variable RESOLVER_CONFIG using the ENVAR parameter, see "Considerations for multiple instances of TCP/IP" on page 50.
- Configure each of the servers you want to run. This might require:
  - Modifying sample procedures and adding them in your PROCLIB
  - Modifying the configuration data set, PROFILE.TCPIP
  - Adding port numbers to *hlq*.ETC.SERVICES
  - Modifying other data sets containing server-specific parameters

You can find the sample procedures and data sets in SEZAINST. Table 1 on page 21 provides additional reference information you can use as you configure and customize each server.

You can find general information about starting, stopping, and dynamically controlling the servers in *z/OS Communications Server: IP System Administrator's Commands*.

Step 3: Configure VMCF and TNF

The Pascal socket interface uses the IUCV/VMCF services for a limited set of inter-address space communication flows. As a result, if you are using any

applications (provided by IBM or others) that use the Pascal socket API, you must ensure that the Virtual Machine Communication Facility (VMCF) and Termination Notification Facility (TNF) subsystems are active before the applications are started. TCP/IP provides the following applications and commands that use the Pascal socket interface:

- SMTP and LPD servers
- TSO HOMETEST, LPQ, LPR, LPRM, LPRSET, TELNET, and TESTSITE commands

If you are using any of these applications or commands, you need to set up VMCF and TNF.

You can configure VMCF and TNF in two different ways: as restartable subsystems or as non-restartable subsystems.

If you configure VMCF and TNF as restartable subsystems and you want the VMCF node name to be used as a default host name during TCP/IP initialization (in cases where no other host name can be located), VMCF must be started before TCP/IP.

Tip: Host name is the value normally specified on the TCPIP.DATA HOSTNAME statement.

Guideline: The VMCF node name is used as a system-name qualifier when processing the TCPIP.DATA file and it is used by the SMTP server as the NJE node name. For this reason, you should use the MVS system name for the VMCF node name specification and specify the NJE node name explicitly by using the NJENODENAME statement in the SMTP configuration data set.

Restartable subsystems

Configuring VMCF and TNF as restartable subsystems has the following advantages:

- Error detection is provided when the subsystems do not seem to be initializing properly.
- You can change the system name on the restart.
- Commands are available to remove users from internal tables, display current users and to terminate the subsystem.

In summary, a restartable VMCF and TNF configuration provides better availability and is therefore recommended.

If you choose to use restartable VMCF and TNF, follow these steps:

1. Update your IEFSSN*xx* member in SYS1.PARMLIB with the TNF and VMCF subsystem statements required by TCP/IP. The specification can be in either the IBM recommended keyword parameter form or the positional parameter form of IEFSSNxx. For example:

```
* The keyword parameter form is:

SUBSYS SUBNAME(TNF)
SUBSYS SUBNAME(VMCF)

* The positional parameter form is:
TNF
VMCF
```

2. Add procedure EZAZSSI to your system PROCLIB. A sample of this procedure is located in the SEZAINST library.

```
//EZAZSSI PROC P=&SYSNAME.
//STARTVT EXEC PGM=EZAZSSI,PARM=&P,TIME=1440
```

3. Start VMCF and TNF using the procedure EZAZSSI before starting TCP/IP. If your node name is the same as the MVS system symbolic &SYSNAME, then you can start VMCF and TNF with the following command:

   ```
   S EZAZSSI
   ```

   If your node name is different than the MVS system symbolic &SYSNAME, start VMCF and TNF with the following command:

   ```
   S EZAZSSI,P=nodename
   ```

   Replace *nodename* with the system name of your MVS system. If you use SMTP, verify that the SMTP NJE node name is specified by using the NJENODENAME statement in the SMTP configuration data set.

Non-restartable subsystems

If you will not be using restartable VMCF and TNF, you should update your IEFSSN*xx* member in SYS1.PARMLIB with the following subsystem statements required by TCP/IP. The specification can be in either the IBM suggested keyword parameter form or the positional parameter form of IEFSSN*xx*.

Restriction: If you are using the keyword parameter form and your IEFSSN*xx* member contains the BEGINPARALLEL statement, the TNF and VMCF statements must precede the BEGINPARALLEL statement, so that TNF and VMCF are initialized serially instead of in parallel. VMCF requires that TNF is initialized first.

The keyword parameter form is:

```
SUBSYS SUBNAME(TNF) INITRTN(MVPTSSI)
SUBSYS SUBNAME(VMCF) INITRTN(MVPXSSI) INITPARM(nodename)
```

The positional parameter form is:

```
TNF,MVPTSSI
VMCF,MVPXSSI,nodename
```

Replace *nodename* on the VMCF line with the system name of your MVS system. If you use SMTP, verify that the SMTP NJE node name is specified by using the NJENODENAME statement in the SMTP configuration data set.

VMCF commands

If you will be using restartable VMCF, the following VMCF commands let you display the names of the current users of VMCF and TNF, and if necessary, remove names from the name lists.

Note: Removing names from the name lists and stopping either subsystem can have undesired results, if done hastily. Use the REMOVE and stop (P) commands carefully and only as a last resort.

If you remove a user, the application is not canceled, nor is the connection severed. In other words, the *removed* application may remain active in the system, and may subsequently abend 0D6/0D4/0C4, or cause TCP/IP to hang. A user that is removed from VMCF may still be a user of TNF and even TCP/IP, and vice versa.

To terminate users and stop VMCF or TNF properly, follow these steps:

1. Display the current users of the subsystems, using one of the following:

   ```
   F VMCF,DISPLAY,NAME=*
   F TNF,DISPLAY,NAME=*
   ```

2. Terminate those users. If termination fails, use the REMOVE command as a last resort to force them from the name list.
3. Stop the subsystem, using one of the following commands:

   ```
   P VMCF
   P TNF
   ```

   If the P command fails, use one of the following commands:

   ```
   FORCE ARM VMCF
   FORCE ARM TNF
   ```

Following are descriptions of the commands:

F TNF,DISPLAY,NAME=[name|*]
: Displays the named user [or all (*) users] of TNF, sorted by ASID.

F TNF,REMOVE,NAME=[name|*]
: Removes either the named user [or all (*) users] from the TNF internal tables.

P TNF Requests TNF to terminate.

F VMCF,DISPLAY,NAME=[name|*]
: Displays the named user [or all (*) users] of VMCF, sorted by name.

F VMCF,REMOVE,NAME=[name|*]
: Removes either the named user [or all (*) users] from the VMCF internal tables.

P VMCF
: Requests VMCF to terminate

Following are sample commands:

```
F TNF,DISPLAY,NAME=TCPV3
F VMCF,DISPLAY,NAME=*
F TNF,REMOVE,NAME=FTPSERV
F VMCF,REMOVE,NAME=*
P TNF
```

Common VMCF problems

Following are some common VMCF problems:

- VMCF or TNF fail to initialize with an 0C4 abend.

  This is probably an installation problem; check the program properties table (PPT) entries for errors. Some levels of MVS do not flag PPT syntax errors properly.
- Abends 0D5 and 0D6 after REMOVEing a user.

  This is probably because the application is still running and using VMCF. It is not recommended that users be removed from VMCF or TNF without first terminating the affected user.
- VMCF or TNF do not respond to commands.

  This is probably because one or both of the non-restartable versions of VMCF or TNF are still active. To get them to respond to commands, stop all VMCF/TNF users, FORCE ARM VMCF and TNF, then use EZAZSSI to restart.
- VMCF or TNF cannot be stopped.

  This is probably because users still exist in the VMCF and TNF lists. Use the *F VMCF,DISPLAY,NAME=** and *F TNF,DISPLAY,NAME=** commands to identify those users who are still active. Then either cancel those users or remove them from the lists using the *F VMCF,REMOVE* and *F TNF,REMOVE* commands.

- Address Space Identifiers (ASIDs) become nonreusable when VMCF and TNF address spaces are stopped or restarted.

  Because VMCF and TNF address spaces provide PC-entered services that must be accessible to all address spaces, they each obtain a system LX. This causes the ASIDs associated with these address spaces to be nonreusable when these address spaces are terminated. If VMCF and TNF are terminated enough times all available ASIDs could be exhausted, preventing the creation of new address spaces on the system. In this case, an IPL will be required. For more information on tuning parameters for the maximum number of ASIDs in a system, see the MAXUSER parameter in *z/OS MVS Initialization and Tuning Reference*.

IUCV/VMCF considerations

The IUCV/VMCF inter-address space communication API enables applications running in the same MVS image to communicate with each other without requiring the services of the TCP/IP protocol stack. The VMCF/TNF subsystems provide these services, which are still available in z/OS Communications Server. Several components of TCP/IP in z/OS Communications Server continue to make some use of these services for the purpose of inter-address space communications. These include:

- The AF_IUCV domain sockets for the TCP/IP C socket interface. The AF_IUCV domain enables applications executing in the same z/OS image and using the TCP/IP C socket interface to communicate with each other using a socket API, but without requiring the services of the TCP/IP protocol stack, as no network flows result in these communications. This is quite different from the more common AF_INET domain that enables socket communication over a TCP/IP network. AF_IUCV sockets continue to be supported in z/OS Communications Server.

  An example of a TCP/IP-provided application that exploits AF_IUCV sockets is the SNMP Query Engine component (SQESERVE). The z/OS UNIX socket library provides a similar functionality to the AF_IUCV domain sockets with its AF_UNIX domain. Users creating new applications should consider using AF_UNIX domain sockets.
- The Pascal socket interface also makes use of the IUCV/VMCF services for a limited set of inter-address space communication flows. As a result, any applications (provided by IBM or others) that use the Pascal socket API also still have a requirement for the VMCF/TNF subsystems. TCP/IP provides several applications and commands that use these interfaces, such as the SMTP and LPD servers, and the TSO TELNET, HOMETEST, TESTSITE, and LPR commands. IUCV/VMCF services require the usage of an address space name of SYSTEM. This means a TSO user cannot have the user ID name of SYSTEM.

Therefore, in z/OS Communications Server you must continue to configure and start the VMCF and TNF subsystems as you did in TCP/IP V3R2. However, because the VMCF/TNF subsystems are no longer used to communicate directly with the TCP/IP protocol stack in z/OS Communications Server, the amount of CPU they will consume will be significantly lower than in the TCP/IP V3R2 environment.

Step 4: Update the VTAM application definitions

You must update the VTAM definitions for the TN3270E Telnet server and any of the following applications that you configure on your system. You can find example VTAM definitions for each of these applications under their respective topics.

- SNALINK
- SNALINK LU6.2

- TN3270E Telnet
- X.25 NPSI Server

SEZAINST(VTAMLST) contains a sample of the VTAM definitions for TN3270E Telnet server applications. You should copy this member, update it, and add it to the ATCCON*xx* member of VTAMLST. This ensures that the TN3270E Telnet server applications are activated when VTAM is started.

Because the TCP/IP LU code cannot handle multiple concurrent sessions, you must code SESSLIM=YES for each TN3270E Telnet server LU defined to VTAM. Otherwise, if SESSLIM=NO, menu or session manager applications that use return session processing might cause session termination.

Step 5: Verify that the required address spaces are active

TCP/IP uses services from other address spaces in its processing. While TCP/IP waits for availability of those services, it is recommended that you verify that the OMVS, resolver, and VTAM address spaces have completed initialization before starting TCP/IP. If using automation to start TCP/IP, have it look for the BPXI004I, EZZ9291I, and IST020I messages, respectively, before issuing the START command.

For information on how the resolver can be started, see "Starting the resolver" on page 732. You can use the resolver's MODIFY DISPLAY command to check that the resolver is active and what resolver setup statements are being used. For the syntax and usage of the command, see *z/OS Communications Server: IP System Administrator's Commands*.

Step 6: Start the TCP/IP address space

Enter the MVS START command from the operator's console to start TCP/IP, specifying the member name of your cataloged procedure. This will start the TCP/IP address space and any of the servers you have defined in the AUTOLOG statement in PROFILE.TCPIP. For example, if the procedure to start the TCP/IP address space was called TCP1 in your PROCLIB, you would enter:

```
START TCP1
```

For information on updating the TCPIP cataloged procedure or configuration statements used to configure the TCPIP address space, see *z/OS Communications Server: IP Configuration Reference*.

Step 7: Set up cataloged procedures and configuration data sets

At this point in the configuration process, you can choose to either set up procedures or you can do each one individually when you set up the appropriate application, function, or server.

See the appropriate topics for more information about setting up a particular application, function, or server.

Chapter 3. Security

The z/OS Communications Server, along with other elements of z/OS, provide numerous enterprise-strength security services to protect your mission-critical data. This topic provides an overview of these technologies and how they can be used for a safe and secure z/OS TCP/IP deployment.

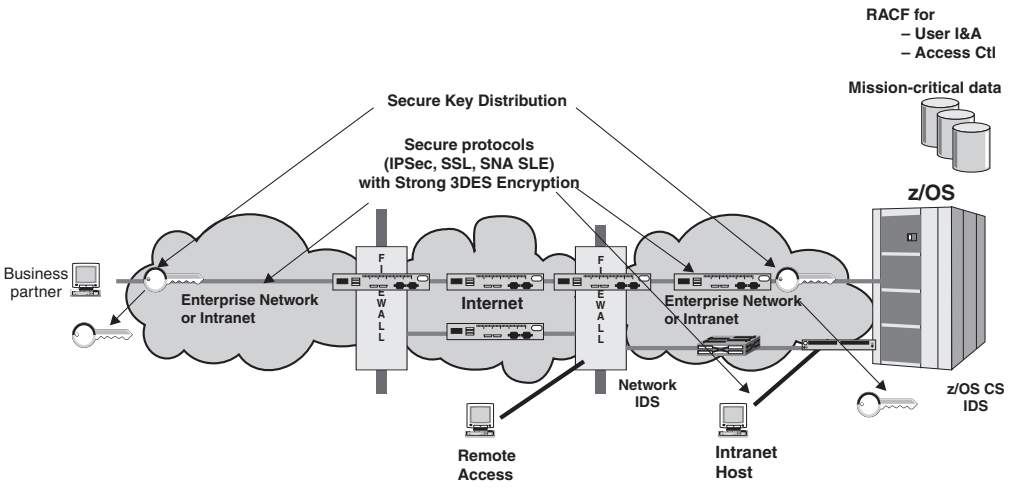

Figure 17. Elements of a secure TCP/IP deployment

Tip: Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

The Communications Server protects data and other resources on the system. Communications Server applications use RACF services to ensure that users requesting application access are identified and authenticated, and to protect data and other system resources from unauthorized access. The Communications Server safeguards the availability of the system by protecting against denial of service attacks from the network.

The Communications Server protects data in the network by supporting a variety of cryptographic-based network security protocols such as IPSec, SSL, and SNA Session Level Encryption. These security protocols ensure that data received is originated by the claimed sender (data origin authentication), that contents were unchanged in transit (message integrity), and that sensitive data is concealed using encryption (data privacy).

The Communications Server provides security event reporting to record potential security violations. These services may help you identify potential sources of subsequent attacks, respond more quickly to network attacks, and manage system resources during periods of high network traffic for key applications.

Note: Some of the security features described in this information have not yet been implemented for IPv6. To determine which functions are supported for IPv6, see the IPv6 support tables in *z/OS Communications Server: IPv6 Network and Application Design Guide*.

Application security

The Communications Server protects data and other system resources accessed by applications included in the Communications Server element. This protection requires verification of the identity of the end user requesting access. This process is called identification and authentication. In addition, access to resources must be limited to those users with permission. This process is called access control. Communications Server applications use RACF for identification and authentication, and access control decisions. Authenticated users are granted access to RACF resources only for which they have permission

Some applications allow anonymous access. Applications that allow anonymous access include anonymous FTP, Remote Execution, and Trivial File Transfer Program (TFTP). The Communications Server ensures that all anonymous access can be controlled by the installation. If anonymous access is allowed, the resources accessed can be limited in several ways:

- The application can be configured to limit resources for which access will be attempted.
- The application can be configured to use a RACF user ID to represent the anonymous user. In this case, access is allowed for those resources specifically permitted for the anonymous RACF user ID and for those resources that are universally accessible.

Most Communications Server applications must be configured specifically to allow anonymous access. One exception is TFTP. TFTP can be configured to control those directories that contain files that can be transferred.

Table 8 depicts a representative set of Communications Server applications, whether end user identification is required, and the security credentials under which resource access is made. For more information on specific application considerations, see the topic about each application.

Table 8. User identification, authentication, and access control for z/OS Communications Server applications

Server	End-user identification	Resource access
FTP	Optional [1]	End-user ID or configured anonymous user ID [2]
LPD	Optional [1]	Server ID or end-user ID
MVS REXECD	Required	End-user ID
MVS RSHD	Required (password optional) [1]	Surrogate user ID or end-user ID
NSSD [network security services (NSS) server]	Required	NSS client user ID
Policy Agent server	Required	Policy client user ID
TFTP	No	Server user ID [2]
UNIX REXECD	Required	End-user ID

Table 8. User identification, authentication, and access control for z/OS Communications Server applications (continued)

Server	End-user identification	Resource access
UNIX RSHD	Required (password optional) [1]	End-user ID or Server user ID (exit routine to verify request)
UNIX shell (Telnet/rlogin)	Required	End-user ID

1. All items listed as optional are installation controlled and can all be configured to require full end-user identification.
2. Accessible files can be configured on a server basis to limit access.

TCP/IP resource protection

The Communications Server uses the System Authorization Facility (SAF) to protect TCP/IP resources from unauthorized access. These resources are represented by resource profiles defined in the SERVAUTH class. When describing resource profile names, the following conventions are used:

- *sysname* is the MVS system name. Substitute your system name.
- *tcpname* is the TCP/IP job name. Substitute your job name.
- *ftpdaemonname* is the job name of the FTP daemon. Substitute your FTPD job name. If your FTPD job name contains fewer than 8 characters, substitute the job name of the process that is started by FTPD, which is usually the original job name with the number 1 appended.
- *rpcbindname* is the job name of rpcbind. Substitute your rpcbind job name. If your rpcbind job name contains fewer than 8 characters, substitute the job name of the process that is started by rpcbind, which is usually the original job name with the number 1 appended.

The use of SERVAUTH is optional. The installation can choose to use any combination of the protections provided by SERVAUTH.

In addition to the use of SERVAUTH protection, further resource protection is provided through such functions as Intrusion Detection Services (IDS), syslogd isolation, and IP filtering, or through controlling access to the VARY TCPIP command.

Local user access control to TCP/IP resources using SAF

You can use System Authorization Facility (SAF) to control which z/OS users can access specific TCP/IP resources, which protects against unauthorized user access to these resources.

You define SAF resource profiles in the SERVAUTH class to control access to the TCP/IP resources. After you define a SAF resource profile, a local user can access the associated TCP/IP resource if their user ID is permitted to the resource profile and given READ access to the resource.

Table 9 on page 112 summarizes the SERVAUTH resource names that are used by TCP/IP.

Table 9. SERVAUTH resource names used by TCP/IP

Function	Description	SERVAUTH resource name
TN3270E Telnet server access control	Controls ability to access TN3270E Telnet server based on SAF user ID associated with TLS-authenticated X.509 client certificate	EZB.TN3270.*sysname*.*tcpname*.PORT*xxxxx*
FTP server access control	Controls ability to access FTP server based on SAF user ID used to log in	EZB.FTP.*sysname*.*ftpdaemonname*.PORT*xxxxx*
DCAS server access control	Controls ability to access DCAS server based on SAF user ID associated with TLS-authenticated X.509 client certificate	EZA.DCAS.*cvtsysname*
OSM access control	Controls ability to access the intranode management network using OSM interfaces	EZB.OSM.*sysname*.*tcpname*
TCP stack access control	Controls user ability to open a socket and get host name or host ID	EZB.STACKACCESS.*sysname*.*tcpname*
TCP local port access control	Controls user ability to bind to a non-ephemeral TCP or UDP port	EZB.PORTACCESS.*sysname*.*tcpname*.*port_safname*
TCP netaccess access control	Controls local user inbound and outbound access to network resources, and local user access to local IP address when explicitly binding to local interface (or using job-specific or destination-specific source IP addresses)	EZB.NETACCESS.*sysname*.*tcpname*.*security_zonename*
Netstat command access control	Provides ability to restrict Netstat usage	EZB.NETSTAT.*sysname*.*tcpname*.*netstat_option*
Policy Agent command control	Provides ability to restrict **pasearch** command, IKE daemon, policy clients, and nslapm2 usage by policy type	EZB.PAGENT.*sysname*.*image*.*ptype*
FTP SITE command control	Provides ability to restrict usage of SITE DUMP and DEBUG commands (commands generate large amount of output)	EZB.FTP.*sysname*.*ftpdname*.SITE.DUMP EZB.FTP.*sysname*.*ftpdname*.SITE.DEBUG
SNMP agent control	Provides ability to control usage of SNMP subagents that connect to the TCP/IP SNMP agent	EZB.SNMPAGENT.*sysname*.*tcpname*
MODDVIPA utility program control	Provides ability to restrict usage of MODDVIPA utility program (creates new DVIPA on system)	EZB.MODDVIPA.*sysname*.*tcpname*
VIPARANGE access control	Controls user ability to bind to a DVIPA within a VIPARANGE	EZB.BINDDVIPARANGE.*sysname*.*tcpname*
Fast Response Cache Accelerator (FRCA) Access Control	Provides ability of user to create FRCA cache (FRCA used by Web servers for caching static Web pages in the stack)	EZB.FRCAACCESS.*sysname*.*tcpname*

Table 9. SERVAUTH resource names used by TCP/IP (continued)

Function	Description	SERVAUTH resource name
TCP connection information service access control	Provides ability to restrict access to the TCP connection information using TCP connection information service; intended for network management applications	EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPCN
Real-time SMF information service access control	Provides ability to restrict access to select real-time SMF records accessible using the SMF information service; intended for network management applications	EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPSM
TCP/IP packet trace service access control	Provides ability to restrict access to select real-time packet trace records accessible using the TCP/IP packet trace service; intended for network management applications	EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPDA
FTP z/OS UNIX file system access control	Provides ability to generally restrict FTP user access to the z/OS UNIX file system	EZB.FTP.*sysname*.*ftpdaemonname*.ACCESS.HFS
Broadcast access control	Provides ability to control whether an application is permitted to set the SO_BROADCAST socket option needed to send broadcast datagrams	EZB.SOCKOPT.*sysname*.*tcpname*.SO_BROADCAST
IPv6 Advanced Socket API access control	Provides ability to control whether an application is permitted to set IPv6 advanced socket API options: IPv6_NEXTHOP IPv6_TCLASS IPv6_RTHDR IPV6_HOPOPTS IPV6_DSPOPTS IPV6_RTHDRDSTOPT IPV6_PKTINFO IPV6_HOPLIMIT	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_NEXTHOP EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_TCLASS EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_RTHDR EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_HOPOPTS EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_DSTOPTS EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_RTHDRDSTOPTS EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_PKTINFO EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_HOPLIMIT
TCP/IP stack initialization access control	Controls ability of applications to open a socket before AT-TLS policy is loaded into the TCP/IP stack	EZB.INITSTACK.*sysname*.*tcpname*
CIM provider access control	Provides ability to restrict access to CIM data	EZB.CIMPROV.*sysname*.*tcpname*
ipsec command access control	Provides ability to control **ipsec** command usage	EZB.IPSECCMD.*sysname*.*tcpname*.*command_type* EZB.IPSECCMD.*sysname*.DMD_GLOBAL.*command_type*

Table 9. SERVAUTH resource names used by TCP/IP (continued)

Function	Description	SERVAUTH resource name
Network security services (NSS) server access control	Controls whether an NSS IPSec client can register with the NSS server for the NSS IPSec certificate service	EZB.NSS.*sysname*.*clientname*.IPSEC.CERT
NSS server access control	Controls whether an NSS IPSec client can register with the NSS server for the NSS IPSec remote management service	EZB.NSS.*sysname*.*clientname*.IPSEC.NETMGMT
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance SAFAccess service.	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.SAFACCESS
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance certificate service.	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.CERT
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance private key service.	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.PRIVKEY
NSS server certificate access control	Controls whether an NSS client can access a CERTAUTH certificate on the key ring of the NSS server	EZB.NSSCERT.*sysname*.*mappedlabelname*.CERTAUTH
NSS server certificate access control	Controls whether an NSS client can access a PERSONAL or SITE certificate on the key ring of the NSS server	EZB.NSSCERT.*sysname*.*mappedlabelname*.HOST
NSS server private key access control	Controls whether an NSS XMLAppliance client can access the private key for a certificate on the key ring of the NSS server	EZB.NSSCERT.*sysname*.*mappedlabelname*.PRIVKEY
Local IPSec network management interface (NMI) access control for display requests	Controls whether a user can issue NMI monitoring requests to the local IKE daemon to retrieve IP filtering and IPSec monitoring data pertaining to a local TCP/IP stack	EZB.NETMGMT.*sysname*.*tcpname*.IPSEC.DISPLAY
Local IPSec NMI access control for control requests	Controls whether a user can issue NMI control requests to the local IKE daemon to manage IP filtering and IPSec function (for example, activate and deactivate requests) pertaining to a local TCP/IP stack	EZB.NETMGMT.*sysname*.*tcpname*.IPSEC.CONTROL

Table 9. SERVAUTH resource names used by TCP/IP (continued)

Function	Description	SERVAUTH resource name
Remote IPSec NMI and **ipsec** command access control for display requests	Controls whether a user can do the following: • Issue NMI monitoring requests to the NSS server pertaining to an NSS client (that is, get requests) • Issue the **ipsec** command with the **-z** option to display options for an NSS IPSec client	EZB.NETMGMT.*sysname.clientname*.IPSEC.DISPLAY
Remote IPSec NMI and **ipsec** command access control for control requests	Controls whether a user can do the following: • Issue NMI management requests to the NSS server pertaining to an NSS client (for example, activate and deactivate requests) • Issue the **ipsec** command with the **-z** option to perform a management action to an NSS IPSec client (for example, to activate and deactivate options)	EZB.NETMGMT.*sysname.clientname*.IPSEC.CONTROL
NSS NMI and command access control	Controls whether a user can do the following: • Issue NMI requests to display connections to the NSS server • Issue the **ipsec** command with the **-x** option to display NSS IPSec client connections to the NSS server • Issue the **nssctl** command to display NSS client connections to the NSS server.	EZB.NETMGMT.*sysname.sysname*.NSS.DISPLAY
IPSec NMI and **ipsec** command access control	Controls whether a user can do the following: • Issue NMI requests to display IKE daemon NSS client information • Issue the **ipsec** command with the **-w** option to display IKE daemon NSS IPSec client information	EZB.NETMGMT.*sysname.sysname*.IKED.DISPLAY
Get partner information ioctl access control	Controls whether an application can use the SIOCGPARTNERINFO ioctl to obtain partner security credentials within a sysplex or subplex over a trusted TCP connection	EZB.IOCTL.*sysname.tcpprocname*.PARTNERINFO

Stack access control

You can create a SAF resource profile to control access to a TCP/IP stack. There are no new TCP definitions required. The resource profile controls whether users or groups of users have access to the TCP/IP stack by controlling their ability to open an AF_INET or AF_INET6 socket and to obtain the host ID or host name. Create the EZB.STACKACCESS.*sysname.tcpname* resource profile in the SERVAUTH class

for the TCP/IP stack to be protected. After you define this resource profile, permit users to the profile and grant them READ access to the resource. If a user does not have READ access to the resource for a stack, the user cannot access the stack. If you do not define a resource profile for a stack, all uses have access to that stack.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the stack access resource profile and permit users to it whenever the SERVAUTH class is active.

Figure 18 provides an overview of stack access control. *sysname* refers to the MVS system variable *sysname*. *tcpname* refers to the TCP/IP job name. User Tom has permission to access both Stack1 and Stack2, Joe does not have permission to access any stack, and Bob has permission to access Stack2 but not Stack1.

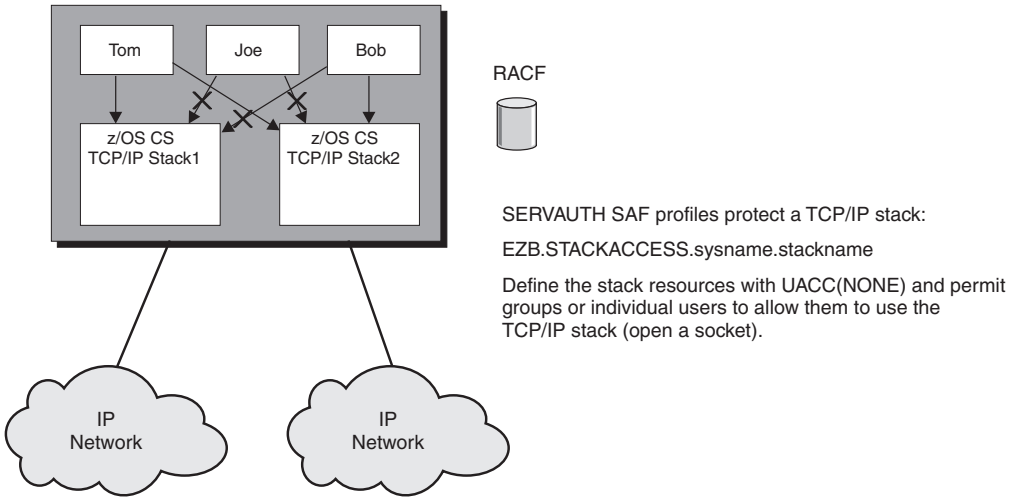

Figure 18. Stack access control overview

Port access control

You can use port access control to protect against unauthorized use of ports. You can control an application's ability to explicitly bind to, or listen on, specific TCP and UDP ports or port ranges by either reserving particular ports or by controlling access to unreserved ports.

Controlling access to particular ports

You can control access to particular ports by port number, by reserving the port using the PORT or PORTRANGE profile statements. Use the PORT and PORTRANGE statements to reserve well-known or configured ports for the applications that need to bind to them. You can use the optional SAF parameter to provide additional access control.

You can reserve an individual port or range of ports with a job name, a wildcard job name (*), a partial wildcard job name (0-7 characters, followed by *), or the special job name of RESERVED. If you specify a job name, the port is reserved for an application that has the specified job name. If you specify a partial wildcard job name, the port is reserved for any application that matches the partial wildcard job name. If you specify a wildcard job name, the port is reserved for any application with any job name. The RESERVED job name shuts down the use of a port or range of ports for any application.

If you specify the SAF keyword on the PORT or PORTRANGE statement, it can provide additional access control by verifying that the user ID associated with an application at the time of a bind to the port is authorized to access the port. The SAF keyword value specifies a portion of the resource name that represents the port. Define the EZB.PORTACCESS.*sysname*.*tcpname*.*port_safname* resource profile in the SERVAUTH class to control access to the port, where *port_safname* is the same value that you specify on the SAF keyword of the PORT or PORTRANGE statement. The user ID that is associated with the application at the time of the bind request must have READ access to this resource for the application to be able to bind to the port.

Figure 19 provides an overview of port access control. In this example, z/OS user WEBSERV (Web server) is permitted to bind to port 80. User Bob is not permitted to bind to port 80.

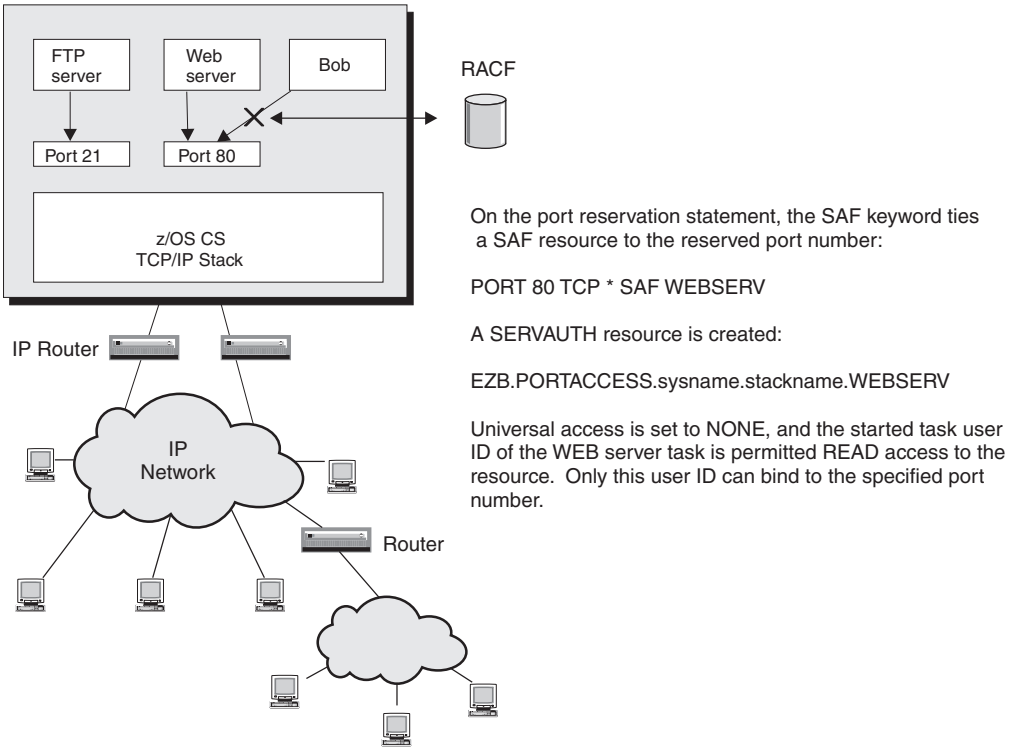

Figure 19. Port access control overview

Controlling access to unreserved ports

You can control which applications are allowed to access ports that have not been reserved by a PORT or PORTRANGE statement. You can use the PORT statement with the UNRSV keyword, or the RESTRICTLOWPORTS parameter on the UDPCONFIG or TCPCONFIG statements.

Using the PORT statement to control access to all unreserved ports: In addition to reserving particular ports, you can also use the PORT statement to control application access to user-specified ports that have not been reserved. Access control is applied when an application issues an explicit bind or a TCP listen.

You can use job names or SAF resources, or a combination of both, to control access to user-specified unreserved ports, or you can unconditionally deny access

to user-specified unreserved ports. You do this by configuring one or more PORT statements in which the port number is replaced by the keyword UNRSV.

Result: PORT UNRSV statements control access to nonzero, unreserved ports specified on explicit binds. Access to unreserved ports that are assigned by the stack is not affected.

If you want to use PORT UNRSV access control, consider the following:

- Using the parameters on the PORT UNRSV statement

  To use only job names to control unreserved port access, configure one or more PORT UNRSV statements using the JOBNAME keyword with specific job names or partial wildcard job names (1 - 7 characters, followed by *). If you specify the wildcard job name (*), the PORT UNRSV statement applies to all job names. If an application's job name matches more than one PORT UNRSV statement, the statement with the closest matching specified job name is used to control access to unreserved ports.

  To use a SAF resource instead of job names to control unreserved port access, configure a PORT UNRSV statement specifying the wildcard job name (*) and the SAF keyword and resource name. Because you can have only one PORT UNRSV statement with the wildcard job name per protocol, this method allows the use of only one SAF resource per protocol.

  To use a combination of job names and a SAF resource to control access, specify the SAF keyword and resource name on one or more PORT UNRSV statements with different job names. You can specify a different SAF resource on each of these PORT UNRSV statements.

  If you do not configure any PORT UNRSV statements for a protocol, all applications are allowed to use unreserved ports. This is the default behavior. To change this behavior and unconditionally deny access to user-specified unreserved ports, configure a PORT UNRSV statement, specifying the wildcard job name (*) and the keyword DENY.

  For the UDP protocol, access is always controlled when an explicit bind is issued (WHENBIND). For UDP applications, there is no distinction between client or server roles because there is no explicit socket API that indicates that the application is a UDP server. All UDP applications that bind their socket to a specific local unreserved port do need to pass any configured UDP port access control checks.

  For the TCP protocol, you can control access to user-specified unreserved ports when the explicit bind is issued (WHENBIND) or when a listen is issued on that port (WHENLISTEN). WHENLISTEN access control is targeted to TCP applications acting as servers (that is, applications able to accept incoming client TCP connections) and is the default for TCP. If the default is used or WHENLISTEN is specified, and no listen is issued for the unreserved port, no access control check is made. WHENBIND access control can affect TCP client applications that bind to a specific local port for outbound TCP connections. Every PORT UNRSV statement for the TCP protocol must specify the same access control. You cannot specify WHENLISTEN on some statements and WHENBIND on other statements. If you do, the conflicting configuration statement will fail.

- Implementing PORT UNRSV access control in stages

  Using PORT UNRSV access control can have unexpected consequences. Consider implementing this function in the following stages:

  1. Determine the necessary port reservations statements for your applications.

For example, you might begin with 'PORT UNRSV TCP * SAF *xyz* WHENBIND', where the SERVAUTH profile has UACC(READ) and auditing of successes is enabled. This would give you an indication of how many applications currently bind to unreserved ports. Verify the applications reported, and if deemed valid, reserve their ports using the PORT or PORTRANGE statements.

2. Enable access control enforcement by specifying DENY or a SAF resource with UACC(NONE) and monitor failures.

   As failures are identified, configure appropriate PORT reservation statements to allow authorized application access to those ports.

- Enforcing PORT UNRSV access control

  If you configure one or more PORT UNRSV statements for a protocol, access is unconditionally denied to any application that explicitly binds to an unreserved port and does not match the protocol and job name on any of the configured PORT UNRSV statements. Applications that explicitly bind to an unreserved port and that do match the protocol and job name on a PORT UNRSV statement are allowed to access the unreserved port, unless the access is restricted by the SAF or DENY keywords. If the SAF keyword is specified, the user ID associated with the application that attempts to access the port must be permitted to the specified SAF resource. If the DENY keyword is specified, access is unconditionally denied.

  Rules: If you configure PORT UNRSV statements for UDP or for TCP with the WHENBIND option, the following rules apply:

  – Every application using that protocol that explicitly binds to a user-specified local unreserved port is subject to an authorization check. If the application does not have authority to access an unreserved port, the bind will fail.

  – For TCP, every client connection that first performs an explicit bind and explicitly specifies a local unreserved port is subject to an authorization check for access to unreserved ports.

  – Because client programs might run under many different user IDs, all address spaces in which the client program can run must be authorized (by job name, SAF resource, or both) to access an unreserved port.

    Alternatively, you can use the WHEN(PROGRAM) type of RDEFINE statements to authorize specific programs to a particular port, regardless of the address space in which they run. However, in this case these programs must be program-controlled resources.

  If you do not configure a PORT UNRSV statement for a protocol, then access to unreserved ports using that protocol is not controlled. If you do configure PORT UNRSV statements for a protocol, access is determined by the PORT UNRSV statement with the job name that most closely matches the application's job name; if the applications's job name does not match any of the PORT UNRSV statements, then access to unreserved ports is denied for that protocol.

Using the RESTRICTLOWPORTS parameter to control access to unreserved ports below port 1024: When the RESTRICTLOWPORTS parameter is specified on the UDPCONFIG or TCPCONFIG profile statements, an application cannot obtain a port in the range 1 - 1023 that has not been reserved by a PORT or PORTRANGE statement, unless the application is APF-authorized or has OMVS superuser [UID(0)] authority. z/OS Communications Server client applications that need to bind to a low port are provided as APF-authorized.

Tip: When you configure the RESTRICTLOWPORTS parameter on the TCPCONFIG or UDPCONFIG profile statements, PORT UNRSV statements for the corresponding protocol control access only to unreserved ports above port 1023.

Network access control

Network access control gives system administrators the ability to assign permission for z/OS users to access certain networks and hosts. With this function, the ability of users to send or receive data between z/OS and certain networks can be controlled through z/OS. Network access control provides an additional layer of security to any authentication and authorization security that is used in the network or at the peer system by disallowing the unauthorized user to communicate with the peer network resource.

Essential elements of this function are as follows:

- The IP network is considered the resource to be protected.
- Use of the IBM zEnterprise™ System (zEnterprise) intranode management network is protected by OSM access control and is exempt from network access control. For more information, see "OSM access control" on page 122.
- IP addresses are classified into *security zones*, in which each zone has a certain level of security sensitivity. A default security zone exists for interfaces that are not explicitly associated with a specific security zone. Security zones consist of one or more, perhaps discontiguous, IP address ranges that have the same security sensitivity and are identified by a specific zone name.
- SAF is used to check whether users or groups of users have READ access to a security zone.
- You define a SAF resource profile for each security zone and provide READ access to these resources to the users or groups of users that you want to have access to particular security zones. A security zone is represented by the EZB.NETACCESS.*sysname.tcpname.zonename* resource name in the SERVAUTH class.
- TCP/IP keeps a mapping of network resources by IP address to security zones. This mapping is consulted on certain inbound and outbound operations to determine the corresponding resource zone name for the most specific network defined. Then the current user's access to that resource is queried using SAF, and the operation is allowed or denied completion accordingly. This mapping is also consulted when the security ioctl is issued to extract the port of entry zone name of a socket's current peer.
- Network access control is used to control z/OS user access to a peer address in an IP network through a sockets application. Resource access checks occur at connection setup or acceptance time for TCP, peer identification time for UDP and RAW, and on the first and potentially subsequent sends or receives (TCP, UDP, or RAW) to a particular destination in a socket's lifetime.
- Network access control is used to control z/OS user access to local addresses when a socket is bound to a local address. Resource access checks occur when an application explicitly binds a socket to a local address, including the IPv4 address INADDR_ANY (0.0.0.0/32) or the IPv6 unspecified address, in6addr_any (::/128). Job-specific or destination-specific source IP addresses (designated by the SRCIP profile statement) are handled as if the application did an explicit bind to the configured address.
- Network access control security checks are made at the transport layer (TCP, UDP, and RAW). Other IP-specific packets generated by the stack are not covered under this function (such as ICMP echo replies, for example). Additionally, there is no user concept when dealing with packets that are being forwarded through the stack, and hence no checks are made.
- Network access control for outbound and inbound can be individually enabled or disabled.

- TCP/IP caches security information following network access control checks. Access is automatically rechecked on the next use of the cache whenever the RACF commands SETROPTS RACLIST, SETROPTS RACLIST REFRESH, or SETROPTS NORACLIST are issued for the SERVAUTH class. If you are using a security product other than RACF, the NetAccess zone table in the TCPIP PROFILE must be rebuilt to cause TCP/IP to recognize changes to the SERVAUTH class profiles for existing sockets.
- The socket calls bind, connect, and those that send data will fail with errno EACCES if the specified IP address is not permitted to be used by the application user. Inbound UDP and RAW datagrams that are not permitted under the current network access control policy are normally filtered out before they get to socket calls that receive data. It is possible for a datagram to arrive under a network access control policy that would allow it to be read, but then be received after a policy change that does not allow it. If the application (or common INET) has issued a select or poll on the socket, the receive call returns an EACCES errno to avoid blocking the application. Inbound TCP connections that are not permitted under the current network access control policy are also normally reset and discarded before they get to the socket backlog. In those cases where the only available new connections are not allowed and a select has been issued, accept processing returns a new socket and the next attempt to send or receive data returns an ECONNRESET error.
- NetAccess inbound filtering needs to predict whether a future receive or accept will succeed. When there are multiple processes or threads operating on the same socket, to achieve consistent results you must ensure that certain calls are done under the same identity, or identities with equivalent network access control policies. For UDP and RAW sockets, the select, receive, and send calls must be done under equivalent policies. For TCP listening sockets, the select and accept calls must be done under equivalent policies.

Figure 20 on page 122 provides an overview of network access control. z/OS user Bob is permitted access to Security Zone A but not Security Zone B. An outbound connect from Bob is permitted to Security Zone A, but not Security Zone B. Bob is permitted to accept connections from Security Zone A but not Security Zone B.

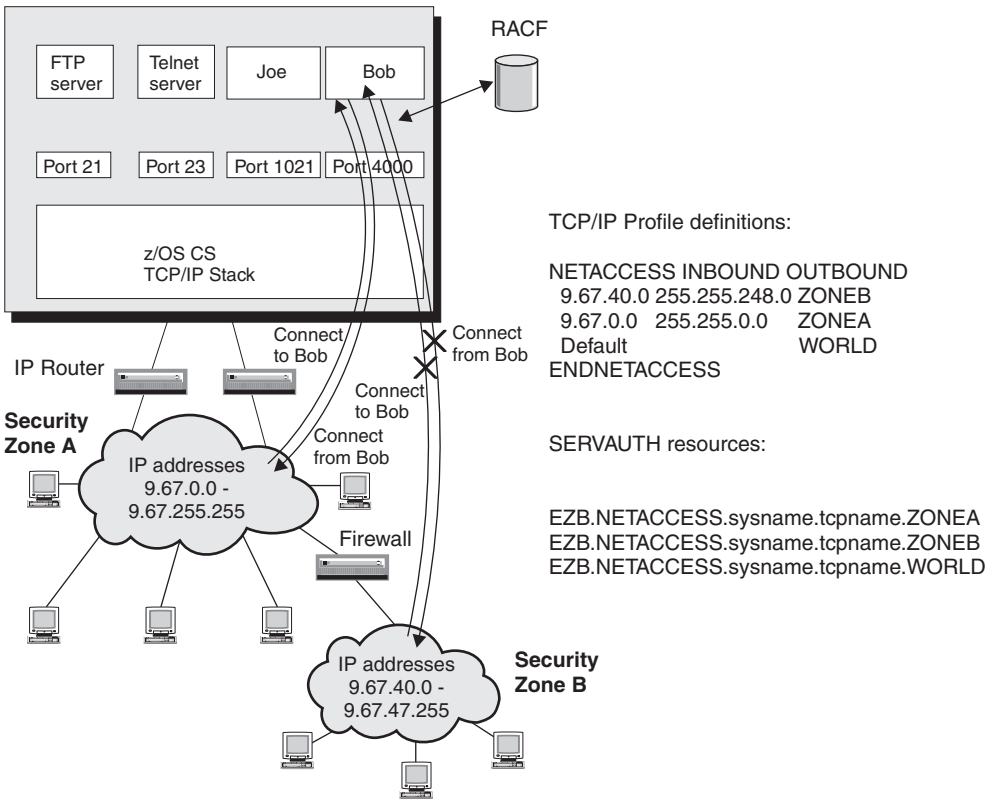

Figure 20. Network access control example

OSM access control

The intranode management network is intended for only authorized applications, such as those performing platform performance management functions. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*.

The intranode management network can be accessed only through OSM interfaces. To send or receive data over OSM interfaces on this network, an application must have READ authorization to the EZB.OSM.*sysname*.*tcpname* resource. If you start one of these authorized applications on a z/OS image, authorize the application user ID to this SAF resource. In addition, authorize to this resource any user IDs that might issue diagnostic commands, such as Ping and Traceroute, over OSM interfaces to verify connectivity. Traffic over OSM interfaces is exempt from network access control.

For more information about the intranode management network, see Chapter 9, "TCP/IP in an ensemble," on page 505.

Socket option access control

Socket option access control gives system administrators the ability to assign permission for z/OS users to set selected socket options using a SAF-compliant security server. Access control is provided for the SOL_SOCKET level, SO_BROADCAST option, and the IPv6 advanced socket API options.

SO_BROADCAST socket option

IPv4 IP addresses are divided into a network portion, an optional subnetwork portion, and a host portion. Normally, UDP and RAW datagrams are delivered to the single peer system identified by the destination IP address. However, when the destination address is a subnetwork or network base address (host portion is all zeros), or a subnetwork or network broadcast address (host portion is all ones), the datagram is delivered to every peer system in that subnetwork or network. Socket semantics require that an application set the SO_BROADCAST option on before attempting to send a datagram to a base or broadcast address. This protects the application from accidentally sending a datagram to many systems. Network access control does not check to see if there are other security zones defined within the scope of a destination subnetwork or network address or whether the user is permitted to send a datagram to all of these security zones.

Control over setting this socket option allows the system administrator to restrict use of subnetwork or network addresses to those users or programs that require them. This support is enforced at the PFS layer and applies to all z/OS Communications Server socket APIs.

TCP/IP programs known to set the SO_BROADCAST socket option include:

- OMPROUTE
- sntpd, when invoked with the **-b** option

Additionally, any programs that use the clnt_broadcast() service in the SUN RPC libraries, or the send_pkt(sock, pkt, addr, broadcast) service in the NCS RPC library with the broadcast parameter set, require permission to the SO_BROADCAST socket option. The following TCP/IP programs use RPC services that require permission to broadcast:

- rpcinfo, when invoked with the **-b** option
- orpcinfo, when invoked with the **-b** option

The socket option to be protected is represented by the resource name EZB.SOCKOPT.*sysname*.*tcpname*.SO_BROADCAST. When this profile is defined, users of any program setting this option require READ permission. Access to the option is also allowed if the security server indicates there is no profile covering this resource. Conditional access lists, such as PERMIT WHEN(PROGRAM(...)), are supported for profiles covering socket option access control resources. There are no new TCP definitions required.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the socket option resource profile and permit users to it whenever the SERVAUTH class is active.

Following is an example of the definitions:

```
RDEFINE SERVAUTH EZB.SOCKOPT.*.*.SO_BROADCAST UACC(NONE)
PERMIT EZB.SOCKOPT.*.*.SO_BROADCAST CLASS(SERVAUTH) ACCESS(READ) ID(OMPROUT)
PERMIT EZB.SOCKOPT.*.*.SO_BROADCAST CLASS(SERVAUTH) ACCESS(READ) ID(*)
WHEN(PROGRAM(ORPCINFO))
```

The program name listed in the conditional access list must be the name the program is invoked by. Most TCP/IP applications are invoked by an alias name rather than the module name. Table 10 on page 124 lists TCP/IP applications that send broadcast datagrams:

Table 10. TCP/IP application load module and alias names

Load module	Alias
EZAORRTE	OMPROUTE
EZASNTPD	SNTPD
EZARPCIN	RPCINFO
EZARORNP	ORPCINFO

Tip: In the UNIX System Services environment, both /bin/rpcinfo and /bin/orpcinfo are externally linked to ORPCINFO. Either command executes the EZARORNP program.

To use program names in conditional access lists, the program must be loaded into a controlled environment from a program controlled data set. TCP/IP applications are distributed in the SEZALOAD load library. To program control this data set, you must add it to the ** profile in the PROGRAM class as follows:

```
RALTER PROGRAM ** ADDMEMBER('TCPIP.SEZALOAD'//NOPADCHK)
```

For more information on program control, see *z/OS Security Server RACF Security Administrator's Guide*.

IPv6 advanced socket API options

You can control access for the IPv6 advanced socket API options that influence outbound packets.

For the IPV6_NEXTHOP, IPV6_TCLASS, IPV6_RTHDR, IPV6_HOPOPTS, IPV6_DSTOPTS, IPV6_RTHDRDSTOPTS, and IPV6_PKTINFO socket options, to set the socket option on setsockopt() or to use the corresponding ancillary data item on sendmsg(), an application must meet one of the following criteria:

- Be APF authorized.
- Have superuser authority.
- The corresponding SERVAUTH resource name in Table 11 is defined, and the application has at least READ access to the resource.

Table 11. Socket option resource names

Socket option/Ancillary data item	Resource name
IPV6_NEXTHOP	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_NEXTHOP
IPV6_TCLASS	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_TCLASS
IPV6_RTHDR	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_RTHDR
IPV6_HOPOPTS	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_HOPOPTS
IPV6_DSTOPTS	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_DSTOPTS
IPV6_RTHDRDSTOPTS	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_RTHDRDSTOPTS
IPV6_PKTINFO	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_PKTINFO
IPV6_HOPLIMIT	EZB.SOCKOPT.*sysname*.*tcpname*.IPV6_HOPLIMIT

For the IPV6_HOPLIMIT socket option, to set a hop limit greater than the default using either the IPV6_UNICAST_HOPS or IPV6_MULTICAST_HOPS socket option on setsockopt() or the IPV6_HOPLIMIT ancillary data item on sendmsg(), an application must meet one of the following criteria:

- Be APF authorized.
- Have superuser authority.
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_HOPLIMIT is defined, and the application has at least READ access to this resource.

TCP/IP applications that set IPv6 advanced socket API options: Table 12 lists the TCP/IP applications that set IPv6 advanced socket API options. In a multilevel secure environment, APF and superuser authority are not sufficient; the security product resource name for the socket options appearing in Table 12 must be defined for every stack. Usage must be explicitly permitted by user ID, or conditional access lists, such as PERMIT WHEN(PROGRAM(...)) must be defined for the load module and alias names listed in the table. For more information about applications in a multilevel secure environment, see "Required configuration in a multilevel secure environment" on page 158.

Table 12. TCP/IP applications that set IPv6 advanced socket API options

Load module	Alias	Socket options set
EZACDOPN	z/OS UNIX **ping**	IPV6_PKTINFO, IPV6_DONTFRAG
EZACDTPN	TSO PING	IPV6_PKTINFO, IPV6_DONTFRAG
EZACDTRT	z/OS UNIX **traceroute**	IPV6_HOPLIMIT, IPV6_PKTINFO
EZACDTTR	TSO TRACERTE	IPV6_HOPLIMIT, IPV6_PKTINFO
EZADNSVR	NAMED	IPV6_PKTINFO
EZAORRTE	OMPROUTE	IPV6_HOPLIMIT, IPV6_PKTINFO
EZASNTPD	SNTPD	IPV6_PKTINFO

For more details on these IPv6 advanced socket API options, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

For examples of the security product definitions, see the EZARACF sample in data set SEZAINST.

Netstat access control

You can control access to Netstat command output from the TSO or UNIX System Services shell environments using the System Authorization Facility (SAF). There are no new TCP definitions required. The Netstat command output is considered the resource to be protected, and you protect it by defining EZB.NETSTAT.*sysname.tcpname.netstat_option* resource profiles in the SERVAUTH class. A user ID has access to the Netstat output for a particular option if a security profile is defined in the SERVAUTH class for that option, and that user ID has READ access to the associated resource. Access is also given if there is no resource profile defined for a resource.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the Netstat resource profiles and permit users to them whenever the SERVAUTH class is active.

An installation can implement a security policy that indicates which users have authorization to selected Netstat options. The level of granularity for this security policy can be either by individual or all Netstat options.

Even though the Netstat RESCache/-q command returns system-wide resolver cache data, at least one TCP/IP stack must be active to ensure that the correct Netstat access controls are enforced for the command. The same EZB.NETSTAT.*sysname.tcpname.netstat_option* naming convention applies to this Netstat command as it does for any other Netstat command.

Fast Response Cache Accelerator access control

Fast Response Cache Accelerator access control allows control of application access to Fast Response Cache Accelerator (FRCA) services. For more information on FRCA, see "Considerations for Fast Response Cache Accelerator" on page 62.

You can control application access to FRCA services by defining the EZB.FRCAACCESS.*sysname.tcpname* resource profile in the SERVAUTH class. Access to FRCA services is allowed if the web server user has READ access to this resource, or if the resource profile is not defined. There are no new TCP definitions required. This function is enabled if the SERVAUTH class is active and the FRCA resource profile is defined. If this resource profile is not defined, the check is not made.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the FRCA resource profile and permit users to it whenever the SERVAUTH class is active.

TCP/IP stack initialization access control

You can control whether an application can access a TCP/IP stack before the required policies have been installed, during the period of time after the stack is active but before Application Transparent Transport Layer Security (AT-TLS) has been initiated from policy. Access checking is performed only if you have configured AT-TLS in the initial PROFILE.TCPIP configuration data set. If AT-TLS is configured, you can control whether an application can access the TCP/IP stack before the required policies have been installed by defining the EZB.INITSTACK.*sysname.tcpname* resource profile in the SERVAUTH class. During the period of time after the stack is active and before AT-TLS has been initiated from policy, all socket requests are blocked if this resource profile is not defined. If this resource profile is defined, access to the stack is permitted only to user IDs that have READ access to the resource. Checking ceases the first time that the Policy Agent processing of the AT-TLS policy is completed, or when a profile change deactivates AT-TLS.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. However, if AT-TLS is enabled, a profile that is not defined has the same result as a user that is not permitted, regardless of the security product you are using. If AT-TLS is enabled, you must activate the SERVAUTH class, and define the INITSTACK resource profile and permit users to it.

TCP/IP packet trace service access control

The TCP/IP packet trace service provides an interface for network management applications to obtain packet trace data. The information provided through the service is considered the resource to be protected. Access to this information can be controlled through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.*sysname.tcpname*.SYSTCPDA.

Access to the information is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled on the stack using the NETMONITOR PKTTRCService statement in PROFILE.TCPIP. For details, see *z/OS Communications Server: IP Configuration Reference*.

If the resource profile is not defined, the service allows access to the packet trace information only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

TCP connection information service access control

The TCP connection information service allows network management applications to obtain information about TCP connection activity. Access to this information can be controlled by an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPCN.

Access to the TCP connection information is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled on the stack using the NETMONITOR TCPCONNService statement in PROFILE.TCPIP. For details, see *z/OS Communications Server: IP Configuration Reference*.

If the resource profile is not defined, the service allows access to the TCP connection information only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

Real-time SMF information service access control

The SMF information service allows network management applications to obtain selected TCP/IP SMF records, such as SMF records supported by FTP and Telnet, in a real-time fashion. Access to this information can be controlled through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPSM.

Access to these SMF records is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled on the stack using the NETMONITOR SMFService statement in PROFILE.TCPIP. For details, see *z/OS Communications Server: IP Configuration Reference*.

If the resource profile is not defined, the service allows access to the SMF data only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

TCP/IP OSAENTA trace service access control

The TCP/IP OSAENTA trace service is an interface that enables network management applications to obtain packet trace data. You should protect the information that is provided by this service. You can control access to this information through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.*sysname*.*tcpname*.SYSTCPOT.

Access to this information is allowed if the user ID associated with the network management application is permitted to (has read access to) to this resource profile. To use this service, ensure that it has been enabled on the stack using the

NTATRCService parameter on the NETMONITOR statement in PROFILE.TCPIP. For details about the NETMONITOR statement, see *z/OS Communications Server: IP Configuration Reference*.

If you do not define this resource profile, the service allows access to the packet trace information only to a superuser, or to those permitted to become a superuser (those with read access to BPX.SUPERUSER).

IPSec network management interface access control

The IPSec network management interface (NMI) enables network management applications to obtain detailed information for and exercise control over IP filtering and IPSec security associations. Access to this interface can be controlled through an external security manager product, such as RACF, by defining the SERVAUTH profile names EZB.NETMGMT.*sysname*.*tcpname*.IPSEC.DISPLAY and EZB.NETMGMT.*sysname*.*tcpname*.IPSEC.CONTROL for display requests and control requests respectively.

Applications can access this interface if the user ID associated with the network management application is permitted (has read access) to the appropriate resource profile.

If the resource profile is not defined, the service allows access to the IPSec NMI only to superusers, or to those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

For more information about the IPSec NMI, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

CIM provider access control

CIM provider access control permits the Communications Server CIM providers to gather CIM data, when the user ID associated with the client of the z/OS CIM server is not defined as a superuser. For more information on the CIM providers, see "Considerations for Common Information Model providers" on page 98.

Access can be controlled by an external security manager product, such as RACF, by defining the resource profile name EZB.CIMPROV.*sysname*.*tcpname* in the SERVAUTH class. For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Access is granted if the user ID associated with the client of the z/OS CIM server is permitted (has read access) to this resource profile.

Tip: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the CIM provider resource profile and permit the client user ID to it whenever the SERVAUTH class is active, if you want the Communications Server CIM providers to be able to gather CIM data.

Syslogd isolation

Syslogd isolation provides a capability for the installation to control which user IDs and job names can write syslogd records to specified syslogd facilities. This function enables the installation to segregate system and application syslogd

records, and to segregate syslogd records from different applications. This function prevents an application level process from flooding a syslogd facility intended for system use, possibly causing system syslogd records to be lost. This function is enabled when user ID and/or job name are specified as additional criteria along with existing facility and priority criteria to select a syslogd repository.

In addition, the user ID and job name associated with the syslogd record writer can optionally be stored in a syslogd record based on a syslogd command-line parameter. This capability is useful when syslogd records for multiple jobs or users are recording in the same syslogd facility. This function enables positive identification of the creator of the syslogd records and ensures that the syslogd record, if spoofed, can be identified.

Syslogd isolation also provides a capability to disable reception of syslogd messages from other hosts in the network. This capability is provided by a syslogd command-line parameter. This parameter disables reception of syslogd messages from all hosts. If an installation wants to allow certain hosts in the network access to syslogd, IP Filtering can be used instead to specify which hosts are permitted to access the syslogd UDP port.

IP filtering

The IP security function can configure the Communications Server to perform packet filtering at the IP layer for IPv4 and IPv6.

IP filters are rules defined to either discard or permit packets. IP filtering matches a filter rule to data traffic based on any combination of IP source or destination address (or masked address), protocol, source or destination port, direction of flow, or time. IP filtering can control traffic being routed, or control access at the host that has the communication endpoint. Even when an external firewall is providing filtering protection for the host, Communications Server IP filtering can provide a secondary line of defense.

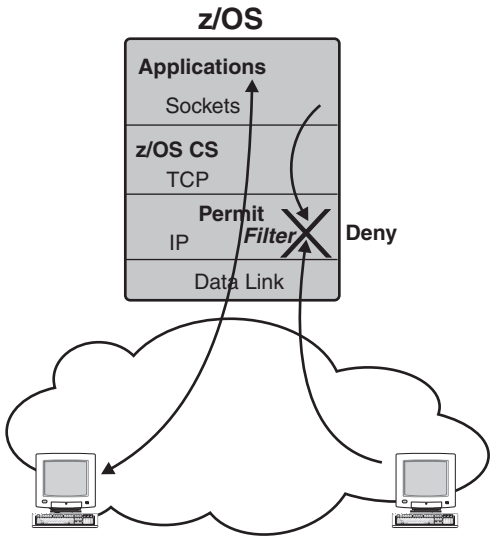

Figure 21. IP filtering at the z/OS communication endpoint

For more information about IP filtering, see Chapter 19, "IP security," on page 923.

Security considerations for the VARY command

You can restrict access to the VARY TCPIP command by defining RACF profiles under the OPERCMDS class and specifying the list of users that are authorized to issue the VARY TCPIP command. You can decide on the level of control that is appropriate for your installation. For example, you might want to allow a user to be able to start or stop a TCP/IP device using the VARY TCPIP command, but you do not want the user to be able to modify the TCP/IP configuration. For further information on restricting access to the VARY TCPIP command, see *z/OS Communications Server: IP System Administrator's Commands*.

Multilevel security

Multilevel security is an enhanced security environment that can be configured on a z/OS system. In this environment, the security server and trusted resource managers enforce mandatory access control policies in addition to the usual discretionary access control policies. To participate in a multilevel-secure environment, the user IDs associated with tasks trying to access z/OS CS resources and those resource profiles in the SERVAUTH class need to have security labels defined. For more information on the multilevel-secure environment and configuring z/OS CS in that environment, see Chapter 4, "Preparing for TCP/IP networking in a multilevel secure environment," on page 153.

Network security principles

This topic describes network security principles that you can use to protect data in your network.

Cryptography: The foundation of good security

The foundation of good security methods begins with cryptography. Cryptography keeps your data and communications secure using techniques such as encryption, authentication, and data integrity. Encryption services protect sensitive data from being read by other than the intended receiver. Cryptographic authentication and data integrity services allow communicating hosts to detect if data is altered in transit. Public key cryptography can identify and authenticate hosts or users. Public key cryptography can also be used in the secure creation of symmetric session keys for both security endpoints. Once a secure session is created, successful data authentication and decryption occur only if both hosts have the correct session keys.

Cryptographic standards and FIPS 140

The National Institute of Standards and Technologies (NIST) publishes Federal Information Processing Standards publication 140 (FIPS 140). This publication specifies security requirements for cryptographic modules for both hardware and software components of computer systems. FIPS 140 places some restrictions on the use of cryptographic algorithms and modules. Some examples of the restrictions are:

- Cryptographic algorithms and keys must be contained within a cryptographic module and accessed through a well defined cryptographic boundary.
- Use of weaker cryptographic algorithms (for example, DES and MD5) is not allowed.
- Use of weaker asymmetric key lengths (for example, RSA digital signature operations using key lengths less than 1024 bits) is not allowed.
- Use of Diffie-Hellman groups with weaker key lengths (key lengths less than 2048 bits) is not allowed. This restriction applies to groups 1, 2, and 5.

See the National Institute of Standards and Technology (NIST) Web site at http://csrc.nist.gov/publications/PubsFIPS.html for the most recent FIPS 140 publication, and other related publications.

On z/OS systems, Integrated Cryptographic Services Facility (ICSF) and System SSL provide cryptographic services. z/OS Communications Server uses ICSF and System SSL in addition to its own cryptographic algorithms in some of its networking security functions, such as AT-TLS and IP security. You can configure ICSF, System SSL, and the z/OS Communications Server networking security functions in FIPS 140 mode, in which they will enforce FIPS 140 restrictions.

See the following references for information about configuring z/OS functions in FIPS 140 mode:

- "FIPS 140 and IP security" on page 930
- Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193
- *z/OS Cryptographic Services System SSL Programming*
- *z/OS Cryptographic Services ICSF Overview*

End to end security

Cryptographic security solutions can be applied to a portion of the data path or end to end, whichever is appropriate for your security policy. Generally, the greatest degree of security is provided when cryptographic methods are used end to end. However, if only portions of the data path are considered untrusted by an enterprise (such as the Internet) it may be adequate to protect only the untrusted portion with cryptography. z/OS offers security protocols that can be configured to protect portions of the data path or the entire data path.

Workload-based security deployment

In making a security protocol selection, an important consideration is the application workload to be protected. In order to illustrate this concept, it is helpful to understand where various protocols are implemented from a protocol layering perspective.

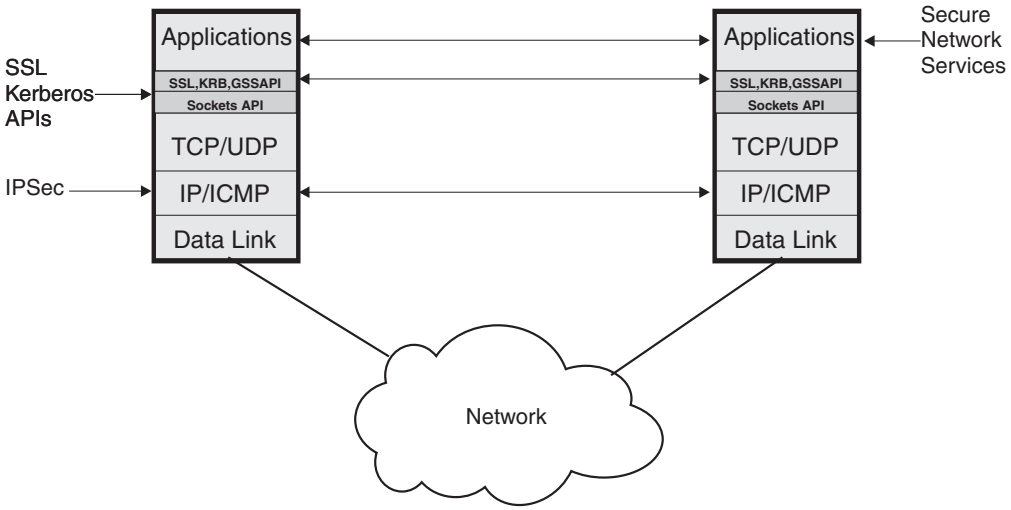

Figure 22. Security protocols from a protocol layering perspective

Existing workload

The network layer is the lowest layer in the protocol stack where end to end security over multiple hops can be applied. Network layer security protocols provide blanket protection for upper-layer application data without requiring modification to the application. IPSec is implemented at the network layer and provides authentication, integrity, and data privacy between any two IP entities. IPSec can protect a segment of the data path (e.g., between two routers), or it can secure the data path end to end. Because IPSec is applied at the IP layer, it is a connectionless security protocol and is applied on a per packet basis.

Secure Sockets Layer (SSL) is another popular security protocol implemented above the transport layer at the application interface layer. TCP applications can be modified to use SSL. Many existing socket applications might be able to use Application Transparent Transport Layer Security (AT-TLS) services provided within the TCP/IP TCP layer. For details, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

SSL requires a reliable transport layer and is therefore not used for UDP applications. SSL provides authentication, integrity, and data privacy. SSL, originally used to secure traffic between a Web browser and Web server, can also secure other applications. SSL is a connection-oriented security protocol and protects all data on a connection or session.

The Communications Server has an SSL-enabled TN3270E Telnet server, which provides secure access to existing SNA applications being accessed over an IP network. Serving as a protocol gateway between the IP network and the SNA network, the SSL-enabled TN3270E Telnet server protects the data path in the IP network from the Telnet client all the way to the z/OS TN3270E Telnet server. If the TN3270E Telnet server resides on a different host from the target SNA application, SNA Session Level Encryption can be used to secure the SNA portion of the data path. SNA application data can be protected without modification to the SNA applications.

New workload

For new applications, security can be built-in. One method of building security into the application on z/OS is to use z/OS System SSL and Kerberos. Another method is to use the Communication Server's policy-driven Application Transparent Transport Layer Security (AT-TLS), which requires no change to the application unless the application must control certain portions of the AT-TLS support.

Newer versions of network services such as SNMPv3, Secure DNS, and z/OS UNIX sendmail, which are supported by the Communications Server, have security built into the application protocol using standards-based specifications for secure interoperability.

Network security protocols

This topic describes network security protocols that you can use to protect data in your network.

IPSec and VPNs

IPSec is defined by the IPSec Working Group of the IETF. It provides authentication, integrity, and data privacy between any two IP entities.

Management of cryptographic keys and security associations can be done manually or dynamically using an IETF-defined key management protocol called Internet Key Exchange (IKE).

There are two versions of the IKE protocol:

- IKE version 1.0 (IKEv1) is defined by RFC 2409, *The Internet Key Exchange (IKE)*, and related RFCs. This is the version that has been supported by z/OS Communications Server for a number of years.
- IKE version 2.0 (IKEv2) is defined by RFC 4306, *Internet Key Exchange Protocol: IKEv2*, and related RFCs. Support for IKEv2 is introduced with z/OS V1R12.

With IPSec, you can create virtual private networks (VPN). A VPN enables an enterprise to extend its private network across a public network, such as the Internet, through a secure tunnel called a security association. IPSec VPNs enable the secure transfer of data over the public Internet for same-business and business-to-business communications, and protect sensitive data within the enterprise's internal network.

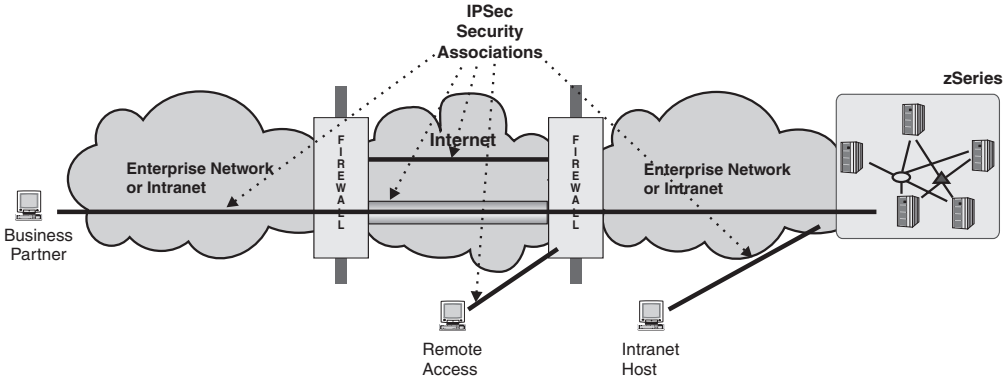

Figure 23. e-business scenarios with virtual private networks

z/OS provides support for IKE and IPSec VPNs, including the following:

- AH and ESP protocols
- Triple DES for strong encryption
- AES with several choices of mode or key length
- IPSec transport and tunnel mode encapsulation
- IKEv1 and IKEv2 negotiations with support for both aggressive and main mode in IKEv1
- Pre-shared key and digital signature methods of authentication
- NAT traversal (IPv4 only)

Hardware features for encryption, decryption and hashing

IBM CP Assist for Cryptographic Functions (CPACF), where available, or a cryptographic coprocessor provide support for IPSec encryption, decryption, and hashing functions. Where such hardware features are not available, IPSec's encryption, decryption, and hashing functions are performed in software.

Additional IPSec assist using System z Integrated Information Processor (zIIP IP security)

On a System z9 or later server, an additional assist for IPSec protocol traffic is available with the System z® Integrated Information Processor (zIIP). To enable zIIP IP security in Communications Server, specify ZIIP IPSECURITY on the

GLOBALCONFIG statement. With zIIP IP security enabled, traffic using the AH and ESP protocols can be processed on available zIIPs. When enabled on a z9 or later z/OS image that includes zIIPs, the zIIP IP security function can reduce the IPSec processing load on general purpose central processors, beyond what is achievable using just CPACF or the Cryptographic Coprocessor.

When zIIP IP security is enabled, you might need to modify some Workload Manager (WLM) definitions. The IPSec traffic that can be processed on available zIIP processors is assigned to an independent WLM enclave. The WLM independent enclave encapsulates the IPSec workload as execution units that are separately classified and managed in a WLM service class. Consider the following:

- All WLM independent enclaves that are not classified are assigned WLM service class SYSOTHER (with a goal of discretionary). In many cases, enclave workload using this service class can result in performance degradation if the workload is left unclassified in the service definition. Also, service that is accumulating in the SYSOTHER service class is an indication that you have unclassified workload in your system.
- Examine the IIPHONORPRIORITY parameter located in the IEAOPT*xx* member of SYS1.PARMLIB. When this parameter is specified as NO, general purpose central processors do not process zIIP-eligible workload when zIIPs are online. Omitting the IIPHONORPRIORITY parameter or specifying IIPHONORPRIORTY=YES allows zIIPs to request help from general-purpose central processors when the zIIPs can not complete all zIIP-eligible workload within a reasonable period of time (see ZIIPAWT in *z/OS MVS Initialization and Tuning Reference*).
- If there are any other workloads that are eligible to run on your zIIPs, analyze your current WLM workload goals and make any necessary adjustments. For example, if you are operating a workload that is more latency-sensitive than the typically longer running IPSec workloads, such as DB2® Distributed Relational Database Architecture™ (DRDA®) workload, consider classifying the IPSec workload to make it less preferable than the workload that is more latency-sensitive.

  Guideline: Make these two performance goal settings for the IPSec independent enclave:

  – Set the WLM service class associated with the IPSec independent enclave to a lower execution velocity goal than that which is being assigned to the more latency-sensitive workload (such as DB2 DRDA). The lower execution velocity goal is chosen because the IPSec independent enclave has no associated transactions.

  – Set the WLM service class associated with the IPSec independent enclave to a greater importance level value (importance is defined in five levels, 1 to 5, with 1 indicating highest importance) than that which is being assigned to the more latency-sensitive workload (such as DB2 DRDA). Each WLM service class is associated with an importance level that specifies how important it is to your business that this workload is meeting its goal. The importance level defines how work is treated by the system. Achieving the velocity goal for IPSec traffic that can be processed on available zIIP processors is less important than the more latency-sensitive workload.

Because an independent enclave enables WLM to manage the priority of all workload in the enclave, you should classify the workload for IPSec traffic. To classify the independent enclave used for IPSec workload, make the following WLM service definitions using the WLM ISPF panels:

1. Create a workload for the IPSec traffic that will be operating on the independent enclave.

   From the primary WLM ISPF panel, select option 2 `Workloads`.
2. Create a service class that contains an appropriate performance goal for the IPSec independent enclave.

   On the primary WLM ISPF panel, select option 4 `Service Classes`. From this panel, define your new service class and associate it with the workload you previously defined. When you define the BASE GOAL information for your single defined period, choose the goal type `Execution velocity`. After this is selected, define a velocity and importance for the service class that you are defining. Set a value that takes into account other traffic that might be competing for zIIP or general central processor resources. (General central processors become a factor when you have set the IIPHONORPRIORITY parameter to the value YES in the IEAOPT*xx* member of SYS1.PARMLIB.)
3. Create a WLM subsystem type for TCP/IP.

   You must specify the subsystem type name as TCP; define it by using the WLM ISPF application. On the primary WLM ISPF panel, select option 6 `Classification Rules`; the `Subsystem Type Selection List for Rules` panel is displayed. Move your cursor to the field `Subsystem-Type` and press the Enter key. When you are prompted for the type of operation that you want to perform, select option 1 `Create`, because you want to create a new subsystem type. On the `Create Rules for the Subsystem Type` panel, specify the subsystem type TCP and a description for this new subsystem type.
4. Create a classification rule for the subsystem type TCP on the `Create Rules for the Subsystem Type` panel of the WLM ISPF application.

   Define a classification rule for the subsystem type. This rule determines what workload is associated with a service class for this subsystem type. You can use the following workload qualifiers for the new independent enclave for IPSec workload:

   - Subsystem Instance (SI) will be set to the job name of the TCP/IP stack
   - Transaction Name will be set to a value of TCPENC01

To verify that the new independent enclave is being used with an appropriate WLM service class, use the System Display and Search Facility (SDSF) ENC command or view the RMF™ Monitor III ENCLAVE report (or use any other method to interactively view RMF data).

For a more detailed description of defining Workload Manager (WLM) service definitions (workloads, service classifications, classification rules, subsystem type, and so on) and WLM in general, see *System Programmer's Guide to: Workload Manager* (IBM Redbooks) and *z/OS MVS Planning: Workload Management*. For information about configuring the IIPHONORPRIORITY parameter in the IEAOPT*xx* member of SYS1.PARMLIB, see *z/OS MVS Initialization and Tuning Reference*. For more information about viewing enclaves using SDSF, see *z/OS SDSF Operation and Customization*. For additional information about the RMF workload activity report, see *z/OS RMF Report Analysis*.

On system models with no zIIPs (z990, or a z9 or later with no zIIPs configured), you can enable zIIP IP security so that you can project the percentage of existing IPSec workload (running on central processors) that would be eligible to run on zIIPs, if zIIPs were available on the z/OS image. To perform projection analysis, specify ZIIP IPSECURITY on the GLOBALCONFIG statement, and specify PROJECTCPU=YES in the IEAOPT*xx* member of SYS1.PARMLIB. Run your IPSec workload, and SMF provides accounting information regarding workload that is

eligible to run on zIIPs. For information about configuring the PROJECTCPU parameter in the IEAOPT*xx* member of SYS1.PARMLIB, see *z/OS MVS Initialization and Tuning Reference*. For information about accounting for zIIP eligibility in SMF record types 30 and 7*x*, see *z/OS MVS System Management Facilities (SMF)*. For information about zIIP-related reporting updates, see *z/OS RMF Report Analysis*.

Guidelines:

- Because cryptographic hardware performance differs significantly between z9 or later processors and processors that preceded the z990, you should not use zIIP IP security for projection purposes on processors preceding the z990.
- TCP/IP consumes slightly more central processing resources when no zIIPs are online and you have coded GLOBALCONFIG ZIIP IPSECURITY. Remove GLOBALCONFIG ZIIP IPSECURITY from your TCP/IP profile after you have completed your zIIP performance projection runs.

For more information about configuring IPSec and VPNs, see Chapter 19, "IP security," on page 923.

For more information on using IPSec with Dynamic VIPAs, see "Sysplex-wide security associations" on page 388.

SSL and TLS

The SSL protocol provides data encryption, data origin authentication, and message integrity. It also provides server and client authentication using X.509 certificates. SSL begins with a handshake during which the server is authenticated to the client using X.509 certificates. Also, the client can optionally be authenticated to the server. During the handshake, security session parameters, such as cryptographic algorithms, are negotiated and session keys are created. After the handshake, the data is protected during transmission with data origin authentication and optional encryption using the session keys.

The cryptographic algorithms that are used for the SSL session are based on the algorithms the server and client are willing to use. During the SSL handshake, the client and server exchange a list of algorithms. The algorithm selected is based on the best match between the client's list and the server's list. The selectable algorithms can be limited by configuring a subset of allowable algorithms at the server. Servers can support encryption using Triple DES as well as other encryption algorithms (RC2, RC4, and DES). A hardware crypto coprocessor, if available, is used for DES and Triple DES encryption.

SSL requires a server X.509 certificate, which is stored in its certificate key ring. The certificate is used as part of the SSL handshake server authentication process. The client validates the server certificate. SSL optionally uses a client X.509 certificate that is used as part of the SSL handshake client authentication process. In order to use client authentication, the client must have a client X.509 certificate. Successful client authentication requires that the Certificate Authority (CA) that signed the client certificate be considered trusted by the server. To be considered trusted, the certificate of the CA must be in the key ring of the server.

See "Transport Layer Security" on page 582 for detailed information on obtaining certificates.

SSL is not defined by the IETF. TLS is based on SSL and is defined by the IETF as RFC 2246.

TN3270E Telnet server security

The Communications Server provides z/OS TN3270E Telnet server (Telnet), that is enabled for both SSL and AT-TLS; the data path in the IP network to Telnet is protected using the SSL protocol. IBM Host On Demand and Personal Communications provide a Telnet client that is enabled for SSL.

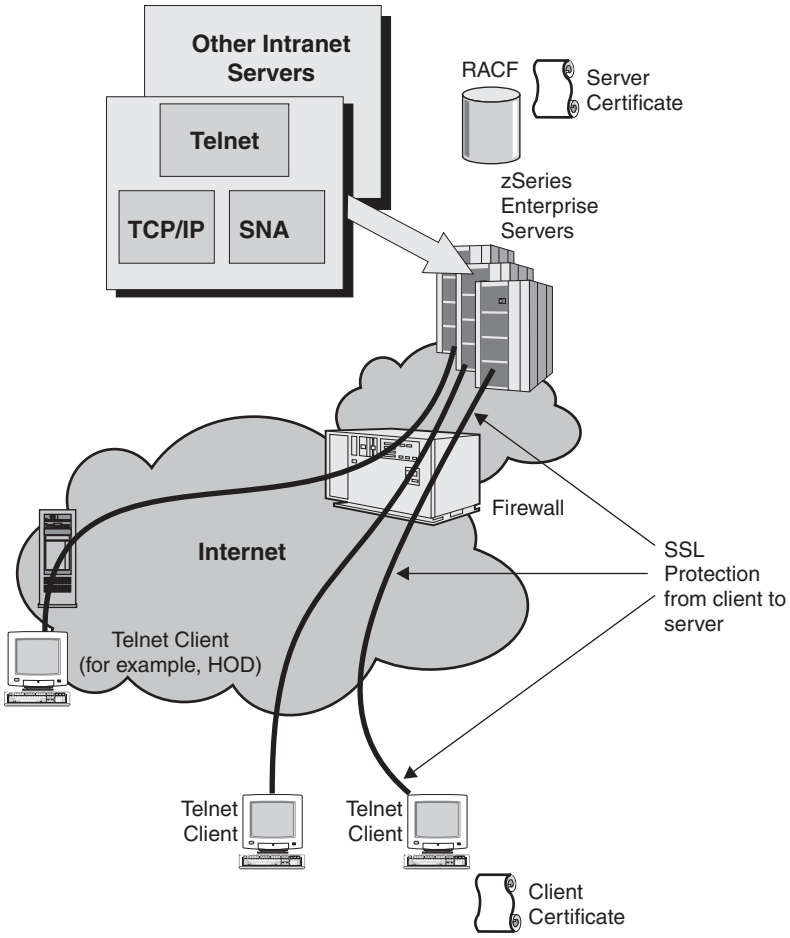

Figure 24. TN3270E Telnet server security overview

The Communications Server Telnet SSL support provides several extensions for RACF-based access control to Telnet. These extensions prevent a client from seeing the USSMSG (log on screen) unless the client is authorized. To use this support, define the client certificate to RACF using RACF digital certificate services. The first level of authorization checking verifies that the RACF user ID represented by the client certificate is defined to RACF. The next level of authorization requires that this RACF user ID be permitted to access the Telnet port. The Telnet port is represented as a RACF resource using the SERVAUTH class.

Multiple port support: You can use Telnet multiple port support to enable a combination of secure and non-secure traffic. To use multiple port support, you define separate ports; one port is dedicated to non-secure traffic and another port is dedicated to secure traffic. Ports with the designation SECUREPORT or TTLSPORT can be secure. Intranet clients are not required to be secure. Intranet clients connect to the BASIC port (port 23 in Figure 25 on page 138). All clients connecting from the Internet are required to be secure; these clients use the SECUREPORT (port 1023 in Figure 25 on page 138). Packet filtering is used at the firewall that separates the intranet and the Internet to control access to the Telnet

ports. To prevent Internet access to the BASIC port, port 23 is blocked at the firewall. The SECUREPORT, port 1023, is permitted at the firewall. In this scenario, the best security is achieved when SSL client authentication with the Telnet RACF extensions is used. This support ensures that the client has the authority to attempt to log on to SNA applications through Telnet. Regardless of the method of authentication used, the SNA application should identify and authenticate the end user using RACF before any application access is granted. If you are using SSL encryption services, the user ID and password are encrypted.

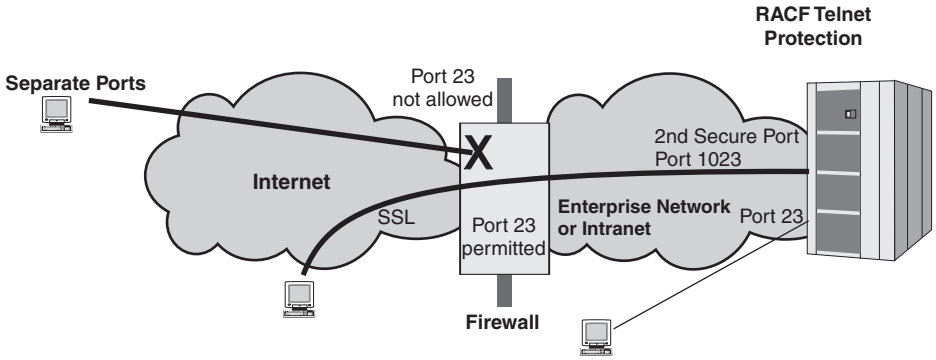

Figure 25. Using multiple Telnet ports to separate secure and non-secure traffic

Figure 26 shows how you can combine IPSec and Telnet security to provide more secure remote access from the Internet to SNA applications than is depicted in Figure 25. In this scenario, IPSec AH protocol is used for authentication between the user's PC and the firewall. The firewall is open for port 1023 for traffic that is authenticated with only IPSec. The firewall discards traffic for port 1023 that cannot be authenticated by IPSec. The additional security provided by IPSec protects the zSeries server from unauthorized access attempts and denial-of-service attacks by hosts outside the VPN.

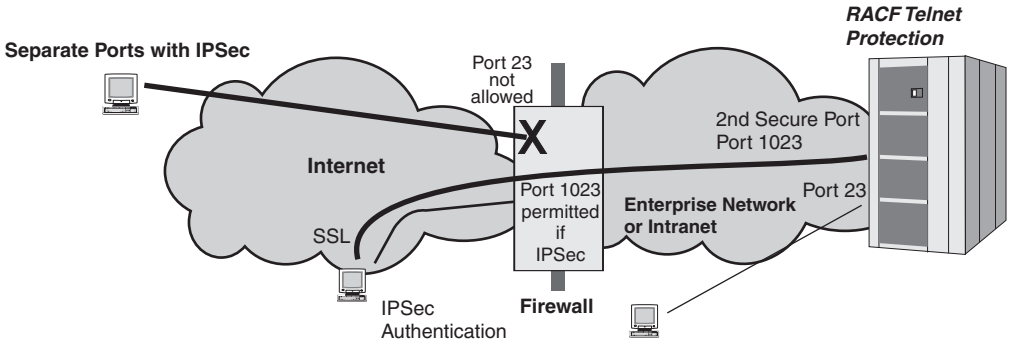

Figure 26. Combining Telnet security with IPSec client-to-firewall authentication

Secure and non-secure connections using a single Telnet port: A single port can be used to support a mix of secure and non-secure traffic. The port has the designation SECUREPORT or TTLSPORT. To support the configuration of various security policies for a single port, the SECUREPORT or TTLSPORT designation indicates that the port can use TLS/SSL, but the port does not have to use TLS/SSL.

Telnet supports both negotiated and non-negotiated TLS/SSL. Negotiated TLS/SSL is an IETF-defined extension to the TN3270 protocol. With negotiated TLS/SSL, the decision to use TLS/SSL for a connection is based on the outcome of a negotiation

between the Telnet client and server using TN3270 protocols. This negotiation is performed after the Telnet connection is established, and if TLS/SSL is negotiated, the TLS/SSL handshake is performed. With non-negotiated TLS/SSL, a TLS/SSL handshake is required immediately after the connection is established. A single port can concurrently use both negotiated and non-negotiated TLS/SSL connections.

Figure 27 shows a single Telnet port that allows a mix of secure and non-secure traffic. Intranet clients are not required to be secure. All clients connecting from the Internet are required to use SSL. Both intranet and Internet clients connect to the port designated as SECUREPORT (port 23 in this example). In this scenario, IPSec AH protocol is used for authentication between the user's PC and the firewall. The firewall is open for port 23 for traffic that is authenticated with only IPSec. The firewall discards traffic for port 23 that IPSec cannot authenticate. In this scenario, packet filtering without IPSec cannot be used at the firewall that separates the intranet and the Internet to control access on the basis of port, because only one port is used. Without IPSec AH, all access control checks are deferred to Telnet. The additional security provided by IPSec at the firewall protects the zSeries server from unauthorized access attempts and denial-of-service attacks by hosts outside the VPN.

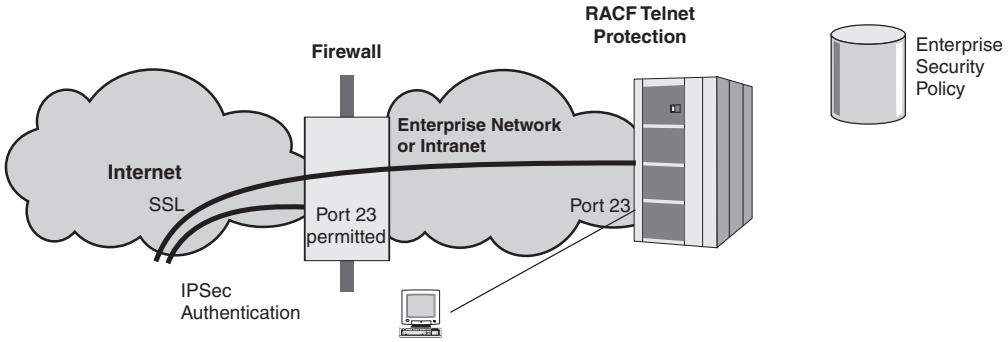

Figure 27. Secure and non-secure traffic using a single Telnet port

Express Logon Feature

With emulator products, the traditional method of authenticating the user is through user ID and password which is kept in sync with the host access control facility (RACF, ACF/2, AS/400® user management, etc.). The Express Logon Feature (ELF) simplifies user ID and password administration for users signing on to SNA applications using Telnet. ELF allows an end user to use an SSL-authenticated X.509 certificate for authentication to the SNA application instead of using a user ID and password. ELF requires IBM Host Integration software. The Host Integration requirements depend on the configuration.

There are two network designs available; a two-tier or a three-tier approach. Both are discussed in Appendix C, “Express Logon Feature,” on page 1489.

TLS-enabled FTP

The Communications Server FTP server and client support Transport Layer Security (TLS). This support enables secure file transfer by providing data privacy, message authentication, and message integrity services for data sent and received using the FTP control and data connections.

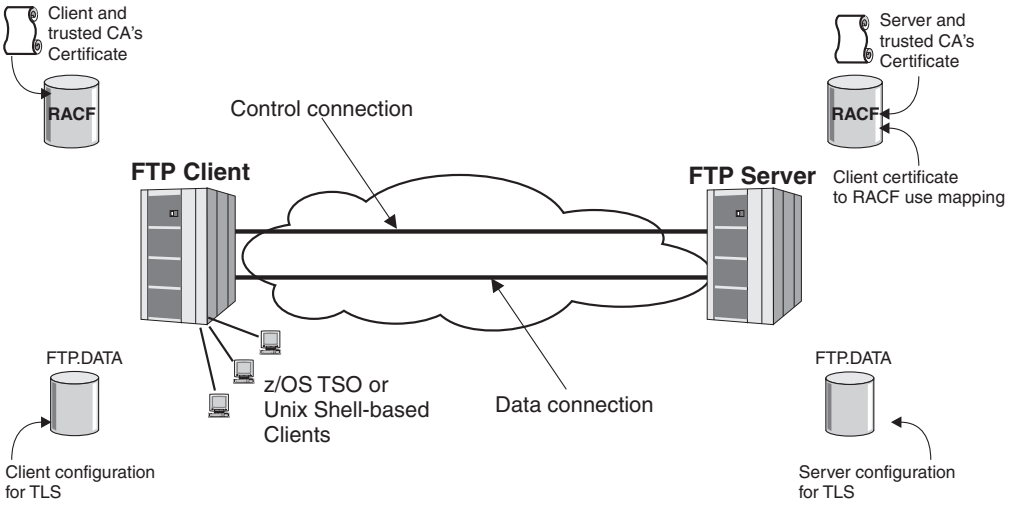

Figure 28. FTP client and server TLS overview

The TLS-enabled FTP server can be configured to run in two modes. Conditional mode allows an installation to use a single port for both TLS and non-TLS FTP control connections. In conditional mode, the FTP client and server negotiate the use of TLS based on a subset of the FTP security negotiation functions documented in RFC 2228. Once the use of TLS is negotiated, the TLS handshake is performed which establishes the TLS session and negotiates security parameters and session keys. Unconditional mode allows an installation to use a separate port for all TLS traffic. The port specified by the TLSPORT statement in FTP.DATA (port 990 by default) is the port designated for control connections for unconditional TLS mode. With unconditional mode, it is assumed that TLS is required, and after the FTP control connection is made, the TLS handshake is performed.

TLS secures the control connection and optionally the data connection. TLS for the data connection requires a TLS session for the control connection. FTP server configuration controls whether the FTP server requires TLS for the control and data connections. This TLS protection by connection type is negotiated during the FTP RFC 2228 negotiation that precedes the TLS handshake. During the lifetime of the control connection, the use of TLS or no TLS for the data connection can be requested by the FTP client using the FTP RFC 2228 commands.

FTP TLS optionally authenticates the client during the TLS handshake using a client X.509 certificate. FTP server configuration specifies whether TLS client authentication is required and what type of validation of the certificate is required. For example, the FTP server can be configured to map the client certificate to a RACF userid and then verify that the userid associated with the certificate matches the userid entered by the end user.

Configuration to control TLS capabilities and options for both FTP client and server TLS are stored in the FTP.DATA data set.

Application Transparent Transport Layer Security

Communications Server provides for invocation of System SSL in the TCP transport layer of the stack. Application Transparent Transport Layer Security (AT-TLS) support is controlled by the TTLS or NOTTLS parameter on the TCPCONFIG statement in the TCP/IP profile. When AT-TLS is enabled, AT-TLS statements in Policy Agent define the security attributes for connections that match AT-TLS rules. This policy-driven support can be deployed transparently

underneath many existing sockets, leaving the application unaware of the encryption and decryption being done on its behalf. Support is also provided for applications that need to negotiate TLS or need to participate in client authentication. These applications must be aware of AT-TLS support and use ioctl support provided by AT-TLS. AT-TLS supports the TLS, SSLv3, and SSLv2 protocols. For more details, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

Kerberos

Kerberos is a network authentication protocol that is designed to provide strong authentication for client/server applications using secret-key cryptography. The Kerberos network authentication protocol assumes that services and workstations communicate over an insecure network. It allows clients and servers to do either one way, or two way (mutual) authentication. It allows for data encryption and prevents passwords from having to be retyped to access networked services and also prevents their transmission in plain text over the network. This feature can help reduce the need to manage multiple passwords.

z/OS Communications Server no longer ships Kerberos Version 4. z/OS Integrated Security Services ships Kerberos Version 5. Because Integrated Security Services Kerberos does not require DCE login and eliminates the need for multiple registries, it is recommended that new applications be written to Kerberos Version 5 and use z/OS Integrated Security Services.

The following Communications Server IP applications now include support for Kerberos Version 5 security protocol:

- The UNIX System Services Telnet Server now allows clients supporting Kerberos Version 5 (as described in RFC 1416) to log in to the shell environment using Kerberos as the authentication protocol.
- The FTP client and Server now support connections to or from other clients and servers supporting Kerberos Version 5 authentication for the FTP protocol (as described in RFC 2228).
- The UNIX System Services RSH server can now also be configured to support client authentication using Kerberos from RSH clients supporting Kerberos Version 5.

OSPF authentication

Communications Server OSPF (Open Shortest Path First) dynamic routing protocol supports message authentication and message integrity of OSPF routing messages through the use of the OSPF MD5 Authentication security protocol as defined by RFC 2328. OSPF MD5 Authentication ensures that an unauthorized IP resource cannot inject OSPF routing messages into the network without detection, thus ensuring the integrity of the routing tables in the OSPF routing network.

OMPROUTE computes a secure MAC for the routing message using the MD5 algorithm. This MAC is sent with the routing message so that the message can be authenticated by the receiver.

Secure DNS

The Communications Server supports DNS at the Version 9.1 of BIND. This level of DNS has built-in security features, DNSSEC and TSIG.

DNSSEC

DNSSEC ensures that DNS query results are not spoofed and in fact originate from a trusted DNS. DNSSEC defines extensions to DNS that provide data integrity and authentication to security aware resolvers and applications through the use of cryptographic digital signatures. DNSSEC is defined by the IETF in RFC 2535.

TSIG

TSIG is a protocol for Secret Key Transaction Signatures for DNS. This protocol allows for transaction level authentication using shared secrets and one way hashing. It authenticates dynamic updates as coming from an approved client, or responses as coming from an approved recursive name server.

SNMPv3

z/OS Communications Server SNMP supports SNMPv3. The legacy community-based protocols SNMPv1 and SNMPv2 are also supported. SNMPv3, defined in RFCs 3410 through 3415 is the standards-based solution for SNMP security. It is categorized as a User-based Security Model (USM) which provides different levels of security based on the user accessing the managed information. To support this security level, the SNMPv3 framework defines several security functions, such as USM for authentication and privacy, and view-based access control model (VACM) which provides the ability to limit access to different MIB objects on a per-user basis, and the use of authentication and data encryption for privacy. However, SNMP is not just enhanced security. It defines an architecture for SNMP management frameworks, with the intent that pieces of the architecture can advance over time without requiring the entire structure to be rewritten. For that reason, three major subsystems are defined:

- Message processing subsystem
- Security subsystem
- Access control subsystem

The framework is structured so that multiple models can be supported concurrently and replaced over time. For example, although there is a new message format for SNMPv3, messages created with the SNMPv1 and SNMPv2 formats can still be supported. Similarly, the user-based security model can be supported concurrently with the community-based security models previously used. For more information on SNMPv3 and configuring SNMPv3 support, see Chapter 25, “Simple Network Management Protocol,” on page 1325. For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1555.

Security event reporting: Integrated Intrusion Detection Services

Intrusion is a broad term encompassing many undesirable activities. The objective of an intrusion may be to acquire information that a person is not authorized to have (*information theft*). It may be to cause business harm by rendering a network, system or application unusable (*denial of service*). Or it may be to gain unauthorized use of a system as a stepping stone for further intrusions elsewhere. Most intrusions follow a pattern of information gathering, attempted access and then destructive attacks. Some attacks can be detected and neutralized by the target system. Other attacks cannot be effectively neutralized by the target system. Many of the attacks also make use of spoofed packets which are not easily traceable to their true origin. Many attacks now make use of unwitting accomplices - machines or networks that are used without authorization to hide the identity of the attacker. For these reasons, detecting information gathering, access attempts and attack accomplice behaviors is a vital part of intrusion detection.

Attacks can be initiated from outside the internal network or from inside the internal network. Particularly vulnerable is an open system such as a public Web server or any machine that is placed in service to serve those outside the internal network. A firewall can provide some level of protection against attacks from outside. However, it cannot prevent attacks once the firewall has authorized an external host to communicate with hosts in the internal network, nor can it provide protection in the case where the attack is initiated from inside the network. In addition, end to end encryption limits the types of attacks that can be detected by an intermediate device such as a firewall.

An Intrusion Detection System can provide detection of some types of attacks. Common intrusion detection system types currently deployed are network sniffers or sensors and vulnerability scanners. Sniffers, placed at strategic points in the network (in front or behind a firewall, in the network, or in front of a host), operate in promiscuous mode, examining traffic real-time that passes through on the local network. Sniffers use *pattern matching* to try to match a packet against a known attack which is expressed as an *attack signature*. Sniffers work best against single packet attacks. Limitations are that they cannot deflect the attacking packet, and they cannot evaluate against encrypted data. Scanners do not detect intrusions in real-time. They examine a system periodically looking for vulnerabilities or evidence of intrusion. Some scanners evaluate historical data and can identify behavioral anomalies and patterns associated with intrusions.

The z/OS Communications Server provides Intrusion Detection Services (IDS) which enable the detection of attacks and the application of defensive mechanisms on the z/OS server. The focus of IDS is self-protection. IDS can be used alone or in combination with an external network-based Intrusion Detection System. The IDS is integrated into the z/OS Communications Server stack and can provide the following functions unavailable from an external Intrusion Detection System.

- z/OS CS IDS evaluates data that has been encrypted by IPSec end to end after decryption on the target server system.
- z/OS CS IDS avoids the overhead of per packet examination against a table of signatures for many known attacks. This is accomplished by integrating the attack detection probes into existing error detection logic. This detection is done in real-time. IDS policy is examined when an attack is detected to determine the action to be taken.
- z/OS CS IDS detects statistical anomalies real-time. Real-time detection is achieved since it is easier for the target system to keep stateful data/internal thresholds and counters.
- z/OS CS IDS implements prevention type of policies that are executed on the system that is the target of the attack. Prevention policies include packet discard and connection limiting.

The IDS is policy driven and the policies are kept in IDS configuration files or LDAP. These policies determine what actions to take for various IDS events. IDS events detected include scans, single packet attacks against the TCP/IP stack, and flooding. Actions include packet discard, connection limiting, and reporting. IDS events can be recorded in syslog files and/or the console. IDS statistics can be recorded in syslog. Packet traces can be taken to document suspicious activities. The TRMDSTAT command provides summary and detailed reporting of IDS events and statistics.

Figure 29 on page 144 shows the z/OS Communications Server IDS architecture.

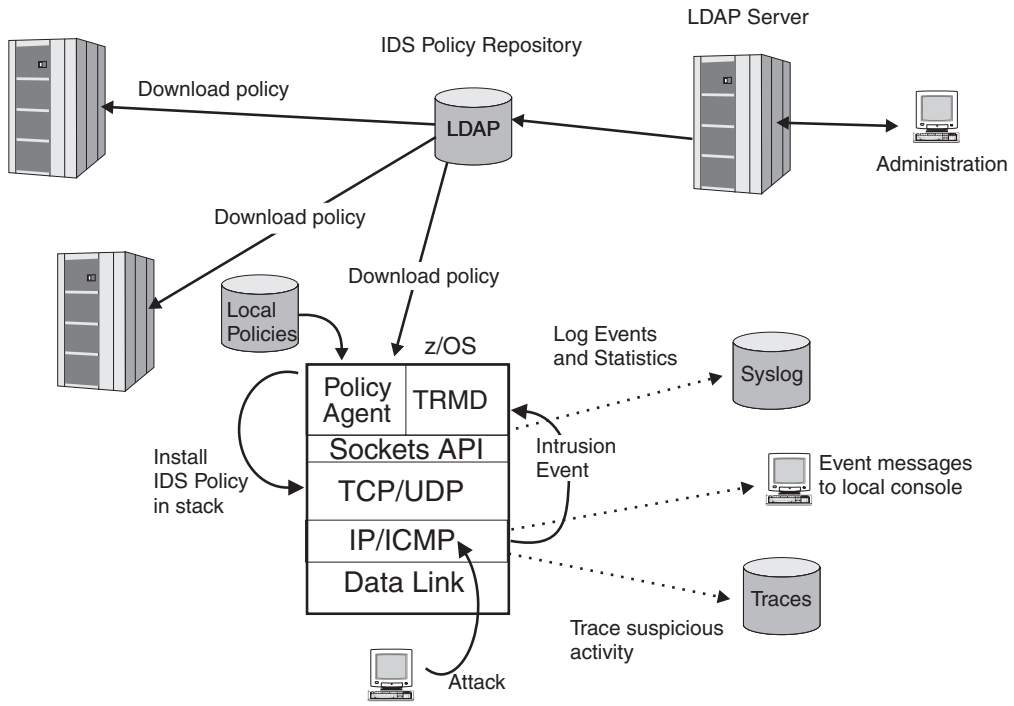

Figure 29. Intrusion Detection Services overview

For more information on IDS, see Chapter 18, "Intrusion Detection Services," on page 897.

Defensive filtering

An external security information and event manager, through analysis and correlation of messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in the TCP/IP stack. A defensive filter is a rule to discard packets, separate from IP security filters. Filter processing matches a defensive filter rule to data traffic, based on any combination of IP source or destination address, protocol, source or destination port, or direction of flow. Filter processing checks defensive filters before IP security filters.

The z/OS UNIX **ipsec** command provides the ability to add and manage defensive filters. Defensive filters are typically added automatically as a result of an external security information and event manager's analysis. However, you can also add a defensive filter by manually issuing the **ipsec** command. The Defense Manager daemon (DMD) is an integral part of managing the defensive filters.

Figure 30 on page 145 shows an overview of defensive filtering and the DMD.

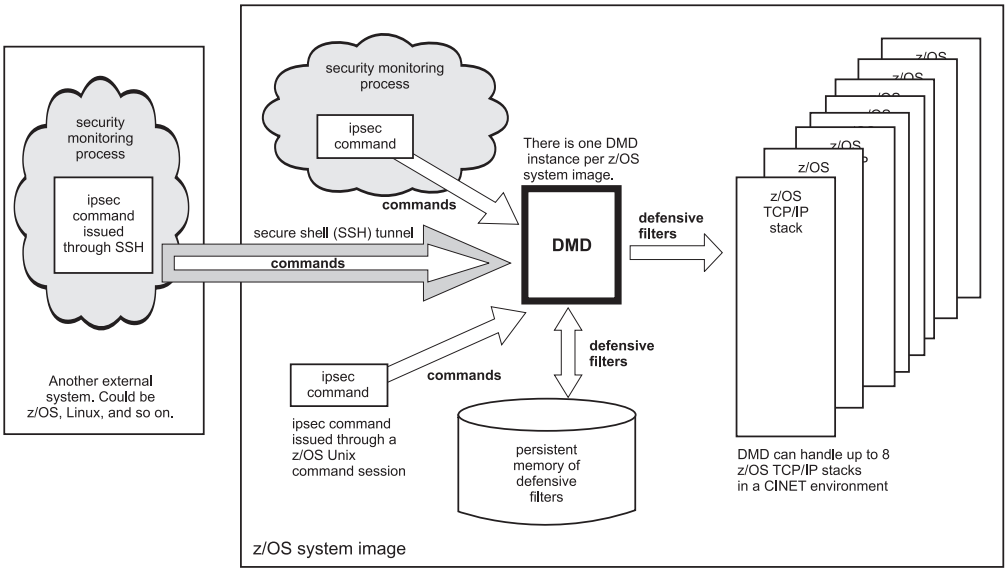

Figure 30. Defensive filtering overview

For more information about defensive filters and the DMD, see Chapter 21, "Defensive filtering," on page 1177.

Network security services for the IPSec discipline

The network security services (NSS) server provides a set of network security services for the IPSec discipline. These services include a certificate service and a remote management service. The certificate service and remote management service are used by NSS IPSec clients. When an NSS IPSec client uses the certificate service, the NSS server creates and verifies digital signatures on the behalf of the NSS IPSec client. The need to store certificates and keying information at the client, which might reside in a less secure zone of the network, is eliminated. When an NSS IPSec client uses the remote management service, the NSS server routes IPSec network management interface (NMI) requests to that NSS IPSec client, which enables the NSS IPSec client to be managed remotely. The NSS IPSec client provides the NSS server with responses to these requests.

You can configure the IKE daemon to act as an NSS IPSec client on behalf of multiple TCP/IP stacks. Each stack appears as a separate NSS IPSec client to the NSS server. Use the **-z** option on the **ipsec** command or use the IPSec NMI to manage NSS IPSec clients that use the remote management service provided by the NSS server. For details about using the **ipsec** command to manage NSS IPSec clients, see *z/OS Communications Server: IP System Administrator's Commands*. For details about using the IPSec NMI to manage NSS IPSec clients, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

An NSS IPSec client requires a SAF user ID on the NSS server system. To use the services provided by the NSS server, this user ID must have read access to specific SERVAUTH resource profiles. The following SERVAUTH resource profiles apply to an NSS IPSec client:

- EZB.NSS.*sysname.clientname*.IPSEC.CERT

  This profile authorizes an NSS IPSec client to access the IPSec certificate service of the NSS server.
- EZB.NSS.*sysname.clientname*.IPSEC.NETMGMT

This profile authorizes an NSS IPSec client to use the IPSec remote management service of the NSS server. The IPSec remote management service of the NSS server enables an NSS IPSec client to be managed by the NSS server.

- EZB.NSSCERT.*sysname.mappedlabelname*.HOST

  This profile authorizes an NSS IPSec client to access a personal certificate or a site certificate on the key ring of the NSS server. A profile entry is required for each personal certificate or site certificate associated with an NSS IPSec client. The certificates are used during a phase 1 security association negotiation that uses the digital signature mode of authentication.

- EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH

  This profile authorizes an NSS IPSec client to access a CERTAUTH certificate on the key ring of the NSS server. A profile entry is required for a CERTAUTH certificate connected to the key ring of the NSS server if the following are true:

  – That certificate's label is configured on the CaLabel parameter of a RemoteSecurityEndpoint statement within the IPSec policy definitions for an NSS IPSec client. For details about the RemoteSecurityEndpoint statement, see *z/OS Communications Server: IP Configuration Reference*.

  – An NSS IPSec client wants to include information about the corresponding certificate authority (CA) to a remote security endpoint. The information is part of the default set of CAs sent when the CaLabel parameter is not specified on the matching RemoteSecurityEndpoint statement.

For additional details about the definition of these profiles, see Chapter 20, "Network security services," on page 1149.

The following SERVAUTH resource profiles apply when you use the **-z** option of the **ipsec** command or the IPSec NMI to manage NSS IPSec clients:

- EZB.NETMGMT.*sysname.clientname*.IPSEC.DISPLAY

  This profile authorizes a user ID to issue the **ipsec** command with the **-z** option to obtain information about an NSS IPSec client, or to make IPSec NMI requests to obtain information about an NSS IPSec client.

- EZB.NETMGMT.*sysname.tcpname*.IPSEC.CONTROL

  This profile authorizes a user ID to make IPSec NMI requests to modify the IPSec state of a local stack.

- EZB.NETMGMT.*sysname.clientname*.IPSEC.CONTROL

  This profile authorizes a user ID to issue the **ipsec** command with the **-z** option to modify the IPSec state of an NSS IPSec client, or to make IPSec NMI requests to modify the IPSec state of an NSS IPSec client.

- EZB.NETMGMT.*sysname.sysname*.NSS.DISPLAY

  This profile authorizes a user ID to issue the **ipsec** command with the **-x** option or to make IPSec NMI requests to obtain information about an NSS server. This profile also authorizes a user ID to issue the **nssctl** command to make NMI requests to obtain information about an NSS server.

For additional details about the definition of the profiles to use the **ipsec** command to manage NSS IPSec clients, see *z/OS Communications Server: IP System Administrator's Commands*. For additional details about the definition of the profiles to use the IPSec NMI to manage NSS IPSec clients, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

The following SERVAUTH resource profile applies when the **-w** option of the **ipsec** command or the IPSec NMI is used to display information about an IKE daemon's NSS IPSec clients:

- EZB.NETMGMT.*sysname*.*sysname*.IKED.DISPLAY

  This profile authorizes a user ID to issue the **ipsec** command with the **-w** option or make IPSec NMI requests to obtain information about an IKE daemon's NSS configuration.

For additional details about the definition of this profile to use the **ipsec** command to manage NSS IPSec clients, see *z/OS Communications Server: IP System Administrator's Commands*. For additional details about the definition of this profile to use the IPSec NMI to manage NSS IPSec clients, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Before accessing an IPSec network security service, an NSS IPSec client must present a valid credential. A valid credential consists of the user ID representing the NSS IPSec client and a valid password or PassTicket. For additional information about using a PassTicket, see *z/OS Security Server RACF Security Administrator's Guide*.

Certificates and private keys that represent an NSS IPSec client are stored on a single SAF key ring. The NSS server must have access to the certificates on this key ring. The private key associated with a certificate is never sent to the NSS IPSec client. When an NSS IPSec client uses the authentication mode of a digital signature, the NSS server creates a digital signature on the client's behalf. Before the NSS server accesses a personal certificate to create a digital signature on behalf of an NSS IPSec client, the NSS server verifies that the NSS IPSec client is authorized to use that certificate (and its associated private key) by checking the EZB.NSSCERT.*sysname*.*mappedlabelname*.HOST profile.

Certificates of certificate authorities that are supported by NSS IPSec clients must also be stored on this single key ring. The NSS server provides NSS IPSec clients with information about certificate authorities to which the client has access. The NSS IPSec client advertises certificate authority information to its peer when digital signature mode is used for authentication. The EZB.NSSCERT.*sysname*.*mappedlabelname*.CERTAUTH profile identifies which certificate authorities an NSS IPSec client can advertise to its IKE peers. For information about this profile name, see "NSS server certificate label naming considerations" on page 1158.

Figure 31 on page 148 shows an example of the IKE daemon acting as an NSS IPSec client for a single TCP/IP stack. The IKE daemon's configuration file identifies which network security services are to be used by a stack, as well as the information about the NSS server from which these services are to be obtained. If the NSS certificate service is enabled for a stack, the IKE daemon uses this service during a phase 1 negotiation when a digital signature mode of authentication is used. If the NSS IPSec remote management service is enabled for a stack, the IKE daemon responds to management requests initiated from the NSS server.

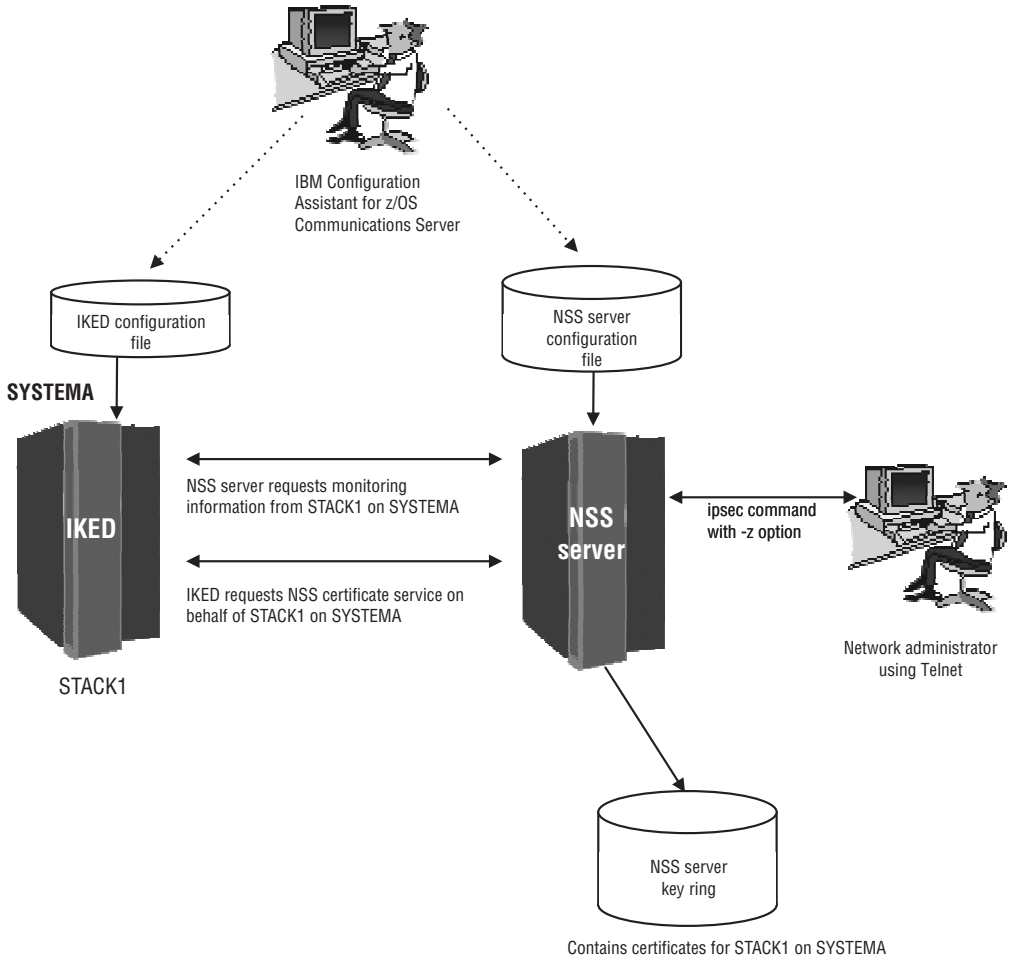

Figure 31. IKE daemon acting as an NSS client for a single TCP/IP stack

The example in Figure 31 is a trivial example involving one TCP/IP stack acting as an NSS client. As shown in Figure 32 on page 149, the NSS server can provide services to many NSS clients. The IKE daemon on a z/OS system can act as an NSS client for up to eight TCP/IP stacks (that is, one for each stack running on that system). Multiple IKE daemons can simultaneously access network security services. These IKE daemons do not have to reside within the same sysplex as the NSS server.

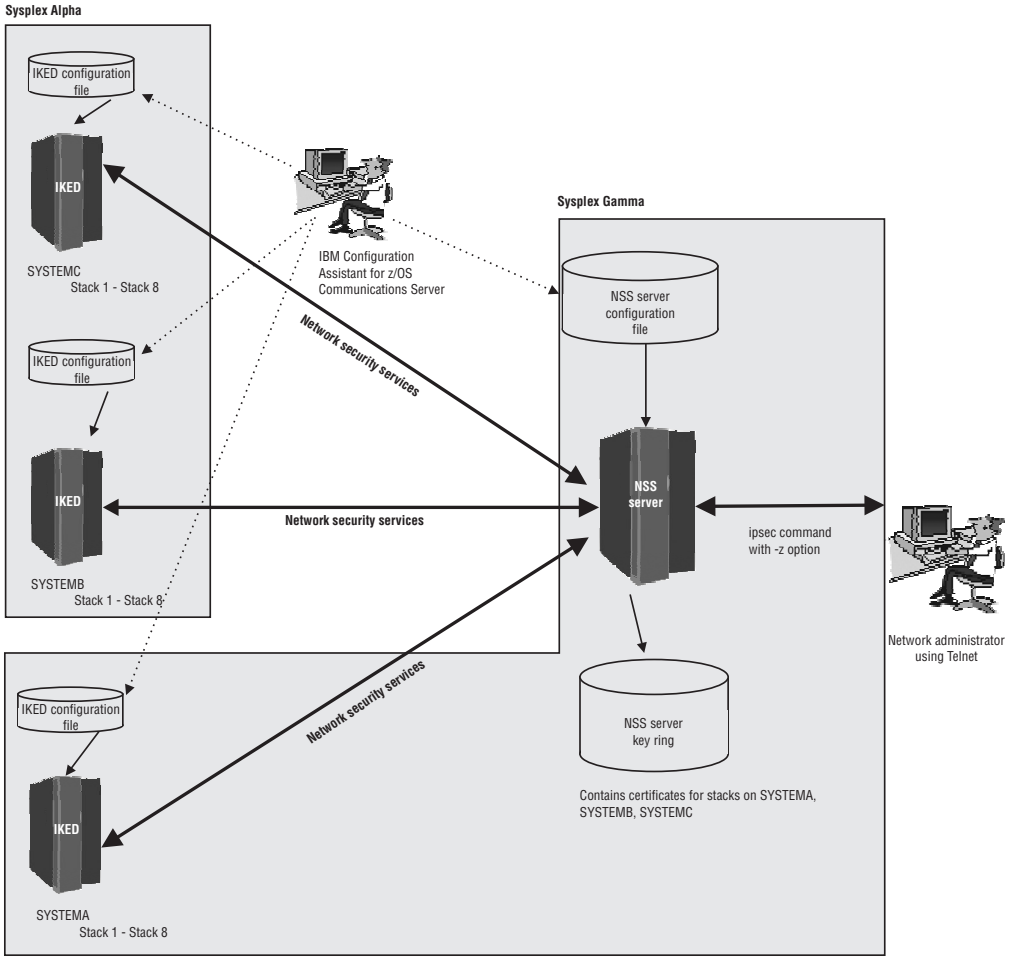

Figure 32. IKE daemon acting as an NSS client for multiple TCP/IP stacks

Network security services for the XMLAppliance discipline

The network security services (NSS) server provides a set of network security services for the XMLAppliance discipline. Services include the SAF access service, the certificate service, and the private key service. NSS XMLAppliance clients can use the network security services in the XMLAppliance discipline. When an NSS XMLAppliance client uses the XMLAppliance SAF access service, the NSS server performs SAF user authentication and access control checks on behalf of the NSS XMLAppliance client. The XMLAppliance certificate service allows an authorized NSS XMLAppliance client to list and retrieve certificates on the configured key ring of the NSS server. The XMLAppliance private key service allows an authorized NSS XMLAppliance client to retrieve private keys that are stored in RACF, generate digital signatures using private keys protected by Integrated Cryptographic Service Facility (ICSF), and perform decryption using ICSF-protected private keys. The NSS server does not support retrieval of ICSF-protected private keys. The NSS server uses its z/OS SAF database to protect unauthorized access to individual certificates and private keys.

Restrictions:

- Because support for digital signature generation and decryption requires the use of ICSF-protected private keys, the applicable Crypto Express2 feature must be defined as a coprocessor, not as an accelerator.
- The XMLAppliance private key service requires that public and private keys be associated with X.509 certificates.

An NSS XMLAppliance client requires a SAF user ID on the NSS server system. To use the XMLAppliance services provided by the NSS server, this user ID must have read access to SERVAUTH resource profiles for each XMLAppliance service. The following SERVAUTH resource profiles apply to an NSS client using XMLAppliance services:

- EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.SAFACCESS

  This profile authorizes an NSS XMLAppliance client to access the XMLAppliance SAF access service of the NSS server.
- EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.CERT

  This profile authorizes an NSS XMLAppliance client to access the XMLAppliance certificate service of the NSS server.
- EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.PRIVKEY

  This profile authorizes an NSS XMLAppliance client to access the XMLAppliance private key service of the NSS server.
- EZB.NSSCERT.*sysname*.*mappedlabelname*.HOST

  This profile authorizes an NSS XMLAppliance client to access a certificate on the key ring of the NSS server. Use the .HOST or .CERTAUTH profile to authorize an NSS XMLAppliance client to list or retrieve a particular certificate.
- EZB.NSSCERT.*sysname*.*mappedlabelname*.CERTAUTH

  This profile authorizes an NSS XMLAppliance client to access a certificate on the key ring of the NSS server. Use the .CERTAUTH or .HOST profile to authorize an NSS XMLAppliance client to list or retrieve a particular certificate.
- EZB.NSSCERT.*sysname*.*mappedlabelname*.PRIVKEY

  This profile authorizes an NSS XMLAppliance client to access the private key associated with a certificate on the key ring of the NSS server. Access to the private key is allowed only if all of the following conditions are true:
  - The private key of the certificate is stored in RACF
  - The private key of the certificate is not stored in the ICSF public key data set (PKDS)
  - The ring usage of the certificate is personal
  - The user ID of the NSS XMLAppliance client has read access to the appropriate certificate label profile (EZB.NSSCERT.*sysname*.*mappedlabelname*.PRIVKEY).
- EZB.NETMGMT.*sysname*.*sysname*.NSS.DISPLAY

  This profile authorizes a user ID to issue the **nssctl** command to make NMI requests to obtain information about an NSS server.

Tip: You can specify a wildcard in the profiles to reduce the number of profile entries that you must define.

Before accessing the XMLAppliance services, an NSS XMLAppliance client must present a valid credential. A valid credential consists of the user ID that represents the NSS XMLAppliance client and a valid password or PassTicket. For additional information about using a PassTicket, see *z/OS Security Server RACF Security Administrator's Guide*.

You control access to certificates and private keys using SAF profiles. The profile name contains a mapped label name that represents the label of the certificate. For information about this profile name, see “NSS server certificate label naming considerations” on page 1158.

Chapter 4. Preparing for TCP/IP networking in a multilevel secure environment

Use this information to configure a z/OS Communications Server stack and applications in a multilevel secure environment.

Tip: Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

The documentation for many of the applications described in this information references the EZARACF member of sample data set SEZAINST. For examples of the RACF commands used for multilevel security, see the EZARACFM member of sample data set SEZAINST.

Understanding multilevel security concepts

IBM's multilevel security for z/OS has access control implications for your entire system. z/OS Communications Server TCP/IP is only one element of a multilevel secure z/OS system environment. Before planning your multilevel secure TCP/IP network, you should be familiar with the concepts and terminology presented in *z/OS Planning for Multilevel Security and the Common Criteria*.

Multilevel secure networking

The security administrator is responsible for defining the security levels and categories required in a multilevel secure environment. These become part of the set of security labels used to enforce mandatory access control policies when applications access resources on behalf of users. All of the systems enforcing mandatory access control policies in a multilevel secure network must have equivalent definitions of these security labels and the systems in the network to which they apply.

In the networking environment, the information that is being protected is the data being read and written through sockets. Sockets are opened and used by applications running under user IDs. In a z/OS multilevel secure environment:

- Each user ID is permitted to use one or more security labels.
- Every job or login session is associated with a user ID.
- A user ID can use only one security label for each job or login session.
- The security label used is limited by the port of entry (source type and location) of the job or login session.

Applications can have read access to information from many sources that can have various security labels. This information might be commingled in the buffers used to write information to the network. TCP/IP treats all socket data buffers as having the security label of the writing task. All sockets are inherently read/write, so TCP/IP requires communicating partners to have equivalent security labels in a multilevel secure environment.

Nonsecure systems

Most systems do not support mandatory access control processing. If these systems are not physically managed, they normally should not participate in a multilevel secure network. Some installations might need to permit them to participate. In these cases, it is recommended that they be assigned a security label with the lowest security level and a single security category that is not common with any other security label.

Managed systems

Systems that do not support mandatory access control processing can participate in a multilevel secure network, if they are physically managed to guarantee that all information on the system has the same single security label and all users of the system are permitted to that security label. These systems are referred to as single-level security or managed systems in this information. This management requires both physical control of the systems and careful management of the network. Managed systems must be prevented from communicating with other managed systems that do not have equivalent security labels.

Systems that support mandatory access control and are configured to implicitly associate the correct security label with each managed system can also communicate with managed systems. The systems that perform mandatory access control are responsible for ensuring that only information from applications with an equivalent security label is sent to a managed system, and that information received from a managed system is given only to applications with an equivalent security label.

Multilevel secure systems

Some systems in the network provide multilevel secure environments. These systems have mechanisms to associate security labels with information accessed through the system and with users logged into the system. The system enforces mandatory access control policies to ensure proper separation of information.

Other systems cannot normally associate a single security label with IP addresses owned by a multilevel secure system. The packets being sent from a single IP address on the multilevel secure system might have originated from applications running under different security labels.

Applications on a multilevel secure system can securely communicate with applications on a managed system. Mandatory access control enforcement occurs only on the multilevel secure system. The multilevel secure system is responsible for ensuring that it sends only information from an application with an equivalent security label to any managed system. It also is responsible for ensuring that information received from a managed system is delivered only to an application with an equivalent security label.

When two applications on multilevel secure systems communicate, the security label of the sending application must be communicated to the receiving system so that the receiving system can enforce mandatory access control prior to delivering the information to an application. One mechanism to accomplish this is for the sending system to pass the security label with each packet. The two multilevel secure systems must share a common definition and representation of the security labels that are passed.

z/OS Communications Server TCP/IP stacks on z/OS multilevel secure systems

A z/OS CS TCP/IP stack running in a z/OS multilevel secure environment can optionally be configured as either a restricted stack or an unrestricted stack. A restricted stack is configured with a user ID that is defined with a security label other than SYSMULTI. An unrestricted stack is configured with a user ID that is defined with a security label of SYSMULTI. A single z/OS system can concurrently run up to eight z/OS CS TCP/IP stacks, which can be any mix of restricted and unrestricted stacks.

In either mode of operation, appropriate mandatory access control processing is performed at the transport layer. z/OS Communications Server stacks can be host systems on trusted subnetworks. z/OS Communications Server stacks do not perform mandatory access control processing at the link or network layers, so security labels are not considered in packet forwarding with the exception of sysplex distributor, as described in "Configuring stack sysplex features in a multilevel secure environment" on page 162. Packets that contain security labels are not forwarded by a restricted stack. These packets are discarded by the restricted stack.

Restricted stacks

In this mode of operation, the stack ensures that all sockets are opened by applications running with a security label that is equivalent to the security label of that stack. This guarantees that all information sent by the stack can be implicitly associated with that stack's security label. The stack also ensures that all information received from the network and delivered to an application is equivalent to the stack's security label. A restricted stack can be viewed by other multilevel secure systems as if it were a managed system.

It is important to note that even though a restricted stack is running under a specific security label, it still receives packets from the network with information covered by different security labels. A restricted stack discards this information rather than deliver it to any local applications. However, this information can appear in storage dumps, logic traces, and packet traces. Diagnostic information should always be protected under the highest security label (SYSHIGH).

Unrestricted stacks

In this mode of operation, the stack allows sockets to be opened by applications with any security label. The stack supports mandatory access control processing that allows its applications to communicate securely with any other managed system or restricted stack.

For applications on unrestricted stacks to communicate securely with each other, Communications Server must be able to determine the security label of the sending application. Unrestricted stacks are permitted to define VIPAs in network security zones with security labels other than SYSMULTI. When one of these is used as either the source or destination IP address of a packet, it implicitly identifies the security label of the information. When both IP addresses in a packet are in security zones with the SYSMULTI security label, the application security label must be explicitly transmitted in the packet. This is known as packet tagging.

Communications Server implements a proprietary form of packet tagging to pass the security label of the sending application to the receiving stack for mandatory access control enforcement against the receiving application. Because of this proprietary format, communications between applications on unrestricted stacks

that require packet tagging are supported only when both of those stacks are on the same z/OS system and are communicating over an IUTSAMEHOST link, or are members of the same z/OS sysplex and are communicating over an XCF link.

Stack recognition of a multilevel secure environment

You can activate the SAF SECLABEL class and define security labels on SERVAUTH profiles. This causes the security server to enforce mandatory access control policies for those resources without fully activating a multilevel secure environment. The z/OS Communications Server stack does not perform its extra mandatory access control policy enforcement until you issue the RACF command SETROPTS MLACTIVE. When running with SETROPTS NOMLACTIVE, you should not use unrestricted stacks or define network security zones with a SYSMULTI security label.

When a NetAccess statement is encountered in TCPIP profile processing and MLACTIVE has been set, the stack activates extra mandatory access control policy enforcement in both restricted and unrestricted stacks as follows:

- New sockets are allowed only if a STACKACCESS profile covers this stack.
- Network access is allowed only to IP addresses that are mapped into network security zones covered by NETACCESS profiles.
- Restricted stacks do not normally allow SYSMULTI tasks to have network access to security zones with security labels that are not equivalent to the stack's security label. For more information, see “Exempting certain users of certain programs from full Network Access Control” on page 161.
- Unrestricted stacks transmit packet labels both internally and externally to enable an extra mandatory access control check, between the sending task's security label and the receiving task's security label, when both IP addresses are in security zones with a SYSMULTI security label.
- Distributing stacks consider security labels in choosing target applications.
- TN3270E Telnet servers consider security labels in mapping connections to LU names.
- Internal configuration consistency checks are performed whenever PROFILE.TCPIP or certain SERVAUTH class profile changes are made.

Common INET in a multilevel secure environment

When you start several TCP/IP stacks under OMVS, you are using the Common INET (CINET) PFS. Users and jobs can optionally establish affinity to a single stack, or they can allow CINET to choose a stack. If stack affinity is not set, CINET replicates the socket() command to all stacks attached to it. If a job or user does not have READ access to any of the attached stacks, RACF might generate audit failure messages for those stacks. As long as at least one stack accepts the socket() command, CINET will return success to the application. CINET then routes subsequent commands on that socket to one or more of the stacks that accepted the socket() call. For further information on CINET, see *z/OS UNIX System Services Planning*.

Network security zones

A network security zone is an administrative name for a collection of systems that require the same access control policy. IP addresses are used to map systems into security zones. This requires that the IP addresses used in your multilevel secure network be predictably associated with a single system or group of systems with the same access control policy. A network security zone can contain a single IP address or any combination of IP addresses and subnetworks. All of the IP

addresses in a security zone must have the same security label, though all IP addresses with the same security label do not have to be in the same security zone.

IBM zEnterprise System ensemble

An IBM zEnterprise System (zEnterprise) node participating in an ensemble has access to the following networks:

- Intraensemble data network.

  The intraensemble data network is accessed through OSX interfaces.
- Intranode management network

  The intranode management network is accessed through OSM interfaces.

The intraensemble data network should be treated the same way as any other data network in a multilevel secure environment. The intranode management network is handled differently.

The intranode management network is for only IPv6 and provides a path for some authorized zEnterprise applications, such as those providing platform performance management functions, to communicate with another authorized system performing platform management. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*.

All traffic flowing over an OSM interface is protected by OSM access control rather than network access control. The intranode management network uses automatically generated IPv6 link-local addresses, so individual systems do not have statically assigned addresses. OSM interfaces provide isolation so that traffic can flow only between a stack connected to an OSM interface and the authorized system performing platform management.

Where your z/OS systems fit in your network

z/OS systems that are not configured with RACF SETROPTS MLACTIVE must be physically managed, as any other managed system.

z/OS systems at V1R5 or later that are configured with RACF SETROPTS MLACTIVE, have appropriate TCP/IP configuration, and have appropriate RACF SERVAUTH class profiles defined, can be placed in trusted subnetworks. Firewalls can allow any managed subnetworks to communicate with these trusted subnetworks. The trusted subnetworks will often be defined as a SYSHIGH security zone and will likely contain several individual IP addresses in other security zones, depending on the mix of restricted and unrestricted stacks within the trusted subnetwork.

Planning stacks on your z/OS systems

Before you begin, determine what z/OS systems need to participate in your multilevel secure network. For each z/OS system, determine what release level it will be running, what sysplex it is a member of, which other multilevel secure systems it needs to communicate with, and what security labels will be used.

The following subtopics include some references to additional information; more information is in *z/OS Communications Server: IP Configuration Reference* and *z/OS Security Server RACF Security Administrator's Guide*.

Required configuration in a multilevel secure environment

Some configuration statements that are optional in a discretionary security environment are required in a multilevel secure environment. The default behavior of the stack in a discretionary security environment is to permit most applications when these statements are not defined. The default behavior of the stack in a multilevel secure environment is to fail every application when these statements are not defined. Every stack must have an EZB.STACKACCESS profile in the SAF SERVAUTH class. All referenced IP addresses, except intranode management network link-local addresses, must be mapped into security zones by NetAccess statements in the TCPIP profile. A profile that covers the resource EZB.FTP.*sysname*.*ftpdaemonname*.ACCESS.HFS must be defined in the SAF SERVAUTH class for file system access by FTP users. The EZB.SOCKOPT profile must be defined for the following options in the SAF SERVAUTH class:

- IPV6_DSTOPTS
- IPV6_HOPOPTS
- IPV6_NEXTHOP
- IPV6_PKTINFO
- IPV6_RTHDR
- IPV6_RTHDRDSTOPTS
- IPV6_TCLASS
- SO_BROADCAST

In addition, if setting a hop limit greater than the default hop limit, the EZB.SOCKOPT profile must also be defined for the following options in the SAF SERVAUTH class:

- IPV6_HOPLIMIT
- IPV6_MULTICAST_HOPS
- IPV6_UNICAST_HOPS

For more information, see “TCP/IP resource protection” on page 111.

Considerations for IPv6-enabled stacks

IPv6 architecture provides for a plug-and-play environment by automatically generating IP addresses when they are not manually configured. To guarantee predictable IP address association with specific systems, you must disable this capability on z/OS Communications Server stacks through manual configuration.

The stack automatically generates link-local IP addresses using the link-local prefix and the interface ID. To make these addresses predictable, you must manually configure the INTFID parameter on all IPv6 INTERFACE statements. If you are enabling dynamic XCF, you must also manually configure the DYNAMICXCF INTFID parameter on the IPCONFIG6 statement.

Some IPv6 interface types support router autogeneration. When this is enabled, the responsible router informs the stack about prefixes that are supported and the stack generates IP addresses from those prefixes and the interface ID. You must disable this capability on all interfaces that support it, by manually configuring at least one prefix or address using the IPADDR parameter on the INTERFACE statement.

These considerations for IPv6-enabled stacks do not apply to the IBM zEnterprise System (zEnterprise) intranode management network that is accessed through OSM interfaces. Traffic over that network is protected by OSM access control rather than network access control.

Deciding whether to use restricted or unrestricted stacks

Many installations will find it easier to run a single unrestricted stack on each z/OS system. The following situations might require you to run one or more restricted stacks on a given system:

- Your installation has administrative requirements that prohibit the use of stacks that allow sockets with different security labels.
- You must allow applications to communicate with applications on a multilevel secure system that is not a z/OS system.
- You must allow applications to communicate with applications on a z/OS multilevel secure system that is not z/OS V1R5 or later.
- Your stacks are not on the same system and are not members of the same sysplex.

Configuring a restricted stack

To configure a restricted stack, do the following:

1. Determine the appropriate security label for this restricted stack. Associate a user ID with the stack job, and permit the user ID to the intended stack security label. Make that security label the default security label in the user ID profile.
2. Define a STACKACCESS profile for this stack in the SERVAUTH class with the same security label. This profile might often be UACC(READ).
3. Determine the interface and VIPA addresses needed for this stack.
4. Define one or more security zone names for this stack.

   If you have discretionary access control policies that require different treatment for some of the IP addresses on this stack, they will need to be in different security zones.
5. Define NETACCESS profiles for this stack in the SERVAUTH class with the same security label.

   If your access control policy requires only mandatory access control enforcement, this profile can be generic with respect to the z/OS system name and the TCP stack job name. It might often be UACC(READ).
6. Define a NETACCESS statement that maps this system's external IP addresses into security zone names. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.
7. If you define a SOURCEVIPA address for this stack, it must be an IP address in a security zone covered by a NETACCESS profile with the stack's security label.

Configuring an unrestricted stack

To configure an unrestricted stack, do the following:

1. Unrestricted stacks must run with the SYSMULTI security label. Associate a user ID with the stack job, and permit the user ID to the SYSMULTI security label. Make SYSMULTI the default security label in the user ID profile.
2. Define a STACKACCESS profile for this stack in the SERVAUTH class with the SYSMULTI security label. This profile might often be UACC(READ).
3. Determine the interface and VIPA addresses needed for this stack.

If you are running server applications that require multiple instances running under different security labels, you will need at least one VIPA for each security label.

4. Define security zone names for this stack.

   If you have discretionary access control policies that require different treatment for some of the IP addresses on this stack, they will need to be in different security zones.

   VIPAs defined for use with specific security labels will need to be in separate security zones.

5. Define NETACCESS profiles for this stack in the SERVAUTH class.

   Profiles created for VIPAs used with specific security labels are defined with the appropriate security label. If your access control policy requires only mandatory access control enforcement, these profiles can be generic with respect to the z/OS system name and TCP stack job name. They might often be UACC(READ).

   Profiles for other zones on this stack are defined with the SYSMULTI security label. If there are z/OS systems sharing the RACF database that are not members of the same sysplex, or that are not z/OS V1R5 or later, any generic profile should have UACC(NONE). A fully qualified profile might often be UACC(READ).

6. Define a NETACCESS statement that maps this system's IP addresses into security zone names. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.

   Tip: If you have multiple unrestricted stacks and you use the OMPROUTE routing daemon, for more information on local address security zones, see "OMPROUTE" on page 167.

7. If you enable SOURCEVIPA on IPCONFIG and IPCONFIG6 statements, in many circumstances you might be able to avoid explicit packet tagging. The source IP address selection algorithm is enhanced to consider security labels. For IPv4 interfaces defined with the LINK statement, the backward search of the HOME list stops at the first VIPA with a security label that is the same as the security label of the application, or with a security label of SYSMULTI. Place IPv4 source VIPAs in the HOME list preceding the physical interface IP addresses that can use them. VIPAs in SYSMULTI security zones should precede those in other zones. For IPv4 interfaces defined with the INTERFACE statement, use the SOURCEVIPAINTERFACE parameter to select the source VIPA. For IPv6 addresses, only addresses that have security labels the same as that of the application or SYSMULTI are considered. Addresses with equal security labels are preferred over those with a security label of SYSMULTI. Place IPv6 VIPAs on VIRTUAL6 INTERFACE statements. Use the SOURCEVIPAINTERFACE parameter on other INTERFACE statements to associate the set of source VIPAs that can be used with each IPv6 interface.

8. If you define TCPSTACKSOURCEVIPA for this stack, to avoid application failures, it must be in a security zone with a SYSMULTI security label.

Configuring global definitions for all stacks

To configure global definitions for all stacks, do the following:

- Define a security zone name for the INADDRANY and LOOPBACK addresses.

  Define a NETACCESS profile for this zone in the SERVAUTH class for each stack. This profile should be specific with respect to the z/OS system name and TCP stack job name, and should have the same security label as the stack job. It might often be UACC(READ).

Define a NETACCESS statement that maps any system's INADDRANY and LOOPBACK IP addresses into this security zone name. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.

- Define one security label that has the lowest security level and one category that is not used in any other security labels. This security label can then be used for all unknown systems. Mandatory access control access under this security label will be more restrictive than under SYSLOW.

  A task using this security label will have R/O access to resources with SYSLOW, W/O access to resources with SYSHIGH, and R/W access to resources with this security label and SYSMULTI. It will have no access to resources with any other security labels because they will be disjoint.

  Any resources created under this security label will only be readable by tasks running under this security label, SYSHIGH, and SYSMULTI. This significantly reduces the risk from unintended, publicly readable or executable, SYSLOW resources.
- Define a security zone name for all unknown systems in the multilevel secure network.

  Define a NETACCESS profile for this zone in the SERVAUTH class. This profile can be generic with respect to the z/OS system name and TCP stack job name. If your installation supports communications with unknown systems on all z/OS systems, make this profile UACC(READ). Otherwise, make it UACC(NONE).

  Define a NETACCESS DEFAULT statement that maps all unspecified IP addresses into this security zone name. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.

Exempting certain users of certain programs from full Network Access Control

There are certain network administration programs that, to be fully functional, need to be exempted from some aspects of Network Access Control. For instance, the Ping and Traceroute functions test the network path to a destination system. They often need to traverse routers or firewalls that are at IP addresses mapped into security zones that are not normally mandatory access control accessible from a particular restricted stack. ICMP error messages from these systems will not be delivered to the function, if they are not exempted from the Network Access Control check that limits all traffic to security labels equivalent to the stack security label. Also, routing protocol daemons, such as OMPROUTE, frequently need to exchange routing table information with adjacent nodes that are in security zones that might not be mandatory access control accessible from a particular restricted stack. To operate correctly, these programs must also be exempted from some aspects of Network Access Control.

A SYSMULTI user with UPDATE authority to the EZB.STACKACCESS profile will be exempt from the Network Access Control restriction that all traffic must be with partners that are in security zones with security labels that are equivalent to the stack's security label or the security label associated with the local IP address. It is recommended that this authority be limited to their usage of the programs that must be exempted. This can be accomplished by first specifying UACC(READ) when defining the STACKACCESS profiles, and then granting conditional update access to each by specifying the following:

```
PERMIT stackaccess_profile_name CLASS(SERVAUTH) ID(*) ACCESS(UPDATE) -
WHEN(PROGRAM(ping,oping,tracerte,otracert,omproute))
```

Note: The WHEN(PROGRAM()) conditional access parameter is not supported on profiles in the SERVAUTH class, except where explicitly stated. PERMITs with WHEN(PROGRAM()) on other profiles might be ignored.

Configuring stack sysplex features in a multilevel secure environment

The following considerations apply to stack sysplex features in a multilevel secure environment:

- If TCPSTACKSOURCEVIPA is configured on a stack, the specified VIPA must be in a NetAccess security zone with a security label that is identical to the stack security label.
- If you use job-specific source IP addressing (see SRCIP in *z/OS Communications Server: IP Configuration Reference*), the specified IP address must be in a NetAccess security zone with a security label that is permitted on the stack and is equivalent to the specified job. If an interface name is used, at least one of the IP addresses configured on that interface must be in a network security zone with a security label that is either SYSMULTI or equal to the specified job.
- If you use destination-specific source IP addressing (see SRCIP in *z/OS Communications Server: IP Configuration Reference*), the specified IP address must be in a NetAccess security zone with a security label that is permitted on the stack and is equivalent to the specified destination. If an interface name is used, at least one of the IP addresses configured on that interface must be in a network security zone with a security label that is either SYSMULTI or that is the same as the specified destination.
- For sysplex distributor, the distributing stack must either be an unrestricted stack or a restricted stack with a security label that is the same as all target stacks. The distributing stack will use the security label of the source security zone and the security labels of the active target applications when selecting a target. The distributing stack will also honor SECLBYSYSTEM when the target application is running under SYSMULTI on an unrestricted stack. In an environment using SECLBYSYSTEM, a distributing stack must be on a system where all security labels are active.
- VIPA takeover must be configured only between stacks with the same security label.
- Distribution of connections that require packet tagging are restricted to flowing over XCF or IUTSAMEHOST links. This restriction applies to the route from the client to the distributor, from the distributor to the target server, and from the target server back to the client.

Defining security labels on other profiles in the SERVAUTH class

A z/OS system with RACF SETROPTS MLACTIVE requires all resource profiles defined in the SERVAUTH class to have a security label. All z/OS Communications Server profiles in the SERVAUTH class have EZA, EZB, or IST as the first qualifier. Resource profiles that require meaningful security labels, such as EZB.STACKACCESS and EZB.NETACCESS, are explicitly identified in this information. The following resource profiles can be defined with the SYSNONE security label:

- EZB.SOCKOPT.*sysname.tcpname*.IPV6_DSTOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_HOPLIMIT
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_HOPOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_NEXTHOP

- EZB.SOCKOPT.*sysname.tcpname*.IPV6_PKTINFO
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_RTHDR
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_RTHDRDSTOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_TCLASS
- EZB.SOCKOPT.*sysname.tcpname*.SO_BROADCAST
- EZB.FTP.*sysname.ftpdaemonname*.ACCESS.HFS
- EZB.RPCBIND.*sysname.rpcbindname*.REGISTRY

Some installations might want to define SO_BROADCAST with the SYSLOW security label to further reduce the exposure of data write_down by restricting datagram broadcast to users running with SYSLOW or SYSMULTI. All other z/OS Communications Server resource profiles can be defined with the SYSNONE security label.

Planning your multilevel secure network

Separate your network into security zones. Each subnetwork of physically managed systems should be defined as a single security zone. Several subnetworks with identical security labels and discretionary access control policy requirements can be assigned the same security zone name. Each trusted subnetwork of self-managed multilevel secure systems likely requires several security zones. The trusted subnetwork can also contain physically managed resources, such as routers and network administrator workstations. The trusted subnetwork security zone is likely to require a SYSHIGH security label. Multilevel secure stacks within the trusted subnetwork must have their interface addresses in security zones with the security label of the stack. VIPAs are usually placed in separate subnetworks dedicated to VIPAs and containing no real interface addresses. Multicast addresses, loopback addresses, and unspecified addresses (IPv4 INADDR_ANY and IPv6 in6addr_any) require security zones as well.

The security administrator does the following:

- Defines security labels in the z/OS security server.
- Creates user IDs in the security server with appropriate security labels.
- Defines common discretionary access control policies.
- Defines the security zone name for each required combination of security label and discretionary access control policy.
- Identifies groups of managed machines that belong in each security zone.
- Provides physical security for each group of machines to ensure only users with appropriate security clearance can use them.
- Configures managed machines so that only the network administrator can set IP addresses.

The network administrator does the following:

- Isolates each group of machines into a subnetwork.
- Configures IP addresses on the machines.
- Configures a firewall to limit each group to only communicate with other subnetworks that have the same security label.
- Assigns network security zone names to subnetworks.
- Defines a NETACCESS statement that maps subnetworks and systems into network security zones. This can be placed in a shared data set that can be included in the PROFILE.TCPIP of all z/OS CS stacks in the network.

Planning for interactive UNIX System Services users in a multilevel secure environment

Interactive users of z/OS UNIX System Services that are permitted to log on with more than one security label must have a separate home directory for each security label. The approach recommended in *z/OS Planning for Multilevel Security and the Common Criteria* is similar to the following.

Steps for creating a separate home directory for each security label

Perform the following steps to create a separate home directory for each security label:

1. For each supported security label:
   a. Log on to an administrative user ID with that security label.
   b. Create a directory with the name of that security label under the /u directory.
   c. For each user permitted to that security label, create a home directory under that security label directory.

   ---

2. Create a symbolic link in the /u directory using the special value "$SYSSECR/", perhaps named symsecr as follows:

   ```
   ln  -s  "$SYSSECR/"  /u/symsecr
   ```

   Tip: When issuing this command from the shell, use double quotation marks around the $SYSSECR/ string so that the shell does not attempt variable substitution before passing it to the ln command.

   ---

3. Define all users' home directories to be '/u/symsecr/*user*' as follows:

   ```
   ALTUSER user OMVS(HOME('/u/symsecr/user'))
   ```

This approach is useful in many other situations where a different configuration is required for different security labels.

Steps for setting stack affinity by security label

Installations that start several TCP/IP stacks under UNIX System Services common INET (CINET) often find it useful to set stack affinity for most interactive users. This can most easily be done by setting the environment variable _BPXK_SETIBMOPT_TRANSPORT to the name of the stack that users should use during login profile processing, as follows:

1. Create a directory for each security label under the /etc directory.

   ---

2. Create a profile script file in each directory containing the following:

   ```
   export _BPXK_SETIBMOPT_TRANSPORT=stackname
   ```

   ---

3. Create a "$SYSSECR/" symbolic link in the /etc directory, perhaps named seclbl as follows:

   ```
   ln -s "$SYSSECR/" /etc/seclbl
   ```

4. Edit the /etc/profile script file and add the following:

```
if  test  –f   /etc/seclbl/profile
then
.  /etc/seclbl/profile
fi
```

Host and domain name by security label

Installations that start several TCP/IP stacks under UNIX System Services CINET often find it necessary to define a different host name or domain name for interactive users based on their security label. The first decision that needs to be made is what host name and domain name each TCP/IP stack will have. Two common approaches are to:

- Assign each of the stacks a different host name in the same domain name.
- Assign each of the stacks on the same z/OS image the same host name, but define a different domain name for each security label.

These names are then implemented by creating a separate resolver configuration file for each security label.

Steps for creating a separate resolver configuration file for each security label

This can be accomplished using the same directory structure under the /etc directory as follows:

1. Log in as a file system administrator with each security label.

2. Create a copy of your current resolver configuration file in each security label directory using the following command:

```
cp  /etc/resolv.conf  /etc/seclbl/rsv.cfg
```

3. Edit these new files as follows:
   a. Change the TCPIPJOBNAME statement to the appropriate stack job name.
   b. Change the HOSTNAME statement to the appropriate host name.
   c. Change the DOMAINORIGIN or first SEARCH statement to the appropriate domain for this security label.

      Tip: For information about interactions between the DOMAINORIGIN and SEARCH statements, see the TCPIP.DATA configuration statements topic in *z/OS Communications Server: IP Configuration Reference*.

4. Replace your current resolver configuration file with a symbolic link as follows:

```
ln  -s  "$SYSSECR/rsv.cfg" /etc/resolv.conf
```

Planning for applications in a multilevel secure environment

In planning for applications in a multilevel secure environment, you must first understand the multilevel security programming rules that apply to socket applications.

Trusted network administration server applications
Applications that are part of the infrastructure, such as DNS and routing. The delivered information is not sensitive and needs to be accessible across many security labels.

Trusted multilevel secure server applications
Applications with a login process using port of entry, that do all resource access under the client's login identity, and that maintain separation of information accessed by different client tasks, such as FTP and otelnet.

Process applications that change identity must do the following:

- Issue _poe() prior to identity change (can be done by parent, for example, INETD).
- Change identity in parent process prior to fork, spawn, or exec to ensure interprocess communication (IPC) resources are properly labeled.
- Access any user resources after the identity change.
- Close unnecessary parent resources prior to exec.

Threaded applications that set identity on a thread must do the following:

- Issue _poe() on handling thread prior to _pthread_security_np().
- Ensure all related processing occurs on threads that have the same identity.
- Change identity on thread prior to spawn, fork, or exec.
- Access any user resources after identity change on the thread.
- Not access any other thread's resources.
- Close all user resources before removing identity from thread.
- Remove user identity from thread before acquiring new work.

All SYSMULTI applications must ensure that they do not put user data on server resources or other user resources. Pay special attention to debugging, logging, or tracing output. Many servers include user level data in output.

Trusted single-level secure server applications
Applications that deliver sensitive information accessed under the server's identity, such as TFTP and HTTP, and applications with a login process that do not use port of entry nor access client information under the server's identity, such as SMTP and MVSHRD.

Network administration commands and client applications
Local commands, requiring special controls and privileges, that are used to query, configure, or diagnose the network infrastructure.

IBM zEnterprise System (zEnterprise) platform management applications
Authorized zEnterprise applications that perform platform management functions. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*.

General user commands and client applications
Local commands that access resources (including network resources) under the invoking user's security environment.

Unsupported applications
Applications that have not been inspected, or have been inspected and are not trusted in a multilevel secure environment.

Configuring z/OS CS applications in a multilevel secure environment

This topic describes configuration for each of the z/OS CS application categories.

Trusted network administration server applications

The following are trusted network administration server applications:

- DNS name server (BIND 9)
- OMPROUTE
- Resolver
- SNTPD
- TIMED
- TRMD
- z/OS syslog daemon (syslogd)
- z/OS UNIX Policy Agent

They can run under a user ID with the SYSMULTI security label in a multilevel secure environment, provided that they adhere to the following configuration instructions.

DNS name server (BIND 9): You can run as many instances of DNS as appropriate for your installation. Name resolution is not considered sensitive information. You can run one instance of the DNS server per z/OS image under a user identity with a SYSMULTI security label.

OMPROUTE: You should run one instance of OMPROUTE for each stack that is using dynamic route configuration. Each instance of OMPROUTE must run under a user ID with SYSMULTI. OMPROUTE communicates with multicast IP addresses. These addresses must be configured into NetAccess security zones. If OMPROUTE must communicate with adjacent nodes that are not in network security zones with security labels equivalent to the security label of the restricted stack or the security label associated with the local IP address, OMPROUTE must run under a user ID that is SYSMULTI and has update authority to the EZB.STACKACCESS resource profile. A SYSMULTI user with UPDATE authority to the EZB.STACKACCESS resource profile is exempt from the restriction that all traffic must be with partners that are in security zones with security labels that are equivalent to the stack's security label or the security label associated with the local IP address. You should carefully protect your routing configuration files to maintain network security. You should consider using any application level security supported by the routing protocol you use. OMPROUTE must be run with stack affinity for the stack that it is servicing.

OMPROUTE uses multicast UDP datagrams to discover adjacent OSPF routing daemons on common subnetworks. Adjacent OMPROUTE instances then establish TCP connections with each other. When two unrestricted stacks running OMPROUTE are attached to a common subnetwork that is neither XCF nor IUTSAMEHOST, adjacency errors will occur. The multicast UDP datagram is successfully transmitted, but the subsequent TCP connection between the two SYSMULTI interface addresses fails because it requires packet tagging. These adjacency failures can be avoided by preventing OMPROUTE from receiving multicast datagrams from partners with which it cannot communicate.

Steps for avoiding adjacency failures: Perform the following steps to prevent OMPROUTE from receiving multicast datagrams from partners with which it cannot communicate.

1. Create a network security zone named URXCF for all interface addresses in XCF or IUTSAMEHOST networks on unrestricted stacks:
   a. Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

      ```
      RDEFINE SERVAUTH EZB.NETACCESS.*.*.URXCF UACC(READ) SECLABEL(SYSMULTI)
      ```

   b. Modify the common NETACCESS profile to define the addresses in this zone:

      ```
      NETACCESS
      192.168.10.0/24 URXCF ; xcf subnet perhaps
      10.254.254.0/24 URXCF ; IUTSAMEHOST subnet perhaps
      ENDNETACCESS
      ```

---

2. Create a network security zone named UROTHER for all interface addresses in other network types on other unrestricted stacks:
   a. Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

      ```
      RDEFINE SERVAUTH EZB.NETACCESS.*.*.UROTHER UACC(READ) SECLABEL(SYSMULTI)
      ```

   b. Prevent the OMPROUTE running for each unrestricted stack from receiving datagrams from this zone with the following RACF command:

      ```
      PERMIT EZB.NETACCESS.*.*.UROTHER CLASS(SERVAUTH) ID(ompurid) ACCESS(NONE)
      ```

   c. Modify the common NETACCESS profile to define the addresses in this zone:

      ```
      NETACCESS
      10.254.1.0/24 UROTHER ; ethernet subnet perhaps
      ENDNETACCESS
      ```

---

3. Create a network security zone named URLOCAL for all interface addresses in other network types on each specific unrestricted stack. OMPROUTE is permitted to use this local interface to connect to adjacent OMPROUTE daemons on adjacent restricted stacks.
   a. Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

      ```
      RDEFINE SERVAUTH EZB.NETACCESS.*.*.URLOCAL UACC(READ) SECLABEL(SYSMULTI)
      ```

   b. Modify the local NETACCESS profile for each stack to define the local addresses in this zone:

      ```
      NETACCESS
      10.254.1.17/32 URLOCAL ; local address in ethernet subnet perhaps
      ENDNETACCESS
      ```

Resolver: The resolver task is started by z/OS UNIX and runs under the same identity as the OMVS address space. This identity normally has a security label of SYSMULTI. The resolver processes its configuration, system console commands, and its CTRACE under this identity.

The resolver is configured to use a set of files, data sets, and name servers in a given sequence when asked to resolve a name or IP address. For information on configuring the resolver search sequence, see *z/OS Communications Server: IP Configuration Reference*.

The name resolution process is performed on the requesting thread of execution under the user identity associated with that thread. Each user must have READ

access to the files and data sets configured. This is best accomplished by making these UACC(READ) with SECLABEL(SYSLOW). For the resolver to contact a name server on their behalf, each user must also have appropriate STACKACCESS permission and NETACCESS permission to the security zone of the name server.

z/OS UNIX might be configured in a CINET environment with multiple AF_INET Physical File Systems (TCP/IP stacks). In this environment, users and jobs can optionally have affinity for a single stack or allow CINET to choose a stack for them. When stack affinity is not set, CINET replicates some AF_INET calls to all attached stacks. Other calls are routed by CINET to a single stack based on routing information that CINET has extracted from those stacks. The socket() call is one of the calls that is routed to all connected stacks. This might produce RACF Failure Audit messages to any stacks that the resolver user is not permitted to. These messages can be eliminated by setting stack affinity prior to using resolver functions.

SNTPD: You can run as many instances of SNTPD as appropriate for your installation. Time is not considered sensitive information. You can run any SNTPD server under a user identity with a SYSMULTI security label.

TIMED: You can run as many instances of TIMED as appropriate for your installation. Time is not considered sensitive information. You can run any TIMED server under a user identity with a SYSMULTI security label.

TRMD: You should run one instance of TRMD for each stack that has IDS or IP security functions configured. Each instance of TRMD can run under a user ID with the same security label as the stack it is servicing, or with SYSMULTI. TRMD must be run with stack affinity for the stack that it is servicing.

z/OS syslog daemon (syslogd): You should run one instance of syslogd per z/OS image under a user ID with the SYSMULTI security label. The AF_UNIX socket (default name /dev/log) created by syslogd must have a security label of SYSMULTI, so that applications running under various security labels can log to it.

Syslogd routes application log messages according to filters configured in /etc/syslog.conf. Log messages from applications running under different security labels can be mixed into an output log file by a filter rule. Each output log file created by syslogd should be configured in a directory with a SYSHIGH security label.

z/OS UNIX Policy Agent: You should run one instance of Policy Agent per z/OS image under a user ID with the SYSMULTI security label. The AF_UNIX socket /tmp/unix.str created by Policy Agent must have a security label of SYSMULTI so that applications running under various security labels can connect to it. The user ID that Policy Agent is running under should have READ access to the EZB.STACKACCESS resource profiles of all stacks on the system.

Trusted multilevel secure server applications

The following are trusted multilevel secure server applications:

- TN3270E Telnet server
- z/OS UNIX FTP server
- z/OS UNIX REXEC server
- z/OS UNIX rpcbind server
- z/OS UNIX RSH server
- z/OS UNIX Telnet server

These applications can run under a user ID with the SYSMULTI security label in a multilevel secure environment, provided that they adhere to the following configuration instructions.

TN3270E Telnet server: You can run up to eight instances of the TN3270E Telnet server (Telnet), as appropriate for your installation. You can optionally configure the NACUSERID statement to enable Network Access Control for your Telnet, or use the procedure's user ID.

Telnet maps TCP connections to LU names configured in LU groups or supplied by an LU mapping exit. All of the LU names in a single LU group or that are provided by a single exit must have the same security label. Telnet ensures that the mapped LU name has an equivalent security label to the NetAccess profile for the network security zone containing the client. If the security label for the NetAccess profile is SYSMULTI, Telnet ensures that the mapped LU name also has a security label of SYSMULTI. When performing user login authentication, the SNA application should use this LU name as the port of entry TERMID. The LU name profile in the TERMINAL class must have equivalent security label definitions on both the Telnet system and the SNA application system.

z/OS UNIX FTP server: You can run as many instances of the FTP daemon as appropriate for your installation. You can run any FTPD under a user identity with a SYSMULTI security label. A single FTPD can span a mix of restricted and unrestricted stacks in a CINET environment.

To use NetAccess profiles for IPv4 clients, configure PortOfEntry4 SERVAUTH in the FTP.DATA file of the server. If you do not, you must configure profiles in the TERMINAL class covering all IPv4 addresses in your multilevel secure network, with the same security label defined on your corresponding NetAccess profiles.

z/OS UNIX rpcbind server: You should run one instance of rpcbind per z/OS image under a user ID with UID(0) and the SYSMULTI security label. You must define the resource profile EZB.RPCBIND.*sysname*.*rpcbindname*.REGISTRY in the SERVAUTH class. Enable applications to register and unregister with rpcbind by granting at least READ access to the resource profile for the user IDs under which the applications run.

Tip: The registration and deregistration procedures PMAPPROC_SET, PMAPPROC_UNSET, RPCBPROC_SET, and RPCBPROC_UNSET are defined in RFC 1833 *Binding Protocols for ONC RPC Version 2*.

Requirements:

- The rpcinfo utility can list and delete rpcbind registrations. You cannot delete rpcbind registrations using rpcinfo unless the user ID has at least READ access to the resource profile.
- Some RPC library calls register and deregister applications with rpcbind or portmapper. These calls include registerrpc(), svc_register(), pmap_set(), and pmap_unset(). An application that uses these library calls must run under a user ID that has been granted at least READ access to the resource profile.

Client programs can request that rpcbind forward RPCs to registered server programs. For each of these target assistance requests, the rpcbind server forks a new process that runs under the security label of the client's network security zone. The user ID under which rpcbind runs must have at least READ access to each of these security labels that you want to support.

Tip: The RPC library routine pmap_rmtcall() issues target assistance requests on behalf of the caller.

z/OS UNIX INET daemon: The z/OS UNIX INET daemon (inetd) can be configured to listen for requests for many different services. You can run inetd under a user identity with a SYSMULTI security label. Each connection to one of its ports causes it to issue the _poe() service and fork a new instance of the server configured to handle that service. The new connection is passed to the server. If a user ID for the forked server is configured in the inetd configuration file, that user ID must be authorized to the SERVAUTH NETACCESS profile for the network security zone containing the client IP address. If the forked server performs additional user login authentication, that user ID must also be permitted to the NetAccess profile.

The following z/OS CS servers are designed to be forked by inetd. They each perform additional user authentication.

- z/OS UNIX REXEC server
- z/OS UNIX RSH server
- z/OS UNIX Telnet server

Trusted single-level secure server applications

The following are trusted single-level secure server applications:

- SMTP server (SMTPPROC)
- TFTP
- TSO REXEC and RSH servers
- z/OS UNIX sendmail

They are not supported in a multilevel secure environment when they are run under a user ID with a security label of SYSMULTI. The following configuration instructions show how to run separate instances of these servers for each required security label.

SMTP server (SMTPPROC): The SMTP server receives mail files from TCP clients or the JES spool, and forwards mail files to other SMTP servers or to the JES spool. User identities and mail security labels are not processed.

You must run a separate instance of SMTP for each security label you need to support. Run each one under a different job name assigned to a user ID with the appropriate security label. You can run multiple SMTP servers on the same unrestricted stack. Define a VIPA in a network security zone with the appropriate security label for each server on that stack. Use the PORT reservation statement in the TCPIP profile or the LISTENONADDRESS keyword in the SMTP configuration file to override the bind address of each job to the appropriate VIPA. You can also run multiple SMTP servers with one server per restricted stack using stack affinity. In this case, it is not necessary to override the INADDR_ANY bind address.

Spool files routed to an instance of SMTP must have an equivalent security label.

Spool files created by SMTP carry the SMTP security label. SMTP servers are only permitted to connect to other SMTP servers with an equivalent security label.

TFTP: The TFTP server delivers files to any requester without user authentication. It should be configured to limit the files it attempts to access. All file access is done under its own user identity. Clients can get files that are publicly readable and

have security labels that the TFTP server dominates. Clients can put existing files that are publicly writable and have a security label that dominates the TFTP server's security label.

Requirement: You must run a separate instance of TFTP for each security label you need to support.

Steps for running a separate instance of TFTP for each security label: Before you begin, plan to run each instance of TFTP under a different job name assigned to a user ID with the appropriate security label. Understand that you can run multiple TFTP servers on the same unrestricted stack.

Perform the following steps to run a separate instance of TFTP for each security label:

1. Define a VIPA in a network security zone with the appropriate security label for each server on that stack.

   _____

2. Perform one of the following:
   - With a unique port number for each entry, use the PORT reservation statement in the TCPIP profile to override the bind address of each job name to the appropriate VIPA and port number.
   - Instead of using the PORT reservation statement and specifying the port using -p in the TFTP start procedure, use the -b TFTP start option to specify the IP address to which this instance of TFTP should bind. If the -b start option is used, each instance of TFTP can use the same well-known port (69).

   _____

3. Ensure the procedure for each instance of TFTP specifies on which port or IP address it will run.

   _____

You know you are done when you have established an environment where separate instances of TFTP can use the same well-known port (if the -b start option was used.)

In a CINET environment, you should establish stack affinity to the intended server stack prior to starting each instance of TFTP.

Guideline: Ensure that files and directories have appropriate security labels prior to using the TFTP server. Be especially careful not to have publicly writable files with a SYSMULTI security label, to eliminate the possibility of two users with different security labels (including two TFTP servers) passing data through the file.

TSO REXEC and RSH servers: The MVRSHD server listens for both rexec and rsh client connections. Requests are submitted as TSO batch jobs and spool output is returned to the client. MVRSHD does perform client authentication and does isolate user data for each connection. However, it does not request port of entry processing during client authentication, and job submission and spool access are performed under the identity of the MVRSHD job rather than the client identity.

RSH client requests are run under the identity and security label of the MVRSHD job. REXEC client requests are run under the user ID specified on the request.

MVRSHD supports an optional startup parameter to control whether or not it inserts the SECLABEL parameter on the generated job card. When SECLABEL=Y is specified at startup, MVRSHD passes its own security label in the SECLABEL job parameter. The user ID specified on the request must be permitted to the MVRSHD server's security label. When the parameter is not specified, or is specified as SECLABEL=N, the default security label of the user ID specified on the request must be identical to the MVRSHD server's security label.

You must run a separate instance of MVRSHD for each security label you need to support. Run each one under a different job name assigned to a user ID with the appropriate security label. You can run multiple MVRSHD servers on the same unrestricted stack. Define a VIPA in a network security zone with the appropriate security label for each server on that stack. Use the PORT reservation statement in the TCPIP profile to override the bind address of each job to the appropriate VIPA.

z/OS UNIX sendmail: The objective of this topic is to guide you through the steps required to set up sendmail in a multilevel secure environment. The contents of this topic are based on the assumption that you understand sendmail concepts and terminology. If you are not familiar with sendmail, you should first read "Configuring z/OS UNIX sendmail and popper" on page 1413.

Considerations for sendmail daemons: Mail must be configured so that it can only be exchanged among equivalent security labels. Essentially, multiple independent mail networks must be set up. Mail support does not need to be configured for every security label supported on a multilevel secure system. On z/OS systems, users must not be configured for sendmail when they log on with the SYSMULTI security label.

The most straightforward way to accomplish multiple independent mail networks is to define a different domain for each security label supported. Single-level security systems have their host name and IP address defined in the domain intended for their security label. Multilevel secure systems can have the same host name defined in each domain name intended for one of the security labels they support. An appropriate IP address on a restricted stack, or a VIPA on an unrestricted stack, is used in each domain for the multilevel secure system. When users log on to a multilevel secure system, their mail address becomes their user ID at that host name within the security label-specific domain. They use only the sendmail daemon on their system that supports that domain. When a user directs mail to a user ID at another multilevel secure host name, by default it is sent to the sendmail daemon on that host that is supporting the same security label-specific domain.

On a multilevel secure system in a single domain environment, each security label with mail support has a different host name. When users log on, their mail address becomes their user ID at the security label-specific host name in the common domain. They use only the sendmail daemon on their system that supports that host name. Users must know which host names are located in network security zones with equivalent security labels.

Of course, a user can address mail to another user at any host and domain name. However, their sendmail daemon will only be able to connect to other mail servers at IP addresses in network security zones with an equivalent security label. Mail sent to hosts that reside in security zones with security labels that are not equivalent will time out. Mail received by the z/OS sendmail daemon, addressed to a local user ID that is defined but is not permitted to the security label of the sendmail daemon, is returned with the unknown user error message.

The sendmail daemon receives mail files from TCP clients or other mail servers. It forwards these mail files to other mail servers, queues mail for later transmission to other mail servers, or passes mail to tsmail (or another local delivery agent) to complete local delivery. In a multilevel secure environment, you must run a separate instance of the sendmail daemon for each security label. The sendmail daemon must not be run under the SYSMULTI security label. In some cases, the sendmail daemon queues mail for delivery. There are several different configuration options that allow the sendmail daemon to process the queue. Each mail queue must have a security label that matches the security label of the sendmail daemon.

Run each sendmail daemon under a different job name assigned to a user ID with the appropriate security label. In a multilevel secure environment, there are special configuration considerations and changes needed to support multiple sendmail daemons running under different security labels. These considerations and changes are as follows:

- You can run multiple sendmail daemons on the same unrestricted stack (using multiple network security zones), or you can run one sendmail daemon on each restricted stack.
- If CINET is active and multiple restricted stacks are used, each sendmail daemon can establish stack affinity through the _BPX_SETIBMOPT_TRANSPORT environment variable and bind to the IPv4 INADDR_ANY address, or to the IPv6 unspecified address (in6addr_any). Otherwise, you must define a VIPA in a network security zone with the appropriate security label for each sendmail daemon.

CINET or INET	Restricted stack	Unrestricted stack
CINET with single stack	VIPA is optional.	VIPA with same SECLABEL is required.
CINET with multiple stacks	Use VIPA or stack affinity.	VIPA with same SECLABEL is required.
INET	VIPA is optional.	VIPA with same SECLABEL is required.

- Sendmail clients are permitted to connect only to sendmail daemons with an equivalent security label. NETACCESS configuration permits sendmail daemons (mail transmission agents, or MTAs) to connect outbound only to other MTAs with an equivalent security label and accept inbound connections only from clients and other MTAs with an equivalent security label. Sendmail configuration should direct sendmail clients to attempt connections that will succeed.
- If the mail submission agent (MSA) or MTA is bound to a specific IP address, a shared sendmail.cf can be used if you are using the same host name in security label-specific domains. If you are using different host names, you must provide a separate sendmail.cf for each security label.
- Whenever a sendmail daemon (MTA) is bound to a specific IP address, the use of job-specific source IP addressing specifying the same IP address is suggested. This ensures that name resolution by peer MTAs results in the intended host name and domain name.

Considerations for sendmail clients and sendmail MSP: If the mail submission program (MSP) feature is used, the feature(`msp') statement in submit.mc directs the sendmail client to connect to localhost by default, which is typically LOOPBACK or LOOPBACK6. In a CINET environment, these addresses can be ambiguous if you are not using stack affinity. This default approach works when

you are running only one restricted stack, or the client is running with stack affinity to a restricted stack. The sendmail daemon must be running on the same restricted stack and must not bind the MSA socket to a specific IP address. In all other cases, the feature(`msp') statement in submit.mc must include the host name of the sendmail daemon. If you are using the same host name for your sendmail daemons with security label-specific domain names, you can use a shared submit.cf that specifies the host name without the domain (that is, not fully qualified). If you are using different host names for your sendmail daemons, you must provide a separate submit.cf for each security label.

The sendmail client and MSP are permitted to connect only to a sendmail MSA or MTA with an equivalent security label.

Other considerations: If DNS is to be used for mail server searches, each VIPA with a unique name should be added to the name server as an MX record. If DNS is not being used for mail server searches, DNS searching can be turned off by adding the /etc/mail/service.switch file containing the following line:

```
hosts files
```

Sendmail.cf has /etc/mail/service.switch as the default location for this file.

If you use a shared aliases file, the user specified as postmaster in /etc/mail/aliases must be permitted to all security labels supported for sendmail. If you need to have different aliases, you must provide a separate aliases file for each security label. The user specified as postmaster in each security label-specific aliases file must be permitted to that security label.

Steps for setting up and running sendmail in a multiple security label environment:
Before you begin: Read and understand "Steps for configuring z/OS UNIX sendmail" on page 1418. The objective of this topic is to guide you through the steps required to set up sendmail in a multilevel secure environment. The contents of this topic are based on the assumption that you understand your sendmail configuration and your network configuration.

Perform the following steps to set up and run sendmail in a multiple security label environment:

1. Create host and domain names as follows:
   a. Decide whether you are using security label-specific domain names or separate host names.
   b. Define a VIPA in a network security zone with the appropriate security label for each sendmail server to which you will bind.

      Tip: This step is optional if stack affinity is used with restricted stacks.
   c. Define the domains and host names in your DNS, or /etc/hosts and /etc/ipnodes files. For example, if your system supported the security labels SYSHIGH, SYSLOW, ORANGES and APPLES, the following are some sample /etc/hosts definitions:

```
;  DIFFERENT HOST NAMES IN THE SAME DOMAIN
10.10.10.1  Z10HIGH.MYCORP.COM
10.10.10.2  Z10LOW.MYCORP.COM
10.10.10.3  Z10ORNGE.MYCORP.COM
10.10.10.4  Z10APPLE.MYCORP.COM
;  SAME HOST NAMES IN DIFFERENT DOMAINS
192.168.10.41 ZOS10.SYSHIGH.MYCORP.COM
192.168.10.42 ZOS10.SYSLOW.MYCORP.COM
192.169.10.43 Z0S10.ORANGE.MYCORP.COM
192.168.10.44 ZOS10.APPLES.MYCORP.COM
```

d. Set up stack affinity and resolver configuration, as described in "Planning for interactive UNIX System Services users in a multilevel secure environment" on page 164.

e. If starting the sendmail servers using started procedures, do one of the following:

- Add a STDENV DD line to the JCL, specifying a file that sets the environment variable RESOLVER_CONFIG to the appropriate file based on the security label for this sendmail server. For example:

```
//STDENV DD PATH='/etc/seclbl/sendmail.env',
//       PATHOPTS=(ORDONLY)
```

- Set the RESOLVER_CONFIG environment variable to the appropriate file (based on the security label of the sendmail server) using ENVAR on the PARM keyword of the EXEC statement. For example:

```
//SENDMAIL EXEC PGM=BPXBATCH,REGION=4096K,TIME=NOLIMIT,
// PARM=('PGM /usr/sbin/sendmail -bd -q1h -L sndmail1',
//      'ENVAR("RESOLVER_CONFIG=/etc/resolv.conf")'
```

---

2. Create security label-specific mail queue directories as follows:

a. If necessary, create the parent SYSMULTI directories. To create these directories, you must log on as a superuser with the SYSMULTI security label and issue the following UNIX System Services commands:

```
mkdir /var
mkdir /var/spool
```

b. Create new mail queue directories for each security label to be supported for sendmail. For each security label to be supported for servers, repeat the following steps:

1) Log on to a TSO user ID with that security label.

2) Issue the following UNIX System Services commands, replacing *seclbl* with the security label name and *sndmuser* with the appropriate sendmail user ID:

```
mkdir /var/spool/seclbl
mkdir /var/spool/seclbl/mqueue
chown sndmuser:sndmgrp /var/spool/seclbl/mqueue
mkdir /var/spool/seclbl/clientmqueue
chown smmsp:smmspgrp /var/spool/seclbl/clientmqueue
```

Tip: Do not create /var/spool/*seclbl* or its subdirectories for SYSMULTI or any other security label that is not to be supported for sendmail. There will not be a server to use them.

3) Create a symbolic link for these mail directories. The following UNIX System Services command issued by a superuser creates the symbolic link and directs the mail to the appropriate queue:

```
ln -s '$SYSSECR/'  /var/spool/secsymr
```

---

3. Change statements in the sendmail.mc configuration file as follows:

a. Change the location of the daemon pid file so that there is a separate one for each security label:

```
define(`confPID_FILE', `/var/spool/secsymr/sendmail.pid')dnl
```

b. Change the location of the local host names file so that there is a separate one for each security label:

```
define(`confCW_FILE', `/etc/secsymr/local-host-names')dnl
```

c. Change the location of the queue directories:

```
define(`MSP_QUEUE_DIR', `/var/spool/secsymr/clientmqueue')dnl
define(`QUEUE_DIR', `/var/spool/secsymr/mqueue')dnl
```

d. Define configuration file variables for the local host name and domain name:

```
define(`MLS_hostname', esyscmd(`hostname -s'))dnl
define(`MLS_domain', esyscmd(`domainname'))dnl
```

e. Change the DAEMON_OPTIONS statements. Code the ADDR parameter, specifying the unqualified local host name. For each sendmail daemon you start, this name will be resolved within the domain specific to the security label that daemon is running under. For example:

```
FEATURE(`no_default_msa')dnl
DAEMON_OPTIONS(`Name=MTA, Addr='MLS_hostname`, Family=inet ')dnl
DAEMON_OPTIONS(`Name=MSA, Port=587,  Addr='MLS_hostname`, Family=inet ')dnl
```

---

4. Change statements in the submit.mc configuration file as follows:

a. Change the location of the client queue directory:

```
define(`MSP_QUEUE_DIR', `/var/spool/secsymr/clientmqueue')dnl
```

b. Define configuration file variables for the local host name and domain name:

```
define(`MLS_hostname', esyscmd(`hostname -s'))dnl
define(`MLS_domain', esyscmd(`domainname'))dnl
```

c. Change the FEATURE(`msp') statement. Code the unqualified local host name for this system. For each user that invokes /bin/sendmail, this name will be resolved within the domain specific to the security label that user is running under. For example:

```
FEATURE(`msp', MLS_hostname)
```

Tip: If MX records in DNS should not be searched, brackets [] must be placed around the name or address.

---

5. Use the m4 compiler to create sendmail.cf and submit.cf files as follows:

a. Create symbolic links for the submit.cf and sendmail.cf files:

```
ln  -s  /etc/seclbl/mail/submit.cf  /etc/mail/submit.cf
ln  -s  /etc/seclbl/mail/sendmail.cf  /etc/mail/sendmail.cf
```

b. Log on with each security label to be supported for mail and create the .cf files:

```
/etc/m4 /etc/mail/sendmail.mc > /etc/mail/sendmail.cf
/etc/m4 /etc/mail/submit.mc > /etc/mail/submit.cf
```

---

6. Create new system mailbox directories for each supported security label. When sendmail is configured to use /usr/lib/tsmail, you must configure /usr/mail to be a symbolic link to a security label-specific directory. The following approach creates a set of security label-specific mount points for mail file systems:

a. Log on as a superuser with the SYSMULTI security label and issue the following UNIX System Services commands:

```
mkdir  /mailmnt
ln  -s  '$SYSSECR/mail'  /usr/mail
```

Tip: If another program other than /usr/lib/tsmail is used, these commands might need to be adjusted accordingly.

b. Perform the following steps for each security label supported for mail on the system:

1) Log on to a superuser ID using the security label.
2) Set an environment variable to your current security label as follows:
```
export SL=$(id -M)
```
3) Issue the following UNIX System Services command:
```
mkdir /mailmnt/$SL
```

---

7. Start a separate instance of the sendmail daemon for each security label you need to support. For instructions on setting up the appropriate user IDs and groups for sendmail, see "Steps for configuring z/OS UNIX sendmail" on page 1418. You can start sendmail daemons either from UNIX System Services or as started procedures. See the EZARACFM sample for examples of defining user IDs and STARTED class profiles for sendmail.

   Repeat either of the following steps to start a sendmail daemon for each supported security label:

   - From UNIX System Services:
     a. Log on to UNIX System Services with the security label that you want to support.
     b. Start the sendmail daemon from the command line.
   - From the MVS console:
     a. Add a user ID and permit the user ID to the appropriate security label.
     b. Use the STARTED class to assign the user ID with the appropriate security label to the procedure.
     c. Start the procedure from the MVS console or using the AUTOLOG statement in PROFILE.TCPIP.

Network administration client applications

The following are network administration client applications:

- DNS utilities:
  - nsupdate
  - rndc
- DNS utilities used for DNS security (DNSSEC):
  - dnsmigrate
  - dnssec-keygen
  - dnssec-makekeyset
  - dnssec-signkey
  - dnssec-signzone
  - rndc-confgen
- Netstat
- pasearch
- Ping
- Traceroute
- trmdstat

For security implications on the use of these commands, see the following information on configuring these applications for use in your multilevel secure environment.

nsupdate: The nsupdate command is used to update the name server database. Because the name server is often running with a SYSMULTI security label and listening on IP addresses in SYSMULTI network security zones, mandatory access control policy does not limit a general user's ability to use the nsupdate command to contact the server. File system access control lists and security labels should be used to limit execution of this command to intended network administrators. Application level security options should also be considered.

rndc: The remote name daemon control (rndc) command allows the system administrator to control the operation of a name server. Because the name server is often running with a SYSMULTI security label and listening on IP addresses in SYSMULTI network security zones, mandatory access control policy does not limit a general user's ability to use the rndc command to contact the server. File system access control lists and keys should be used to limit execution of this command to intended network administrators.

DNS utilities used for DNS security (DNSSEC): The dnssec-keygen program is used to generate keys. The dnssec-makekeyset program is used to create a key set from one or more keys. The dnssec-signkey program is used to sign one child's key set. The dnssec-signzone program is used to sign a zone. The rndc-confgen program is used to create a rndc.conf file.

Netstat: Use the Netstat command to display stack settings, and information about open ports and established connections. You might want to restrict the availability of some Netstat options to network administrators. For information on restricting Netstat options, see "Netstat access control" on page 125.

pasearch: The pasearch command is provided to interrogate the stack policies currently in place on a system. It requires that the user have superuser privileges. Only network and security administrators that need to know policy settings should be permitted to issue this command. To limit access, set the file mode access permission bits using the CHMOD command.

Ping: The Ping command is used to verify the network path to a given destination. It sends ICMP Echo Request datagrams to the destination and listens for ICMP Echo Reply responses. Normal Network Access Control limits a user's ability to send and receive these datagrams. On a restricted stack, all users are limited to sending and receiving datagrams to destinations in network security zones with security labels equivalent to the stack. On an unrestricted stack, users are limited to destinations equivalent to their own security label. Users with a SYSMULTI security label on an unrestricted stack are limited to those security zones with which they are authorized to communicate.

You can permit SYSMULTI users to use the Ping command for IP addresses in security zones with security labels that are not equivalent to that stack by using the RACF PERMIT command to give them UPDATE access to the STACKACCESS profile for that stack. You can configure this permission so that it is in effect only for specific programs invoked by the users. For example, to permit users to invoke the Ping command, specify the WHEN(PROGRAM(OPING,PING)) parameter on the PERMIT command.

Traceroute: The Traceroute function is used to verify the network path to a given destination and identify each intermediate system. It sends UDP datagrams to the destination with increasing hop count values, and listens for ICMP TIME EXCEEDED INTRANSIT and PORT UNREACHABLE responses. Normal Network Access Control limits a user's ability to send and receive these datagrams. On a

restricted stack, all users are limited to sending datagrams to destinations in network security zones with security labels equivalent to the stack, and receiving datagrams from intermediate systems in equivalent security zones. On an unrestricted stack, users are limited to destinations equivalent to their own security label. Users with a SYSMULTI security label on an unrestricted stack are limited to those security zones with which they are authorized to communicate.

You can permit SYSMULTI users to trace the route to addresses in security zones that are not equivalent to that stack by PERMITing them with UPDATE access to the STACKACCESS profile for that stack. This PERMIT can be limited to only apply when using certain programs, such as Traceroute, by using the WHEN(PROGRAM(tracerte,otracert)) clause on the PERMIT.

trmdstat: The trmdstat command is provided to process syslogd output files and generate IDS reports. The network or security administrator using this command needs to be authorized to read the syslogd output files. This often requires a user security label of SYSHIGH or SYSMULTI.

IBM zEnterprise System platform management applications

Some IBM zEnterprise System (zEnterprise) authorized applications communicate over the intranode management network, such as those providing platform performance management functions. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*.

These applications are not supported in a multilevel secure environment when run under a user ID with a security label of SYSMULTI. They are supported when run under a user ID with a specific security label. Some of these applications listen using specific multicast IP addresses and ports to determine the remote IPv6 link-local IP address and port number to use for communication with another authorized system performing platform management.

For the zEnterprise authorized platform management application to connect to the intranode management network, at least one TCP/IP stack on each z/OS image must be connected to an OSM interface. That stack can be an unrestricted stack, or it can be a restricted stack running with a security label that is equivalent to the security label used for the zEnterprise system management agent application.

You must configure TCP/IP and the security server as follows:

- Permit the application to the STACKACCESS resource profile of the stack with one or more OSM interfaces.
- Define an OSMACCESS resource profile on the stack with the OSM interface, using the same security label as that of the application.
- Permit the application to the OSMACCESS resource profile.
- Define a NETACCESS resource profile for the multicast IPv6 address that is used by the application.
- Permit the application to the NETACCESS profile for that multicast address.

General user client applications

The following are general user client applications:

- dig
- dnsdomainname, domainname
- host
- hostname
- MISCSERV (echo, discard, character generator)

- NSLookup
- TSO REXEC client
- TSO RSH client
- TSO Telnet client
- z/OS UNIX FTP client
- z/OS UNIX REXEC client
- z/OS UNIX RSH client

These commands are supported for use by general users in a multilevel secure environment. Mandatory access control policy enforcement limits the stacks that can be used, the servers that can be contacted, and the local resources that can be used. No extra, application specific, multilevel secure environment configuration is required. For discretionary security environment considerations, see the information for a particular application and see *z/OS Communications Server: IP Configuration Reference*.

Unsupported applications

The following applications are not supported in a multilevel secure environment:

- HOMETEST command
- LPD
- LPQ command
- LPR command
- LPRM command
- LPRSET command
- NCPROUTE
- NPF
- Portmapper
- SMTP
- SNMP NetView® client
- TELNET client command
- TESTSITE command
- TNF
- VMCF
- z/OS UNIX Network SLAPM2 subagent
- z/OS UNIX OMPROUTE SNMP subagent
- z/OS UNIX popper
- z/OS UNIX RSVP agent
- z/OS UNIX SNMP client command
- z/OS UNIX SNMP server and agent
- z/OS UNIX Trap Forwarder Daemon

Any other commands or applications not explicitly mentioned in this information have not been inspected and are not supported in a multilevel secure environment.

Changing your multilevel secure networking environment

Changes to certain parts of your multilevel secure configuration should be well planned. Changes to the NETACCESS statement in PROFILE.TCPIP, the security label associated with the TCPIP started task, the security label associated with the EZB.STACKACCESS or EZB.NETACCESS profiles in the SERVAUTH class, or the definition of profiles in the SECLABEL class can result in an IP address being associated with a different security label. These changes imply that corresponding changes have been implemented that affect the security management of the affected systems. For systems that support mandatory access control policy enforcement, those policies must be updated at the same time. For systems that do not support mandatory access control policy enforcement, the physical user access procedures, system data content, firewall configurations, and router configurations must be updated at the same time.

The safest method of controlling mandatory access control policy changes is to use the RACF options MLSTABLE and MLQUIET. When the RACF options are set to MLACTIVE, MLSTABLE, and NOMLQUIET, TCP/IP does not permit an existing NETACCESS configuration to be changed with a VARY TCPIP,,OBEYFILE command. When the RACF option MLQUIET is set, RACF requires the TCP/IP job user ID to be RACF SPECIAL to open data sets referenced by VARY TCPIP,,OBEYFILE commands. For more information on setting and using these options, see *z/OS Security Server RACF Security Administrator's Guide*.

In an MLSTABLE environment, all user and application access to data should be halted before entering the MLQUIET environment. All network access can be halted by stopping all TCP/IP stacks. If security administrators must access the system through the TN3270E Telnet server (Telnet), consider running a restricted stack with only Telnet for the security administrators. Permit the Telnet NACUSERID or the procedure's user ID to the EZB.STACKACCESS profile for this stack. Stop all other TCP/IP stacks. After the local policy changes and all coordinated changes on other systems are complete, set NOMLQUIET and restart your production TCP/IP stacks and network servers.

Every stack running on a system with the RACF option MLACTIVE does an internal consistency check on several PROFILE.TCPIP statements and their associated SERVAUTH profiles. This consistency checking occurs at the end of initial profile processing, after the VARY TCPIP,,OBEYFILE command modifies the profile, and whenever RACLIST is issued for the SERVAUTH or SECLABEL classes. Some applications, such as OMPROUTE, also cause the consistency checking to occur because they internally issue an equivalent of the VARY TCPIP,,OBEYFILE command. TCP/IP writes a message to the job log for each inconsistency it finds that could compromise the security of information flowing through the stack. If inconsistencies are found, a final message (EZD1217I) summarizing the number of problems found is written to the system console.

By default, the stack will continue running when inconsistencies are found. It is recommended that you override this default by specifying GLOBALCONFIG MLSCHKTERMINATE in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, before starting production workloads. Before making security related configuration changes, it is recommended that you first stop all production workloads. You can then specify GLOBALCONFIG NOMLSCHKTERMINATE in PROFILE.TCPIP or in the data set referenced by a VARY TCPIP,,OBEYFILE command. This parameter can only be changed from MLSCHKTERMINATE to NOMLSCHKTERMINATE when the RACF option NOMLSTABLE is set or when both MLSTABLE and MLQUIET are set.

The stack performs the following consistency checks:

- The stack does not currently have a NETACCESS statement configured.
- The TCP/IP job security label must be currently active on this system.
- A STACKACCESS profile for this stack must exist.
- The STACKACCESS profile must have the same security label as the TCP/IP job.
- The NETACCESS statement must have both INBOUND and OUTBOUND turned on.
- A NETACCESS profile must exist for each defined NETACCESS security zone.
- If NETACCESS DEFAULTHOME is configured, it must have a zone with the same security label as the TCP/IP job.
- If NETACCESS TcpStackSourceVIPA is configured, it must be in a zone with the same security label as the TCP/IP job.
- The special address INADDR_ANY (0.0.0.0) must be in a NETACCESS security zone.
- The special address INADDR_ANY (0.0.0.0) must be in a zone with the same security label as the TCP/IP job.
- On an IPv6-enabled stack, the special IPv6 unspecified address [in6addr_any (::)] must be in a NETACCESS security zone.
- On an IPv6-enabled stack, the special IPv6 unspecified address [in6addr_any (::)] must be in a zone with the same security label as the TCP/IP job.
- On an IPv6-enabled stack, every INTERFACE statement must have a manually configured INTFID. (OSM interfaces are exempt from this check.)
- On an IPv6-enabled stack, every INTERFACE that supports autoconfiguration must have at least one manually configured IPADDR. (OSM interfaces are exempt from this check.)
- On an IPv6-enabled stack with dynamic XCF, DYNAMICXCF INTFID must be configured on the IPCONFIG6 statement.
- Every home address on the stack must be in a NETACCESS security zone. (OSM interfaces are exempt from this check.)
- Every home address that is not a VIPA must be in a zone with the same security label as the TCP/IP job. (OSM interfaces are exempt from this check.)
- Every home address that is a VIPA must be in a zone with an equivalent security label as the TCP/IP job.
- On a restricted stack, VIPAs must not be in a security zone with the SYSMULTI security label.

There are several consistency checks that are not performed by the stack. These remain the responsibility of the system security administrator:

- The NetAccess zone definitions must agree across stacks. It is recommended that common definitions from a shared data set be included in all stack profiles.
- Subnetworks or networks are entirely contained in a single NetAccess security zone. NetAccess checks for authorization to a specific destination address, but broadcast packets are delivered to all addresses within a subnetwork or network. Addresses owned by multilevel secure stacks are the only addresses that can be safely configured into a network security zone different than their subnetwork or network.
- RACF definitions must be consistent across RACF data sets. It is recommended that installations use RACF facilities to manage this consistency. SECDATA and SECLABEL class profile consistency is critical to preserve the meaning of

SECLABEL profile names. It is suggested that installations define SERVAUTH profiles for all zones that are generic across all systems and stacks, except those containing the loopback address and the unspecified address (IPv4 INADDR_ANY and IPv6 in6addr_any).

Continue making changes to either PROFILE.TCPIP statements or RACF profiles until no consistency errors are reported. Then, specify GLOBALCONFIG MLSCHKTERMINATE in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command. At that point, it is safe to set NOMLQUIET and restart production workloads.

Chapter 5. TCP/IP Customization

Before you begin customizing, it is assumed that you know what configuration data sets are used by the TCP/IP address space, their search order, and considerations for what type of TCP/IP stack you will be running in your environment (for example, Enterprise Extender (EE) and multiple stacks). See Chapter 2, "IP configuration overview," on page 11 for this information.

After reading this information, you will know how to configure and start syslogd and the TCP/IP stack. You should understand the relationships of TCP/IP configuration files as they apply to the TCP/IP address space. The four main configuration files that you will be working with are:

- TCPIP.DATA
- PROFILE.TCPIP
- HOSTS.LOCAL
- ETC.IPNODES

You should be able to use the following commands to verify customization:

TSO PING and z/OS UNIX ping
: Sends IP datagrams to a specified destination host, requesting a reply, and measures the round trip time. This helps you to verify the interfaces defined to the TCP/IP address space.

TSO NETSTAT, z/OS UNIX netstat, and DISPLAY TCPIP,,NETSTAT
: Queries TCP/IP about the network status of the local host or the contents of the resolver cache. With Netstat, you can verify most TCP/IP customization values that can be set from PROFILE.TCPIP. You can also display detailed information about the contents of the system-wide resolver cache, or statistical information such as the number of cache queries.

TSO HOMETEST
: Verifies your host name and address configuration.

TSO TRACERTE and z/OS UNIX traceroute
: Displays the route that a packet takes to reach a requested destination.

Configuring the syslog daemon

The syslog daemon (syslogd) processing is controlled by a configuration file called /etc/syslog.conf, in which you define logging rules and output destinations for error messages, authorization violation messages, and trace data. Logging rules are defined using a *facility* name and a *priority* code. For locally generated messages, the user ID and job name of the program that generated the message can also be specified in the rule. For messages arriving over the network, the rule can include the IP address or host name of the sender. The *facility* name and *priority* code are passed on the logging request from an application when it wants to log a message. The user ID and job name are provided by the system. See *z/OS Communications Server: IP Configuration Reference* for more information about logging rules.

You can specify statements and rules in the configuration file using a variety of EBCDIC code pages. Use the SYSLOGD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

As shown in the following sample /etc/syslog.conf file, comments can be added to the configuration file by placing the number (#) character in column one of the comment line. Everything following the number (#) character is treated as a comment. This sample is available in /usr/lpp/tcpip/samples/syslog.conf.

```
#  Licensed Materials - Property of IBM
#  5694-A01
|#  Copyright IBM Corp. 2010
|#  Status = CSV1R12
#
# /etc/syslog.conf - control output of syslogd
#
# The # sign begins a comment which extends to the end of the line.
#
# Blank lines are ignored.
#
# See IP Configuration Reference for detailed information about
# the syntax.  These comments are meant to provide only a general
# overview.
#
# There are two types of configuration information:
#
# 1) Global configuration values that control the behavior of syslogd.
# 2) Rules that specify types of messages which syslogd will
#    store, and where syslogd will store them.
#
# Global configuration statements:
# --------------------------------
#
# The following global statements control the syslogd automatic archive
# function.  All statements except BeginArchiveParms should only be
# specified once.  If you specify them multiple times the last
# instance is used.  The BeginArchiveParms statement can be repeated
# multiple times, and each instance pertains to the rules that follow
# it, until another instance is specified.  Each instance completely
# replaces the previous instance.
#
# The automatic archive function archives UNIX file destinations to
# MVS sequential or generation data group (GDG) data sets.  The
# particular UNIX files that are to be archived must include the -N
# parameter.  Alternatively, you can specify the -X parameter to
# reinitialize a file when an archive occurs.  This means the contents
# of the file are deleted.  Use the -X parameter only if you do not
# want to save the contents of the log file.  If you don't specify
# the -N or -X parameter, then the file does not participate in
# automatic archival.
#
# Archival occurs for the following events:
#
# - At the time of day configured on the ArchiveTimeOfDay statement.
# - When one or more UNIX file systems reach the percentage full
#   configured on the ArchiveThreshold statement.
# - When the MODIFY procname,ARCHIVE command is issued.
#
# ArchiveTimeOfDay
#   Specifies the local time of day in hours and minutes using a 24
#   hour clock.  Syslogd archives all eligible files at the specified
#   time of day.  There is no default - if you don't specify this
#   statement, then syslogd does not perform time of day archival.
#
# ArchiveThreshold
#   Specifies the percentage of file system full that triggers an
```

```
#   archive.  This value applies to all UNIX file systems represented
#   by the set of UNIX files in all rules.  When any file system
#   reaches the specified percentage full, files in that file system
#   are archived until the percentage full reaches half of the
#   configured value.  Files are archived starting with the largest
#   and working toward the smallest.  For example, if you configure
#   80% full, files are archived until the file system is only 40%
#   full.  The default is 70%.
#
# ArchiveCheckInterval
#   Specifies the value in minutes for checking the percentage full
#   for UNIX file systems.  The default is 10 minutes.
#
# BeginArchiveParms
#   Specifies archive data set details.  The following parameters
#   can be specified.  DSNPrefix is required but all other parameters
#   are optional (although they might need to be specified for your
#   installation in order for archival to succeed).
#
#   DSNPrefix
#     Specifies the data set name prefix for the archive data set.
#     The complete data set name is formed by concatenating this
#     prefix value with the unique qualifier specified on the -N
#     parameter on a particular rule, and with a unique suffix value.
#     See IP Configuration Reference for complete details on the data
#     set name.
#
#   Unit
#     Specifies the unit for the archive data set.
#
#   Volume
#     Specifies the volume for the archive data set.
#
#   MgmtClas
#     Specifies the management class for the archive data set.
#
#   StorClas
#     Specifies the storage class for the archive data set.
#
#   RetPd
#     Specifies the retention period in days for a sequential archive
#     data set.  Valid values are 0 - 9999.
#
# The following are example statements that illustrate how to
# configure automatic archival.  See the section on syslogd rules for
# details about specifying rules.
#
#   ArchiveTimeOfDay         00:01
#   ArchiveThreshold         70
#   ArchiveCheckInterval     10
#
#   BeginArchiveParms
#     DSNPrefix              USER1.ARCHIVE
#     Volume                 VOL001
#     RetPd                  30
#   EndArchiveParms
#
#   *.SYSLOGD.daemon.notice  /var/logs/syslogd/daemon.notice -N daemon.notice
#
# NOTE: The archive data set name for the above example will be:
#
#   USER1.ARCHIVE.DAEMON.NOTICE.Dyymmdd.Thhmmss
```

```
#
# Syslogd rules:
# --------------
#
# Four criteria can be used to select locally generated
# messages for processing:
#
# 1) user ID associated with application generating the message
#
#    * can be specified for the user ID if the user ID is not
#    important.
#
# 2) job name of application generating the message
#
#    * can be specified for the job name if the job name is not
#    important.
#
# 3) facility of the message, as specified by the application
#
#    This is user, mail, news, uucp, daemon, auth, cron, lpr, or
#    local0-local7.  Consult the documentation for the application
#    to determine which facility the application specifies.
#
#    A special facility, mark, specifies that syslogd should log
#    mark messages on a regular basis.  These can be used to verify
#    that syslogd was operational during a specific time interval.
#
# 4) priority of the message, as specified by the application
#
#    This is emerg, panic, alert, crit, err, error, warn, warning,
#    notice, info, or debug. A filter rule condition using a specified
#    priority will match messages with that priority or higher; higher
#    meaning more severe.
#
#    A special priority, none, specifies that messages with the
#    specified user ID, job name, or facility should not be
#    selected.
#
# These criteria are specified together as
#
#    userid.jobname.facility.priority
#
# or, if user ID and job name are both *, as
#
#    facility.priority
#
# This can be combined in a series as
#
#   userid.jobname.facility.priority;userid.jobname.facility.priority
#
# When using syslogd rules with a series of conditions separated by
# semicolons, all of the individual conditions are evaluated
# left-to-right for each message. Each matching condition results in
# either a TRUE (meaning log the message) or a FALSE (meaning don't
# log the message). Conditions that don't match are ignored.
# The final result of evaluating each matching condition left-to-right
# is the result of the last matching condition. Rules that have no
# matching conditions for a message result in a FALSE.
# Matching exclude conditions (those with priority of none) result
# in a FALSE. As an example, consider the difference between the
# following two rules for a message with facility of daemon and
# a priority of emerg.
```

```
                    #
                    # daemon.none;*.emerg  /tmp/mylogfile
                    # *.emerg;daemon.none  /tmp/mylogfile
                    #
                    # The first rule, first condition, results in FALSE. The first rule,
                    # second condition, results in TRUE. Therefore, the message will be
                    # logged to the destination for this rule.
                    # The second rule, first condition, results in TRUE. The second rule,
                    # second condition, results in FALSE. The message will not be logged
                    # for this rule.
                    #
                    # The order of conditions within the filter is significant.
                    #
                    # Three criteria can be used to select messages received over the
                    # network for processing:
                    #
                    # 1) IP address or hostname of the sender. The IP address may be in
                    #  IPv4 or IPv6 format or may be a hostname that resolves to an
                    #  IPv4 or IPv6 address. If an IP address is used, an optional prefix
                    #  length may be specified with the /x notation.
                    #
                    # 2) facility of the message. See the description of facility above.
                    # 3) priority of the message. See the description of priority above.
                    #
                    # These criteria can be specified together as
                    #
                    #   (ip_address).facility.priority
                    #
                    #   or
                    #
                    #  (hostname).facility.priority
                    #
                    # If the the IP address or hostname is not to be considered in selecting the
                    # rule, then omit it and specify just facility.priority
                    #
                    # The following rule will match locally generated messages or
                    # messages received over the network from any source IP address
                    # that have the specified facility and priority (or higher).
                    #
                    # facility.priority
                    #
                    # The criteria for selecting messages for processing are combined
                    # with a destination, which tells syslogd what to do with selected
                    # messages.
                    #
                    #   criteria    destination
                    #
                    # The destination can be a file, one or more user IDs, SMF, syslogd
                    # at a remote host, or all logged-in users, or the operlog log stream.
                    #
                    # If the destination is a file, it may be optionally followed by two
                    # options, -F and -D. -F should be followed by an octal number that
                    # indicates the permissions value to be used if syslogd must create
                    # the file. -D should be followed by an octal number that indicates
                    # the permissions value to be used if syslogd must create the
                    # directory to contain the file. These options are only effective
                    # if syslogd is started with the -c start option. See the
                    # Communications Server IP Configuration Reference for details.
                    #
                    # The following example stores messages with facility daemon or
                    # local1 in the file /directory/logfile.
                    #
```

```
#   daemon.*;local1.*   /directory/logfile
#
# The directory structure used in this sample configuration is
# expected to be created automatically by syslogd, with a new
# directory of log files for each day.  This requires two types
# of configurations outside of the scope of this configuration
# file:
#
# 1) syslogd command-line option
#
#    The syslogd -c command-line option should be enabled, causing
#    syslogd to create log files and directories if they do not
#    already exist.
#
# 2) cron job
#
#    A cron job should be utilized to wake up syslogd at the
#    beginning of each day to switch to new log files in a new
#    directory.  Here is the cron job definition:
#
#      1 0 * * * kill -HUP `cat /etc/syslog.pid`
#
#    This job should be defined for a user ID with UID zero so that
#    it has permissions to send the signal to syslogd.
#
#    See UNIX System Services Planning and UNIX System Services
#    Command Reference for more information about cron.
#
# A sample shell script is provided for removing log files which are
# a specifed number of days old.  It assumes the same directory
# structure which is used in this sample configuration.
#
# All example rules except for the last one are commented-out.  Some
# or all of the example rules will need to be changed for your
# environment.  Each example rule contains an explanation of changes
# which may be required.
#
######################################################################
#
# Write all messages with priority crit or higher to the MVS operator
# console.  See the UNIX System Services Planning manual for more
# information about the /dev/console special file.
#
# *.crit             /dev/console
#
######################################################################
#
# Write all messages with facility of daemon and a priority of error
# or higher to the operlog log stream. The operlog facility must be
# active in order to be able to log messages to the operlog log
# stream.
#
# daemon.err             /dev/operlog
######################################################################
#
# Write all messages from syslogd itself to the file
# /var/log/YYYY/MM/DD/syslogd.log and to the system console.
#
# Notes:
#
# a) If syslogd is invoked as a started task or from a shell script
#    (e.g., /etc/rc) with job name SYSLOGD, the name of the
```

```
#    long-running syslogd job is SYSLOGD followed by a digit.
#
#    If syslogd runs with a different job name on your system, the
#    rule will have to be changed accordingly.
#
# b) During initialization, syslogd writes messages to
#    /dev/console.  These rules cover messages during steady-
#    state.
#
# *.SYSLOGD*.*.*      /var/log/%Y/%m/%d/syslogd
# *.SYSLOGD*.*.*      /dev/console
#
######################################################################
#
# Write all messages from inetd to the log file inetd and to the
# console.
#
# Notes:
#
# a) If inetd is invoked as a started task or from a shell script
#    (e.g., /etc/rc) with job name INETD, the name of the
#    long-running inetd job is INETD followed by a digit.
#
#    If inetd runs with a different job name on your system, the rule
#    will have to be changed accordingly.
#
# *.INETD*.*.*       /var/log/%Y/%m/%d/inetd
# *.INETD*.*.*       /dev/console
#
######################################################################
#
# Write all messages with priority err or higher from applications
# which specify facility "daemon" to the log file daemon.
# Because we chose to log messages from syslogd and inetd separately,
# we'll filter out those messages from this rule using special
# priority none.
#
# Notes:
#
# a) In this example, SYSLOGD followed by some other character is the
#    job name of syslogd.  If it is different on your system, change
#    the rule.
# b) In this example, INETD followed by some other character is the
#    job name of inetd.  If it is different on your system, change the
#    rule.
#
# daemon.err;*.SYSLOGD*.*.none;*.INETD*.*.none /var/log/%Y/%m/%d/daemon
#
######################################################################
#
# Write all messages from applications which specify facility "auth"
# to the log file auth.
#
# auth.* /var/log/%Y/%m/%d/auth
#
######################################################################
#
# Write all messages from applications which specify facility "mail"
# to the log file mail. Use file permissions of 640 octal if the file
# has to be created. Use permission of 770 octal if the directory has
# to be created. syslogd must be started with -c for these options
# to have any effect.
```

```
#
# mail.* /var/log/%Y/%m/%d/mail -F 640 -D 770
#
######################################################################
#
# Write all messages with priority err and higher from otelnetd and
# other applications which specify facility "local1" to the log file
# local1.
#
# local1.err       /var/log/%Y/%m/%d/local1
#
######################################################################
#
# Write all messages from otelnetd and other applications which
# specify facility "local1" when running as user SMITH to the log file
# local1.smith.  This could be useful if, for example, otelnetd traces
# need to be collected for a problem which user SMITH is experiencing
# and you do not wish to collect otelnetd traces from all user IDs.
#
# SmITh.*.local1.*  /var/log/%Y/%m/%d/local1.smith
#
######################################################################
#
# Write all messages with priority err and higher to SMF.  These will
# be stored in SMF record type 109.  SMF must be active and
# configured to accept record type 109.  The user ID associated with
# syslogd must have read access to BPX.SMF.  See UNIX System Services
# Planning for more information about BPX.SMF.
#
# *.err        $SMF
#
######################################################################
#
# Write all messages with priority crit and higher to the syslogd on
# host 192.168.1.9. The host may be specified by IPv4 address, by IPv6
# address, or by a name that resolves to an IPv4 or IPv6 address.
#
# *.crit      @192.168.1.9
#
######################################################################
#
# Write all messages with priority crit and higher that arrive from
# host 192.168.0.6 to the operlog log stream.
#
# (192.168.0.6).*.crit      /dev/operlog
#
######################################################################
#
# Write all messages with priority crit and higher that arrive from
# any host with IP address in the range 192.168.0.0 to 192.168.0.255
# to the operlog log stream.
#
# (192.168.0.6/24).*.crit      /dev/operlog
#
######################################################################
#
# Write all messages with priority err and higher to log file errors.
#
# THIS EXAMPLE STATEMENT IS UNCOMMENTED.
#
*.err            /var/log/%Y/%m/%d/errors
#
```

Starting and stopping syslogd

Syslogd can be started only by a task or user with superuser authority (UID 0). You can start syslogd from a procedure or from the UNIX shell. If you start syslogd from a procedure that does not use BPXBATCH, the resulting job name is the same as the procedure name. If you start syslogd from the UNIX shell or from a procedure that uses BPXBATCH, the resulting job name is the user ID or the value of the _BPX_JOBNAME environment variable.

Rules:

- If you start syslogd from the UNIX shell or from BPXBATCH, start it as a background shell command by specifying an ampersand (&) as the last character on the command. If you do not specify the ampersand, control does not return to the shell until syslogd ends. Specifying an ampersand is especially important if syslogd is started from a shell script, such as /etc/rc.
- If you start syslogd from a cataloged procedure that uses BPXBATCH, you need to include a sleep command in your script after the start for syslogd to provide syslogd the time to initialize before the shell script ends. For more information about including a sleep command, see *z/OS UNIX System Services Planning*.
- If you start syslogd from a cataloged procedure that uses BPXBATCH, you need to use an HFS file for the STDOUT and STDERR DD statements; otherwise the job will not end.

If there is no TCP/IP transport active when syslogd starts or if TCP/IP is recycled, syslogd will establish or reestablish communication with TCP/IP when it becomes available.

Syslogd can run in one of three modes:

- Normal

  In this mode, syslogd processes logging requests from the local system and applications using the syslog() function. Additionally, syslogd receives and logs messages sent over the TCP/IP network by remote systems running syslogd. These remote systems can be z/OS systems or non-z/OS systems. Only one instance of syslogd can be run on a z/OS system if syslogd is started in this mode.
- Local-only

  In this mode, syslogd processes logging requests from only the local system and applications. This instance of syslogd does not receive or process messages sent over the network from remote syslog daemons. Use the **-i** option to start syslogd in the local-only mode.
- Network-only

  In this mode, syslogd processes only messages sent over the network by remote systems running syslogd. This instance of syslogd does not process logging requests from the local system or applications. Use the **-n** option to start syslogd in the network-only mode.

In all three modes, syslogd can send messages to remote syslog daemons.

Requirement: You must install and activate the AF_UNIX domain prior to starting syslogd in normal or local-only mode.

As shown in Table 13 on page 194, how you choose to run syslogd depends on your logging requirements.

Table 13. Mode to use for different logging requirements

Logging requirement	How to run syslogd
You have a low volume of messages that you want to process from the network.	Run a single instance of syslogd in normal mode.
You do not want to process any log messages from remote syslog daemons over the network.	Run a single instance of syslogd in local-only mode.
You have a high volume of log messages from remote syslogd daemons that you want to log with syslogd.	Run two instances of syslogd. Start syslogd in local-only mode to process all local messages. Start another instance of syslogd in network-only mode to process the remote syslog messages. Two instances of syslogd provide better performance than running a single instance of syslogd in normal mode, especially in high-volume situations.

Restriction: A maximum of two instances of syslogd can be started. If you are going to start more than one instance of syslogd on the same z/OS image, one instance must be started in local-only mode and one instance must be started in network-only mode. Never run just one instance of syslogd in network-only mode. If an instance of syslogd is not processing local system and application messages, these messages are written to the MVS console and might result in message flooding on the MVS console.

For more accurate recording of timestamps, you need to set the TZ environment variable to local time. You can set the TZ environment variable in the following ways:

- When starting syslogd from the z/OS shell:

  Export the TZ environment variable before starting syslogd; you should do this in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

  ```
  export TZ=EST5EDT
  ```

- When starting syslogd as a started task, use either of the following methods:
  - Specify TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

    ```
    // PARM='ENVAR("TZ=EST5EDT")/'
    ```

  - Export the TZ environment variable in a file specified with the STDENV DD statement. For example:

    ```
    // PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
    //STDENV DD PATH='/etc/syslogd.env',PATHOPTS=(ORDONLY)
    ```

    Place the following statement in the /etc/syslogd.env file:

    ```
    TZ=EST5EDT
    ```

    The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRM*xx* PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
```

For more information on specifying run-time options, see *z/OS Language Environment Programming Guide*. For details on setting the TZ environment variable, see *z/OS UNIX System Services Command Reference*.

Following is the syntax for the syslogd command:

syslogd [–c] [–d] [–D *value***] [–f** *conffile***] [–F** *value***] [–i] [–m** *markinterval***] [-n] [–p** *logpath***] [–u] [-x] [-?] &**

The **syslogd** command recognizes the following options:

-c Create log files and directories automatically. The **-c** option is required to use the automatic archive function (see "Configuring syslogd for automatic archiving" on page 204).

-d Run syslogd in debugging mode (see "Diagnosing syslogd configuration problems" on page 207 for more information).

-D Default access permissions (modes) to be used by syslogd when creating directories. This parameter is valid only when specified in conjunction with the **-c** option. The parameter value is specified as an octal number 1 – 4 characters in length. Leading zeros can be omitted. The following values can be ORed together to form the parameter value:

Value	Description
2000	Set GID
1000	Sticky bit (deletion restricted to owner or superuser)
0400	User read
0200	User write
0100	User list directory
0040	Group read
0020	Group write
0010	Group list directory
0004	Other read
0002	Other write
0001	Other list directory

If the -D option is not specified, the default value 0700 is used. Value 0000 and bits other than the ones shown are not valid. For example, you cannot set the set-UID bit for a directory. z/OS does not use the set-GID bit during directory creation regardless of whether the bit was set in the directory permissions.

-f Configuration file name. You can also specify the configuration file using the SYSLOGD_CONFIG_FILE environment variable. The **-f** option overrides the environment variable.

-F Default access permissions (modes) to be used by syslogd when creating log files. This parameter is valid only when specified in conjunction with the **-c** option. The parameter value is specified as an octal number 1 – 4

characters in length. Leading zeros can be omitted. The following values can be ORed together to form the parameter value:

Value	Description
0400	User read
0200	User write
0040	Group read
0020	Group write
0004	Other read
0002	Other write

If the -F option is not specified, the default value 600 is used. The actual permissions are modified by the syslogd process umask value at the time when the file is created. This parameter is used only when syslogd must create a log file dynamically; it has no effect on log files that already exist. Value 0000 and bits other than the ones shown are not valid. For example, you cannot set the execute bits, set-UID, set-GID, or the sticky bit for log files.

-i Start in local-only mode, and do not receive messages from the IP network. This option is mutually exclusive with the **-n** option. If syslogd is started with the **-i** option, another instance of syslogd can be started with the **-n** option. This is the only supported way to run two instances of syslogd on the same z/OS image. Syslogd can still send messages to remote syslogd instances when running in local-only mode.

-m Number of minutes between mark messages. The default value is 20 minutes. The following rule must be coded for each logfile that you want a mark record recorded in: mark.info.

-n Start in network-only mode, and receive messages from only the IP network. This option is mutually exclusive with the **-i** option. If syslogd is started with the **-n** option, another instance of syslogd can be started with the **-i** option. This is the only supported way to run two instances of syslogd on the same z/OS image. Syslogd can still send messages to remote syslogd instances when running in network-only mode.

-p Path name of the z/OS UNIX character device for the datagram socket. The default value is /dev/log. You can also specify the path name using the SYSLOGD_PATH_NAME environment variable. The **-p** option overrides the environment variable.

Note: This option is not used frequently. If you selected the **-p** option, syslogd will not function properly.

-u For records received over the AF_UNIX socket (most messages generated on the local system), include the user ID and job name in the record. In this case, a forward slash, the user ID, and the job name will follow the local host name for messages received over the AF_UNIX socket. The forward slash, which immediately follows the local host name, can be used to determine whether or not the user ID and job name is being recorded. If not recorded, a blank immediately follows the local host name. When user ID or job name is not available, *N/A* will be written in the corresponding field.

-x Disable host name resolution for messages received from the IP network.

This option is mutually exclusive with the **-i** option. Using this option can improve the performance of syslogd when processing messages received from the IP network. It has no effect for local messages. When you use this option, the IP address (instead of the host name) of the origin host is logged, along with the message text. If the host name can be determined from the rule without having to make a resolver call, the host name is used instead of the IP address. When the **-x** option is not used, syslogd always attempts to resolve the host name associated with a log message arriving from the IP network. If the host name cannot be determined, the IP address is logged as the message origin instead of the host name.

-? Show syslogd command-line options.

To specify the job name and pass the appropriate environment variables to the syslogd process, start syslogd using a shell script such as the following:

```
#
# Start the syslog daemon
#

export _BPX_JOBNAME='syslogd'
/usr/sbin/syslogd -f /etc/syslog.conf &
```

You can execute this shell script directly from the /etc/rc file to start syslogd at z/OS UNIX initialization.

If an incorrect argument or number of arguments is entered, syslogd exits and the return code is 1. In all other situations in which syslogd exits, the return code is 0.

To terminate syslogd, you can issue the STOP command, issue the MODIFY command, or send a SIGTERM signal.

```
STOP jobname

MODIFY BPXOINIT,TERM=processID

kill -s TERM processID
```

To force syslogd to reread its configuration file and activate any modified parameters without stopping, issue the MODIFY *procname*,RESTART command or send a SIGHUP signal. This also causes any host names specified in rule selectors or destinations to be resolved again to IP addresses. After rereading the configuration file, syslogd continues to append log messages to the files that you specify in /etc/syslog.conf.

```
MODIFY procname,RESTART

kill -s HUP processID
```

The syslog daemon stores its process ID in the /etc/syslog.pid file or the /etc/syslog_net.pid file, so that it can be used to terminate or reconfigure the daemon. If syslogd is started in normal or local-only mode, the /etc/syslog.pid file is used to store the process ID. If syslogd is started in the network-only mode, the /etc/syslog_net.pid file is used to store the process ID.

Rule: If the BPX.SMF FACILITY class resource is defined and SMF records are to be written by syslogd, the user ID with which syslogd runs must also be permitted to SAF resource BPX.SMF. See SEZAINST(EZARACF) for more information.

Tips:

- Messages are read from the UNIX domain datagram socket (unless the **-n** option is specified), and from the IPv4 (AF_INET) or IPv6 (AF_INET6) Internet domain datagram socket (unless the **-i** option is specified).
- Messages written to a local instance of syslogd with the kern facility are converted to the user facility. If syslogd receives a log message over the network with the kern facility, the facility is not changed.

For more information about the facilities used by z/OS Communications Server functions, see Table 3 on page 35.

Configuring syslogd to receive remote messages

The ability to receive messages from remote syslogd instances can be very useful in providing a consolidated log of messages from multiple hosts into a consolidated z/OS message log. For example, in scenarios where you are running Linux hosts on zSeries processors, and these Linux hosts are performing processing in cooperation with or on behalf of z/OS systems, you might want to have certain important messages generated on the Linux hosts visible from a z/OS system. This capability would enable z/OS operators to be alerted of specific conditions on the Linux hosts that might require actions to be taken locally or on the Linux hosts.

If you decide that this remote logging capability is useful in your environment, there are several configuration considerations that should be examined prior to enabling this function. It is also important to note that the syslogd remote logging capability can work in both directions; the z/OS syslogd can forward some of its messages to another remote syslogd instance, or the z/OS syslogd instance can be the receiver of remote syslogd messages. The considerations described here focus primarily on the latter scenario, where the z/OS syslogd is the recipient of remote messages.

Improving the efficiency of syslogd remote logging functions

While the ability for the z/OS syslogd to receive remote messages can be very useful, it is important that proper planning take place to ensure that the additional remote message traffic that syslogd receives does not create a performance issue or impede the ability for the local z/OS syslogd to perform its processing. The following configuration options can help reduce such risks:

- Configure the remote syslogd instances to forward only messages that are important enough to consolidate on the z/OS system. For example, high-volume debug traces should be collected on the local host instead of having them forwarded to a z/OS system. Syslog daemon implementations typically provide the ability to define configuration statements that dictate which type of messages are forwarded to remote hosts. For example, the z/OS syslogd enables you to filter messages based on the facility and priority associated with a message. For more information about the specific configuration of your remote syslogd instances, consult the documentation available for the platform on which the remote syslogd instance is running.
- If the remote message traffic that the local z/OS syslogd instance is expected to receive is substantial, consider configuring a network-only instance of syslogd and a local-only instance of syslogd. This helps ensure that the logging of locally generated z/OS syslogd messages is not impacted by high-volume remote message traffic.
- When the local z/OS syslogd instance receives a message from a remote syslogd, it determines the disposition of the message based on its own configuration statements. These configuration statements enable you to determine which

received messages are of interest and how these messages should be logged. The following are some guidelines on how these statements can be configured for remote message receipt:

– The z/OS syslogd can log messages to various destinations, including zSeries File System files, the MVS console, the MVS operations log, SMF records, and so on. If the destination for the remote messages is the MVS console or MVS system log designated with the /dev/console destination, consider whether logging these messages to the MVS operations log (that is, the OPERLOG log stream) designated by the /dev/operlog destination is a suitable alternative. Logging messages to the OPERLOG log stream is more efficient and consumes less system resources than logging messages to the MVS console.

  The OPERLOG log stream must be configured and active before using the syslogd /dev/operlog destination. If the OPERLOG log stream is not active when syslogd attempts to log a message to the /dev/operlog destination, message FSUM1234 is logged with a facility.priority value of daemon.error. If the OPERLOG log stream later becomes active, message FSUM1235 is logged with a facility.priority value of daemon.info, and logging to OPERLOG automatically begins. For more information about using OPERLOG, see *z/OS MVS Planning: Operations*.

– You can identify which messages the z/OS syslogd should process by identifying the known remote syslogd instances from which you expect to receive messages. For example:

```
(host1.xyz.com).*.*        /dev/operlog
(host2.xyz.com).*.*        /dev/operlog
```

  In this example, syslogd resolves the specified host names to the IP addresses associated with those hosts during initialization by invoking the system resolver services. After initialization is complete and syslogd begins receiving remote messages, it first checks to determine whether the incoming messages match any of the specified configuration statements. In this example, syslogd processes only remote messages that have a source IP address associated with the hosts host1.xyz.com or host2.xyz.com, and logs these messages in the MVS operations log. Assuming that no other configuration statements are specified, any messages received from other hosts are discarded.

  Specifying configuration statements that identify each remote host using a host name also has the additional benefit of enabling these remote messages to include a host name identification when they are logged locally, without incurring the overhead of a host name resolver lookup for each incoming message. The per-message host name resolver lookup can be disabled using the **-x** syslogd option. If the ability to perform a resolver lookup for every message is necessary or useful in your environment, you should use the system resolver cache function (see "Customizing the resolver" on page 733 and "Resolver caching" on page 744). If host name resolution is performed, and the message was received over a link-local IP address, the resolved host name might include scope information that identifies the interface over which the message was received. For more details on support for scope information on a host name, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

  In addition to host names, remote syslogd instances can also be identified using IPv4 or IPv6 addresses or by specifying an IPv4 subnetwork or IPv6 network prefix. For example:

```
(10.42.105/24).*.*         /dev/operlog
(10.43.110.15).*.*         /tmp/otherlog
```

In this example, any remote messages received from hosts using an IP address in subnetworks 10.42.105.0 to 10.42.105.255 are logged in the MVS operations log, while messages received from the host identified by 10.43.110.15 are logged in the /tmp/otherlog file.

– In addition to identifying the remote syslogd instances that can forward messages, you can also use additional filters to determine which remote messages you want to log locally. For example:

```
(host1.xyz.com).*.crit        /dev/operlog
(host2.xyz.com).*.crit        /dev/operlog
```

With these configuration statements, syslogd logs only messages received from hosts host1 and host2 that have a critical priority to the MVS operations log. Assuming that no other configuration statements are specified, any other messages received from those hosts are discarded.

Security considerations

As with all network communication protocols, give careful consideration to the security requirements that might be appropriate to protect this remote message logging function in your environment. The following are some of the considerations to be examined:

- How do you ensure that the messages sent by a given host did in fact originate on that host, and that these messages have not been modified or replayed by a third party in the network?

  One mechanism that can be used to answer these questions is to deploy a Virtual Private Network (VPN) using IPSec across the remote syslogd instances and the local z/OS syslogd. IPSec configured with the Authentication Header (AH) protocol provides data integrity, data origin authentication, and an optional replay protection service. To deploy IPSec for syslogd traffic, configuration is required on both the local z/OS system and the remote hosts on which the syslogd instances that are forwarding messages reside. On the z/OS side, this is accomplished by defining an IP security policy. In this IP security policy, you specify filter rules that indicate all the remote hosts that are allowed to send UDP traffic to the local syslogd on port 514, along with the IPSec actions that define the IPSec attributes for this traffic. The IPSec policy can be defined in such a way that if any UDP datagrams destined for local UDP port 514 are received that do not match the IP security policy, they are discarded by the local TCP/IP stack. This provides an additional level of protection against denial of service attacks for syslogd, as unauthorized messages are discarded without syslogd needing to process them.
- What if the forwarded messages contain sensitive data? How do you protect the confidentiality of the data as it traverses the network?

  You can use the IPSec Encapsulating Security Payload (ESP) protocol to provide data confidentiality (encryption). Note that the ESP protocol can also be used to provide some of the same functions that the AH protocol provides, such as data integrity, data origin authentication, and replay protection.

Obviously, the security considerations for deploying remote syslogd logging depend on your local environment and your local security policies. For more information about the z/OS configuration for IPSec, see “Overview of using IP security” on page 929. For more information about configuring IPSec on the remote hosts, consult the documentation for that platform.

Availability considerations

Syslogd availability is important to the logging of both local and remote messages. The following configuration considerations can help improve the availability of the z/OS syslogd remote logging services:

- Ensure that there is a process in place to restart a z/OS syslogd after a failure that results in the termination of syslogd. This can be accomplished by placing syslogd in the AUTOLOG list in the TCP/IP profile. This enables TCP/IP to initially start the syslogd instance as a started task, and also enables TCP/IP to monitor whether syslogd has a socket bound to the syslogd port used for remote message receipt (UDP port 514). This approach works well for single-stack INET configurations. If multiple TCP/IP stacks are deployed on a single system (that is, a CINET configuration), you should not use the AUTOLOG list. Alternatively, an installation can use any available automated operations software package to automate the start and restart of syslogd. For more information about the AUTOLOG statement, see *z/OS Communications Server: IP Configuration Reference*.
- On MVS systems that are not part of a sysplex and that have TCP/IP stacks with multiple network interfaces, using a static VIPA address can provide for better availability characteristics should a specific network interface or network experience an outage. This involves configuring a static VIPA in the TCP/IP profile or reusing an existing one. No special configuration of the local syslogd is needed. However, you should configure the remote syslogd instances to use the static VIPA address as the destination address when forwarding messages. This can typically be accomplished by either specifying the static VIPA as the destination address, or specifying a host name that maps to the static VIPA in the remote syslogd configuration.
- When the recipient syslogd instance is running in a sysplex environment, additional availability features are available that should be explored. For example, you can use a multiple application-instance dynamic VIPA (DVIPA) to represent the syslogd instance on a given system, and the remote syslogd instances are configured to use that DVIPA address as the destination IP address for the messages they forward. In this configuration, if a failure to the MVS system or TCP/IP stack on which the syslogd instance is running occurs, the DVIPA is automatically moved to a predefined backup system that is currently active. This enables the syslogd instance on that backup system to begin processing these remote messages in a transparent manner. In this configuration, using the MVS operations log (OPERLOG) as the destination provides additional benefits, because the operations log is implemented as a coupling facility log stream that any system in the sysplex can access. For additional information related to static and dynamic VIPAs, see Chapter 7, “Virtual IP Addressing,” on page 351.

Additional considerations

Syslogd on z/OS receives remote messages as UDP packets on port 514. Because UDP is a connectionless protocol that does not provide reliable communications, the potential exists that some UDP packets containing forwarded syslogd messages can be dropped, either in the network as a result of network congestion or on the z/OS system if the syslogd is overloaded and cannot process incoming messages fast enough. If this occurs, these messages are not seen by the z/OS syslogd instance, nor is the remote syslogd instance made aware of the dropped messages. As a result, make provisions to enable direct access of syslogd messages on the remote hosts. In addition, you should perform a detailed evaluation on the risks associated with the potential for message loss, prior to using any z/OS-based automated operations software to trigger actions based on the remote messages received by the z/OS syslogd.

Offloading log files

z/OS Communications Server includes a syslogd configuration file in /usr/lpp/tcpip/samples/syslog.conf, a REXX program for removing old log files in /usr/lpp/tcpip/samples/rmoldlogs, and a JCL procedure for starting syslogd in SEZAINST(syslogd). These are intended to be used together, though each may need to be customized for your installation.

Guideline: You should use this method of offloading or archiving files only if you do not use the automatic archive function of syslogd that is described in "Configuring syslogd for automatic archiving" on page 204. Because both of these methods rely on creating new log files, results are unpredictable if you try to use both methods together.

The sample syslogd configuration file is installed in /usr/lpp/tcpip/samples/syslog.conf. It can be copied to /etc/syslog.conf after customization. If it is copied somewhere else, the syslogd **-f** command-line option must be used to tell syslogd where to find the configuration file.

The sample REXX program for removing old log files is installed in /usr/lpp/tcpip/samples/rmoldlogs. It can be copied to an installation-defined directory after customization. The sample JCL procedure can be copied to an installation-defined library after customization.

The sample configuration uses date stamps in the names of directories of log files to organize log files by year (%Y), month (%m), and day (%d) as follows:

```
*.err      /var/log/%Y/%m/%d/errors
```

Log files for February 14, 2001, for example, would be stored in directory /var/log/2001/02/14. Variable substitution occurs using the Language Environment C function strftime(). Variables are case sensitive. For more information and a complete list of variables, see *z/OS XL C/C++ Run-Time Library Reference*.

A cron job should be used to send the SIGHUP signal to syslogd every day at midnight so that it switches to a new set of files. The cron job should be created for a user ID with UID 0. The definition of the cron job is:

```
0 0 * * * kill -HUP `cat /etc/syslog.pid`
```

Tip: An accent mark (`) is used in this definition, not a single quotation mark.

The log file names vary based on the day, so sending SIGHUP to syslogd after the day changes causes syslogd to create new files.

Because some messages sent just after midnight may be logged by syslogd before it processes the SIGHUP signal, it is possible that a few messages sent after midnight will be stored in the log files for the previous day.

The sample REXX program can be run daily to remove all log files older than the number of days specified in the program. Comments in the REXX program describe how to configure the number of days. The definition of a cron job to run the REXX program every day at 1:00 A.M. is:

```
0 1 * * * localdir/rmoldlogs
```

localdir is the name of the installation-defined directory where the customized version of /usr/lpp/tcpip/samples/rmoldlogs was copied.

Setting permissions for log files and directories

When you specify the **-c** start option, syslogd creates log files and directories dynamically. By default, directories are created with the permissions value 0700, which means that only the owner can read, write, and list the contents of the directory. Similarly, if syslogd needs to create a file, the default permissions value is 600, which again means that only the owner can read and write to the file. Because a user ID with UID 0 must run syslogd, the owner is always a superuser. To change the default permissions used by syslogd, use either the -F or the -D start option to set the global default permissions for files and directories, respectively.

Tip: The -F and -D start options have no effect on files or directories that already exist.

You can also use the -F and -D configuration options to override global defaults for individual syslogd rules. Specify -F or -D (or both) with octal values following the file name. For example:

```
*.err      /var/log/%Y/%m/%d/errors -F 640 -D 644
```

The file permission bits, whether provided on the rule or as global defaults, are modified by the syslogd process file creation mask (umask), and then used to set the file permission bits of a file that is being created.

If you are considering allowing users other than a superuser to have access to log files, before changing the syslogd default permissions for files and directories, be sure to consider the following options:

- Before starting syslogd, create the log file (and containing directory if necessary) with permissions and ownership that allows the other users to have access. If a single user needs access, you can make the file user ID (UID) match that of the user ID that needs access. If multiple users need access, set a new or existing group ID (GID) as the file's GID, and set the permissions to allow members of the group to have read access, write access, or both. The file or directory UID and GID can be set with the **chown** command. Be sure to give the syslogd user ID write access to the log files. This technique is useful only if the files are not being created dynamically by syslogd.
- If you are not using file access control lists (ACLs), files and directories created by syslogd have the owner UID 0. By default, the owning GID is set to that of the parent directory. However, if the FILE.GROUPOWNER.SETGID profile exists in the UNIXPRIV class, the owning GID is determined by the set-GID bit of the parent directory, as follows:
  - If the set-GID bit of the parent directory is on, the owning GID is set to that of the parent directory.
  - If the set-GID bit of the parent directory is off, the owning GID is set to the effective GID of the process.

  When there are no file access control lists, the only way to manage log files with different access requirements that must be accessed by different groups of users is to create the containing directories with the appropriate GIDs before starting syslogd, and let syslogd dynamically create the log files in the appropriate directories. The log files then inherit the GID of the directory, if the directory has the set-GID bit on.
- A third way to provide access to log files for different users or groups of users is to use file access control lists. For information about setting file access control lists, see the **setfacl** command in *z/OS UNIX System Services Command Reference*. The ACLs for dynamically created directories and files can be inherited from

defaults set on the parent directory. When using this method, be sure that the syslogd user ID continues to have write access to the log files.

Configuring syslogd for automatic archiving

You can set up syslogd to perform automatic archival of eligible z/OS UNIX files that are configured as destinations on syslogd rules. Eligible files are those that you tag using the -N or -X parameter on the rule definitions. You can choose to archive at a specific local time of day, or when the file systems that contain the eligible files become too full, or both. You can also perform an on-demand archive using an operator command.

Guideline: You should use this method of archiving files only if you do not offload files using the provided sample configuration and procedure that are described in "Offloading log files" on page 202. Because both of these methods rely on creating new log files, results are unpredictable if you try to use both methods together.

To configure syslogd for automatic archiving, you must perform the following:

- Configure the events that trigger automatic archival
- Configure the archive details for each z/OS UNIX file

Steps for configuring the events that trigger automatic archival

Before you begin: Automatic archiving can be performed at a specific local time every day, or when one or more of the z/OS UNIX file systems that contain the eligible files become too full. Determine whether you want to configure one or both of these triggers.

Requirement: You must specify the **-c** start option when you are using the automatic archive function.

Perform the following steps to configure syslogd archive triggers:

1. Specify the ArchiveTimeOfDay statement in the syslogd configuration file to specify the local time of day using hours and minutes in a 24 hour clock format.
2. Specify the ArchiveThreshold statement in the syslogd configuration file to specify the percentage of the file system that must be full to trigger an automatic archive.

   Guideline: You should set up the syslogd file destinations as one or more separate z/OS UNIX file systems. Threshold-based archiving works best when the file systems contain only data written by syslogd.
3. Specify the ArchiveCheckInterval statement in the syslogd configuration file to specify the interval in minutes at which syslogd should check to determine how full the file systems are.

Result: The configuration statements that define archive triggers are global statements. If you configure these statements multiple times, the last instance is used.

Steps for configuring the archive details for each z/OS UNIX file

Automatic archiving operates on eligible z/OS UNIX files. You can configure which files are eligible by specifying parameters on each individual rule. You can also configure global parameters that affect the archive process and determine the destination data sets for each file.

Guideline: You need to protect the syslogd archive data sets using available data set access controls to ensure that only authorized personnel are allowed to read these data sets. Syslogd archive data sets might contain sensitive information.

Perform the following steps to configure the archive details for each z/OS UNIX file:

1. Specify the BeginArchiveParms statement in the syslogd configuration file. The BeginArchiveParms statement specifies a data set name prefix that is extended with a unique qualifier for each file to be archived, for the set of rules that follows this statement.
2. Specify the -N parameter on each rule that uses a z/OS UNIX file, to mark the file as eligible for automatic archiving. You can also specify the -X parameter on a rule, to indicate that the file should be re-initialized when an archive event occurs. If you do not specify the -N or -X parameters on a rule, then nothing happens to the destination file when an archive event occurs.

   If you use generation data group (GDG) data sets as an archive destination, the GDG base must already be created. The following sample JCL creates a GDG base called USER1.SYSARCH.

```
//USER1X   JOB MSGLEVEL=(1,1),MSGCLASS=D,NOTIFY=USER1
//GDGA EXEC PGM=IDCAMS
//*
//GDGMOD   DD DSN=USER1.SYSARCH,
//      VOL=SER=CPDLB1,
//          UNIT=SYSALLDA,
//          SPACE=(TRK,(0)),
//          DCB=(LRECL=80,RECFM=FB,BLKSIZE=6800,DSORG=PS),
//          DISP=(,KEEP)
//SYSPRINT DD SYSOUT=*
//SYSIN    DD *
  DEFINE GENERATIONDATAGROUP -
         (NAME(USER77.MYGDG) -
         EMPTY -
         NOSCRATCH -
         LIMIT(255) )
```

   For more information about GDG data sets, see *z/OS DFSMS Using Data Sets*.

Using syslogd for z/OS UNIX application programs

You can use the logging facilities of the syslogd server with your z/OS UNIX application programs. Include the syslog.h header file with C programs so that they can open a log facility, send log messages to syslogd, and close the facility:

```
#include <syslog.h>

1 openlog("oec", LOG_PID, LOG_LOCAL0);
2 syslog(LOG_INFO, "Hello from oec");
3 closelog();
```

1 Open a log facility with the name of local0. Prefix each line in the log file with the program name (oec) and the process ID.

2 Log an info priority message with the specified content.

3 Close the log facility name.

The preceding statements created the following line in the log file:

```
May 26 11:27:51 mvs18oe oec[3014660]: Hello from oec
```

For more information about the syslog function, see *Advanced Programming in the UNIX Environment*, published by Addison-Wesley or *z/OS XL C/C++ Run-Time Library Reference*.

Usage notes

- It is possible to run two instances of syslogd. One instance must be started so that it processes messages from only the local host (**-i** option); the other instance must be started so that it processes messages from only the network (**-n** option).
- If you run two instances of syslogd, one for local messages and another for network messages, and you also configure the automatic archival function, do not configure the same UNIX file destinations in the two configuration files. The archival function renames, closes, and reopens the UNIX files. If two instances of syslogd are performing the archival function on the same set of files, results of the archival function are unpredictable. The same is true for the configured archive destination data sets. Be sure to configure unique UNIX file destinations and archive data set names for the two syslogd instances.
- syslogd can run swappable or nonswappable. When an application makes an address space nonswappable, it might convert additional real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing syslogd to run in a nonswappable state can reduce the installation's ability to reconfigure storage in the future. Use the following guidelines to set the desired state:
  - If the FACILITY class resource BPX.STOR.SWAP is not defined to the system:
    - syslogd will run nonswappable.
    - syslogd cannot be prevented from running nonswappable.
  - If the FACILITY class resource BPX.STOR.SWAP is defined to the system with UACC(NONE):
    - syslogd will run swappable by default (no access to BPX.STOR.SWAP).
    - syslogd can run nonswappable (given at least READ access to BPX.STOR.SWAP).
  - To define the FACILITY class resource BPX.STOR.SWAP issue the following commands:

    ```
    RDEFINE FACILITY BPX.STOR.SWAP UACC(NONE)
    SETROPTS RACLIST(FACILITY)REFRESH
    ```
- If you want syslogd to receive log data from remote syslogd servers, ensure that syslogd can bind to UDP port 514 by reserving that port for the syslogd job in your PROFILE.TCPIP data set. Ensure that the syslog service is defined in your services file or data set (for example, /etc/services). The following example port reservation in PROFILE.TCPIP assumes that syslogd runs as job syslogd1:

  ```
  PORT
  ...
  514 UDP syslogd1     ;syslogd daemon
  ...
  ```

  The following example shows the services file or data set file entry:

  ```
  syslog     514/udp
  ```
- Configuration file errors are written to the operator console because initialization is not complete until the entire configuration file has been read.
- Facility mark is not affected by the *.priority usage. Mark messages are written only to the destinations of rules that specify mark.info.
- If a mark interval of zero minutes is specified, mark messages will be written every thirty seconds.

Diagnosing syslogd configuration problems

You must install and activate the AF_UNIX domain prior to starting syslogd in normal or local-only mode. To determine whether AF_UNIX was successfully started, check for a message in the console log similar to the following:

```
BPXF203I DOMAIN AF_UNIX WAS SUCCESSFULLY ACTIVATED.
```

syslogd supports a debug mode, which is selected using the **-d** command-line option. If you run syslogd from the UNIX shell using this debug mode, syslogd writes debug messages to STDOUT. These messages can be used to diagnose problems in the syslogd configuration or to collect documentation when reporting a syslogd problem to IBM support.

You can use the SYSLOGD_DEBUG_LEVEL environment variable to limit the amount of debug messages. You can specify the following debug levels:

Value	Level
1	Base debugging information.
2	Configuration file processing.
4	Message handling information for messages being logged by syslogd.
8	Automatic archive processing.
16	Operator command processing.
32	Thread-specific processing.
64	Mutex lock processing. Locks that are specific to threads are logged only if the debug level includes 32.

You can add these values together in any combination to select the type of debug messages to be written. For example, SYSLOGD_DEBUG_LEVEL=91 includes all debugging information except for message handling and thread-specific processing (including locks). The default debug level is 127, which includes all debug information.

Rule: Do not use the **-d** option for normal operations.

If you are running syslogd in batch with **-d**, debug output is written to SYSPRINT, SYSTERM, or SYSERR, whichever is found first. The sample syslogd procedure SEZAINST(syslogd) defines SYSPRINT so that debug messages are stored in the job output. The following example shows how to change the SYSPRINT DD statement to write debug output to a file.

```
SYSPRINT DD PATH='/var/syslog/syserr',PATHOPTS=(OWRONLY,OCREAT)
```

Use caution using **-d** when syslogd is started from /etc/rc. If **-d** is used in this way, the shell background character (&) must be used to run syslogd in the background. Otherwise, /etc/rc does not end and UNIX System Services initialization does not complete.

If you are using the automatic archive function of syslogd, it is possible that an archive of a particular file fails. A failure can occur for many reasons, including dynamic allocation errors for the target data set, or read/write errors for the UNIX file or target data set. If a failure occurs, syslogd attempts to archive the file again when the next archive trigger event occurs, but it is possible that all archive attempts continue to fail. If all attempts fail, the original UNIX file to be archived still exists in the UNIX file system, renamed with a suffix of the form

D*yymmdd*.T*hhmmss*, and the target data set might also exist and contain partial data. You should examine the error messages in the syslogd destination output file for the daemon facility to determine which files have failed, and manually recover or delete such files and the associated partial archive data sets.

Configuring TCPIP.DATA

The TCPIP.DATA configuration data set is the anchor configuration data set for the TCP/IP stack and all TCP/IP servers and clients running in z/OS. With a z/OS TCP/IP stack, you can define the TCPIP.DATA parameters in a z/OS UNIX file or in an MVS data set. The TCPIP.DATA configuration data set is read during initialization of all TCP/IP server and client functions. All functions must access this data set in order to find basic configuration information, such as the name of the TCP/IP address space, the TCP/IP host name, and the data set prefix to use when searching for other configuration data sets. The TCPIP.DATA file contains the following major groups of configuration parameters:

- Application operating characteristics
- Resolver operating characteristics
- Socket library diagnostic data statements
- Resolver diagnostic data statements

Use of TCPIP.DATA and /etc/resolv.conf

The TCPIP.DATA data set is also known as one of the resolver configuration data sets. In fact, this name is now more commonly used to refer to this important file in the UNIX System Services environment because the socket library contains a component called the resolver. In a UNIX system, you use the /etc/resolv.conf file for the same purpose as you use TCPIP.DATA in your MVS system.

TCPIP.DATA specifies the name of the TCP/IP address space. Because the data set search order can vary, your installation will determine which data set you can use. See Chapter 2, “IP configuration overview,” on page 11 for search order, data set, and file retrieval information.

If you use TCPIP.DATA, it can be shared between multiple systems with a system name. But, if TCPIP.DATA is allocated via SYSTCPD DD and an application forks, any allocations from the parent of SYSTCPD are lost to the child process.

In z/OS UNIX System Services, each application can have its own environment variable, RESOLVER_CONFIG='xxx'. There are no concerns for forked child processes; however, this means that you cannot share the same data set or file among multiple systems.

Creating TCPIP.DATA

Create a TCPIP.DATA file by copying the sample provided in SEZAINST(TCPDATA) and modifying it to suit your local conditions.

Allocate this data set with either sequential (PS) or partitioned (PO) organization, a fixed (F) or fixed block format (FB), a logical record length (LRECL) between 80 and 256, and any valid block size for a fixed block. This file can also be the file /etc/resolv.conf, or a z/OS UNIX file that is pointed to by either the environment variable RESOLVER_CONFIG or the SYSTCPD DD in a JCL procedure. If you have a z/OS UNIX file, the maximum line length can be 256. The environment variable RESOLVER_CONFIG can also point to an MVS data set or PDS.

You can use any name for the TCPIP.DATA data set if you access it using the //SYSTCPD DD statement, or use ENVAR to set RESOLVER_CONFIG, in the JCL for all the servers, logon procedures, and batch jobs that execute TCP/IP functions. If you are not using the //SYSTCPD DD statement, the environment variable, or /etc/resolv.conf, then the data set name must conform to the conventions described in "Configuration files for the TCP/IP stack" on page 28. Another alternative is to use the well-known data set name SYS1.TCPPARMS(TCPDATA). You will eventually issue the HOMETEST command with TRACE RESOLVER activated to verify the actual data set name the system finds for TCPIP.DATA. However, because HOMETEST is an MVS sockets application, it does not use RESOLVER_CONFIG or /etc/resolv.conf in its search order. For this reason, it is recommended that /etc/resolv.conf and TCPIP.DATA contain exactly the same information or consider using the resolver GLOBALTCPIPDATA setup statement.

Rule: Since TCPIP.DATA statements might need to be read and used multiple times by the resolver, the FREE=CLOSE JCL parameter should not be used when allocating SYSTCPD. To allow TCPIP.DATA statements to be changed while still allocated for long running programs, consider using a member of an MVS partitioned data set instead of an MVS sequential data set. For these long running applications, the resolver MODIFY REFRESH command should then be used to indicate that TCPIP.DATA statements have been changed.

TCPIP.DATA statements

Each configuration statement can be preceded by an optional *system_name*. This permits configuration information for multiple systems to be specified in a single *hlq*.TCPIP.DATA data set. The *system_name* is matched against the name of the system on which you are running. The name of the system is specified as part of the VMCF subsystem initialization, as the *nodename* value on the following parameter and statement:

- P= start parameter of the EZAZSSI started procedure
- VMCF statement of the IEFSSN*xx* member of parmlib

For more information about starting VMCF, see "Step 3: Configure VMCF and TNF" on page 103.

The statements are processed in the order they appear in the data set. The following rules apply to this processing:

- If the *system_name* does not match the name of the system, the configuration statement is ignored.
- If *system_name* is blank, the configuration statement is in effect on every system.
- If the *system_name* matches the host's name, the configuration statement that follows it is in effect.
- The ***last*** statement that matches is effective.

For example, if you have the following three TCPIPJOBNAME statements, MVS6 would look for a TCP/IP cataloged procedure named TCPBTA2, MVSA would look for TCPV3, and all other systems would look for TCPMCWN.

```
      TCPIPJOBNAME TCPMCWN
MVS6: TCPIPJOBNAME TCPBTA2
MVSA: TCPIPJOBNAME TCPV3
```

But if you reversed the order, all systems would try to find the procedure named TCPMCWN.

```
MVS6: TCPIPJOBNAME TCPBTA2
MVSA: TCPIPJOBNAME TCPV3
      TCPIPJOBNAME TCPMCWN
```

Take special care with those TCPIP.DATA statements that can be specified multiple times, such as the SEARCH, SORTLIST, NSINTERADDR/NAMESERVER, OPTIONS, and LOADDBCSTABLES statements. Because these statements are cumulative, if you specify a *system_name* value, it might need to be used on all instances of the same statement. Consider the following examples.

Example 1:

```
                NSINTERADDR 5.5.5.5
                NSINTERADDR 1.1.1.1
           TN03: NSINTERADDR 1.1.1.1
           TN03: NSINTERADDR 2.2.2.2
           TN04: NSINTERADDR 3.3.3.3
           TN04: NSINTERADDR 4.4.4.4
```

After these TCPIP.DATA statements are processed, the following ordered list of DNS addresses is available:

```
On TN03:
     5.5.5.5
     1.1.1.1
     1.1.1.1
     2.2.2.2
On TN04:
     5.5.5.5
     1.1.1.1
     3.3.3.3
     4.4.4.4
All others:
     5.5.5.5
     1.1.1.1
```

Example 2:

```
           TN03: NSINTERADDR 1.1.1.1
           TN03: NSINTERADDR 2.2.2.2
           TN04: NSINTERADDR 3.3.3.3
           TN04: NSINTERADDR 4.4.4.4
                 NSINTERADDR 5.5.5.5
                 NSINTERADDR 1.1.1.1
```

After these TCPIP.DATA statements are processed, the following ordered list of DNS addresses is available:

```
On TN03:
     1.1.1.1
     2.2.2.2
     5.5.5.5
     1.1.1.1
On TN04:
     3.3.3.3
     4.4.4.4
     5.5.5.5
     1.1.1.1
All others:
     5.5.5.5
     1.1.1.1
```

A sample TCPIP.DATA data set (TCPDATA) can be found in SEZAINST. For detailed information on each of the statements, see *z/OS Communications Server: IP Configuration Reference*.

Using MVS system symbols in TCPIP.DATA

For ease of management when configuring a complex environment, use MVS system symbols such as &SYSCLONE, &SYSNAME, and &SYSPLEX. The resolver translates these symbols as it reads TCPIP.DATA, reducing the number of TCPIP.DATA files that must be maintained in a multisystem environment. For detailed information about symbols and how to define them, see *z/OS MVS Initialization and Tuning Reference*.

Configuring PROFILE.TCPIP

During TCP/IP address space initialization, a configuration profile data set (PROFILE.TCPIP) is read that contains system operation and configuration parameters. A sample data set, SEZAINST(SAMPPROF), can be copied and modified for use as your default configuration profile.

If you are not familiar with the search order for this data set, see "PROFILE.TCPIP search order" on page 29 for information about understanding data set search orders. See *z/OS Communications Server: IP Configuration Reference* for the complete statement syntax and descriptions of the configuration statements.

For ease of management when configuring a complex environment, you can use one of the following PROFILE.TCPIP data set features:

- Group related statements into separate files and use the INCLUDE statement in PROFILE.TCPIP to include them in your configuration.
- Use MVS system symbols (such as &SYSCLONE, &SYSNAME, and &SYSPLEX). Because TCP/IP translates these symbols as it reads this file, this feature reduces the number of PROFILE.TCPIP data sets that must be maintained in a multi-TCP/IP environment.

Note: For detailed information about symbols and how to define them, see *z/OS MVS Initialization and Tuning Reference*.

The PROFILE data set contains the following major groups of configuration parameters:

- TCP/IP operating characteristics
- TCP/IP physical characteristics
- TCP/IP reserved port number definitions (application configuration)
- TCP/IP network routing definitions
- TCP/IP diagnostic data statements

This information explains the first three areas of configuration. For routing configuration information, see Chapter 6, "Routing," on page 255. For information about configuring diagnostic statements, see *z/OS Communications Server: IP Diagnosis Guide*.

Changing configuration information

If you want to change the TCP/IP configuration without stopping and starting the TCP/IP address space, you can dynamically change many of the TCP/IP configuration options established by the PROFILE.TCPIP data set. To do this, put the changed configuration statements in a separate data set and process it with the VARY TCPIP,,OBEYFILE command.

For more information about VARY TCPIP, see *z/OS Communications Server: IP System Administrator's Commands*. Also, see the Modifying information in each configuration statement in *z/OS Communications Server: IP Configuration Reference* for a description of how to dynamically change the information for that configuration statement.

Note: If you attempt to edit PROFILE.TCPIP while TCPIP is active, and PROFILE.TCPIP is defined in the TCPIP PROC as a sequential data set (for example, //PROFILE DD DISP=SHR,DSNAME=TCPIP.PROFILE.TCPIP), the *Dataset in use* message might be displayed. To avoid this, specify FREE=CLOSE, as follows:

```
//PROFILE  DD DISP=SHR,DSNAME=TCPIP.PROFILE.TCPIP,FREE=CLOSE
```

This allows you to edit the profile while TCP/IP is active. Typically, when TCP/IP starts, it keeps the PROFILE allocated and does not release the allocation until the end of the step (in this case, the end of the job). If you specify FREE=CLOSE, the release occurs once the data set is read. MVS releases the enqueue on the PROFILE, which allows you to edit it.

If the PROFILE is a member of a PDS, [for example, SYS1.TCPPARMS(PROFILE)], FREE=CLOSE is not needed.

Setting up TCP/IP operating characteristics in PROFILE.TCPIP

Figure 33 on page 215 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. This sample can be copied from SEZAINST(SAMPPROF). Figure 33 on page 215 includes the portion of the sample that shows how to set up TCP/IP operating characteristics. Descriptions for the statements follow Figure 33 on page 215.

Figure 33. Example of TCP/IP operating characteristics in PROFILE.TCPIP

Following is a description of the statements shown in Figure 33. For more information about any of these statements, see *z/OS Communications Server: IP Configuration Reference*. For information specific to IPv6 support, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

ARPAGE

Use ARPAGE to set the number of minutes between a revalidation and deletion of ARP table entries for LCS devices. An installation that wants to describe this value in seconds versus minutes should use the IPCONFIG ARPTO statement.

Note: The ATM ARP requests are controlled via the ATMLIS statement, and the MPCIPA and MPCOSA ARP requests are not controlled by the TCP/IP address space.

GLOBALCONFIG

Use GLOBALCONFIG to print out several counters in text format. These counters include number of TCP retransmissions and total number of TCP segments sent from the TCP/IP system. Most installations will use the SMF facility of MVS to collect these counters in a more standard way.

Use the ECSALIMIT parameter on the GLOBALCONFIG statement to limit TCP/IP's use of common storage. The POOLLIMIT parameter can be used to limit TCP/IP's use of private storage pools.

IPCONFIG

Use IPCONFIG to configure various settings of the IP layer of TCP/IP. Use ARPTO to specify the ARP time out value in seconds for LCS devices. See the ARPAGE description for more information.

Use CLAWUSEDOUBLENOP on vendor devices that document the need for double NOPs on each CCW.

Use DATAGRAMFWD if this TCP/IP is to be a router and needs to forward datagrams to other routers. Use IGNOREREDIRECT when a dynamic routing program is used and ICMP redirect packets are to be ignored by the TCP/IP address space. MULTIPATH is used to inform TCP/IP how to distribute traffic across equal cost routes.

Use IPSECURITY to restrict this host to be a network firewall.

SOURCEVIPA enables interface fault tolerance for z/OS clients that establish outbound connections. When SOURCEVIPA is set, outbound datagrams use the corresponding virtual IP address (VIPA) in the HOME list instead of the physical interfaces IP address. SOURCEVIPA has no effect on RIP servers such as NCPROUTE or OMPROUTE.

TCPSTACKSOURCEVIPA allows z/OS clients to specify a sysplex wide source IP address for TCP connections. When TCPSTACKSOURCEVIPA is

set, outbound TCP datagrams use the IP address specified in the TCPSTACKSOURCEVIPA statement instead of static VIPA addresses or physical interface addresses.

Use SYSPLEXRouting to communicate interface changes within a sysplex domain to the workload manager (WLM). DYNAMICXCF allows the cross communication facility within a sysplex to dynamically generate connections within a sysplex domain. If DYNAMICXCF is used with a dynamic routing program like OMPROUTE, the BSDROUTINGPARMS and the OMPROUTE configuration files need to be updated with subnet mask and cost information. For more information on additional configuration parameters required, see the usage notes related to the DYNAMICXCF parameter under the IPCONFIG statement in *z/OS Communications Server: IP Configuration Reference*.

Use REASSEMBLYTIMEOUT to specify the TCP/IP reassemble timeout value in seconds, and the TTL specifies the TCP/IP time to live or hop count value.

Use PATHMTUDISCOVERY to indicate to TCP/IP that it is to dynamically discover the path MTU, which is the minimum of MTUs of each hop in the path.

Use STOPONCLAWERROR to indicate to the TCP/IP stack to stop channel programs (HALTIO and HALTSIO) when a device error is detected.

Use QDIOACCELERATOR to request accelerated packet forwarding for OSA-Express QDIO Ethernet and HiperSockets interfaces.

IPCONFIG6

Use IPCONFIG6 to update the IP layer of TCP/IP with information that pertains to IPv6.

Use DATAGRAMFWD to enable the transfer of data between networks.

Use DYNAMICXCF to enable Dynamic XCF support for IPv6.

SOMAXCONN

Use SOMAXCON to specify the maximum number of sockets queued on a listener.

SRCIP

Use the SRCIP - ENDSRCIP profile statement block to configure one of the following functions:

- Enable an application to use a designated IP address as its source address for outbound TCP connections, or to enable a TCP server application to bind to a specific IP address when establishing its listening socket.
- Indicate that the default source address selection algorithm should prefer public or temporary IPv6 addresses for specific jobs.

For outbound TCP connections, when a source IP address has been designated for a specified job name or destination address and the source IP address exists at the time the outbound TCP connection is initiated, this source IP address is used, overriding other source IP address selection methods as described in "Source IP address selection" on page 218. This source address selection is performed for applications that issue a connect() call and that have not previously bound the socket to an IP address, or for those that bind to the IPv4 INADDR_ANY address or to the IPv6 unspecified address (in6addr_any) before issuing the connect() call.

For TCP server applications, when the application performs a bind to INADDR_ANY or in6addr_any and a matching JOBNAME rule for SERVER or BOTH is specified, the designated IP address is used on the listening socket. This has the effect of making the server application bind specific, where client applications can connect to the server using only the designated IP address. This capability can be useful when the applications do not provide a method for the user to specify a specific IP address for their listening sockets, or in situations when the server application creates listening sockets using an ephemeral port that is assigned dynamically by TCP/IP. For scenarios when the application binds to specific, well-known ports, the BIND keyword on the PORT reservation statement in the TCP/IP profile can be used instead and has precedence over the SRCIP block specifications.

If you use distributed DVIPAs as a designated source within the SRCIP block, you might also need to specify the EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement. For more information about the GLOBALCONFIG statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

Guidelines:

- Applications that bind to INADDR_ANY or in6addr_any that match on a SRCIP JOBNAME or DESTINATION statement do not have the designated IP address as their source address upon completion of the bind() call. The source address is not set to the designated address until completion of the subsequent connect() (client applications) or listen() (server applications) call. This is important to note for applications that issue a getsockname() call after a bind() call to retrieve the source IP address. This processing is different from the processing that occurs when a TCP server application is converted to being bind specific using the BIND keyword on the PORT statements in the TCP/IP profile. When using the BIND keyword on the PORT statement, the designated IP address is set upon completion of the bind() call, and some applications such as DB2 depend on this behavior.
- When using a SRCIP JOBNAME statement for an IPv6 server application, an IPv6 address should be coded and not an IPv6 interface. Otherwise, the source address that is chosen for that IP interface might not be the best choice for the server application to be bound to. For information about the default source address selection algorithm, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

TCPCONFIG

Use TCPCONFIG to configure various settings of the TCP protocol layer. If a keep-alive value other than 120 minutes is needed by an installation, use the INTERVAL statement to change the default keep-alive value. FINWAIT2TIME can be used to specify a different timeout value for a TCP Connection which is in a FINWAIT2 state. SENDGARBAGE will cause the keep-alive packet to contain one byte of random data and an incorrect sequence number, assuring that the data is not accepted by the remote TCP. The TCPTIMESTAMP option can be used to choose whether or not to participate in timestamp negotiation.

The behavior of acknowledgments and delaying their transmission can be altered by using the DELAYACKS statement.

If RESTRICTLOWPORTS is specified, only applications that meet at least one of the following criteria are allowed to bind to low ports (1–1023):

- The port is reserved for the application via the PORT or PORTRANGE statement.
- The application runs with APF authorization.
- The application runs with effective POSIX UID zero.

If an installation wants to control TCP buffering (to limit storage usage or to manage large bandwidth devices), use the TCPSENDBFRSIZE, TCPRCVBUFRSIZE, and TCPMAXRCVBUFRSIZE parameters.

Use TTLS to configure the TCP/IP stack for AT-TLS support.

UDPCONFIG

Use UDPCONFIG to configure various settings of the UDP protocol layer. NOUDPCHKSUM can be used to eliminate check summing overhead for IPv4 UDP packets. This option is ignored for UDP datagrams flowing over an IPv6 network, as UDP Checksum is a required function on an IPv6 network.

If RESTRICTLOWPORTS is specified, only applications that meet at least one of the following criteria are allowed to bind to low ports (1–1023):

- The port is reserved for the application via the PORT or PORTRANGE statement.
- The application runs with APF authorization.
- The application runs with effective POSIX UID zero.

If an installation wants to control UDP buffering (to limit storage usage or to manage large bandwidth devices), use the UDPSENDBFRSIZE and UDPRCVBUFRSIZE parameters. UDPQUEUELIMIT can be used to set a queue limit for UDP. This is useful for installations that want to limit the size of the queue of UDP datagrams that an application can have waiting before the TCP/IP address space starts discarding them.

Source IP address selection

TCP/IP determines the source IP address for a TCP outbound connection, or for a UDP or RAW outbound packet, using the following sequence, listed in descending order of priority.

1. Sendmsg( ) using the IPV6_PKTINFO ancillary option specifying a nonzero source address (RAW and UDP sockets only)
2. Setsockopt( ) IPV6_PKTINFO option specifying a nonzero source address (RAW and UDP sockets only)
3. Explicit bind to a specific local IP address
4. bind2addrsel socket function (AF_INET6 sockets only)
5. PORT profile statement with the BIND parameter
6. SRCIP profile statement (TCP connections only)
7. TCPSTACKSOURCEVIPA parameter on the IPCONFIG or IPCONFIG6 profile statement (TCP connections only)
8. SOURCEVIPA: Static VIPA address from the HOME list or from the SOURCEVIPAINTERFACE parameter
9. HOME IP address of the link over which the packet is sent

For a TCP connection, the source address is selected for the initial outbound packet, and the same source IP address is used for the life of the connection. For the UDP and RAW protocols, a source IP address selection is made for each outbound packet. A more detailed description of this sequence follows.

How TCP/IP selects a source IP address: TCP/IP uses the following sequence to select the source IP address for an outbound packet. For detailed information about the TCP/IP profile (PROFILE.TCPIP) and configuration statements, see *z/OS Communications Server: IP Configuration Reference*.

1. Sendmsg that specifies the source address in the ancillary IPV6_PKTINFO data

   If this is a UDP or RAW socket, and IPV6_PKTINFO ancillary data is specified on sendmsg() with a nonzero source IP address, this address is used as the source IP address.

2. Setsockopt IPV6_PKTINFO

   If this is a UDP or RAW socket, and the IPV6_PKTINFO socket option is set and it contains a nonzero source IP address, this address is used as the source IP address.

3. Explicit bind to a specific local address

   If the socket is already bound to a specific local IP address other than INADDR_ANY or in6addr_any, TCP/IP uses this specific local IP address.

4. bind2addrsel socket function (IPv6 only)

   The bind2addrsel socket function, which is available only to AF_INET6 sockets, binds a socket to a stack-selected local address and port that is appropriate to communicate with a given destination address.

5. PORT profile statement with the BIND parameter

   If the socket is bound to a source port and to the INADDR_ANY or in6addr_any IP address, and there is a corresponding PORT profile statement with the BIND parameter specified, TCP/IP uses the address specified by the BIND parameter.

6. SRCIP profile statement

   If this is a TCP socket and either the socket is not yet bound or the socket is bound to the INADDR_ANY or in6addr_any IP address, TCP/IP checks the job name and destination IP address against the SRCIP entries in the following order:

   a. JOBNAME entries, other than JOBNAME *
   b. DESTINATION entries
   c. JOBNAME * entries

   If a match is found, TCP/IP uses the designated source in the most specific matching entry to provide the source IP address to be used.

   Restriction: JOBNAME entries that specify a source of PUBLICADDRS or TEMPADDRS apply to only IPv6 source IP address selection. The JOBNAME entries do not influence the setting of the source IP address during this step of the source IP address selection sequence. For information about how PUBLICADDRS or TEMPADDRS entries influence the selection of the source IP address and the default source address selection algorithm, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

7. TCPSTACKSOURCEVIPA parameter on the IPCONFIG or IPCONFIG6 profile statement

   All of the following conditions must be met:

   - This is a TCP socket.
   - SOURCEVIPA is enabled on IPCONFIG or IPCONFIG6.
   - SOURCEVIPA is not disabled for the socket.
   - The application has not issued a specific bind for this socket, even to the INADDR_ANY or in6addr_any IP address.

- The address specified on the TCPSTACKSOURCEVIPA parameter is a static VIPA or active dynamic VIPA.

If these conditions are met and this is an IPv4 packet, TCP/IP uses the address specified on the TCPSTACKSOURCEVIPA parameter.

If these conditions are met and this is an IPv6 packet, TCP/IP uses the default source address selection algorithm to select one of the addresses configured for the VIPA interface referenced by the TCPSTACKSOURCEVIPA parameter. For information about the default source address selection algorithm, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

Guideline: Because the SRCIP profile statement provides all of the functionality of the TCPSTACKSOURCEVIPA parameter and additional granularity, consider using the SRCIP statement instead of specifying the TCPSTACKSOURCEVIPA parameter. Specifying JOBNAME * in a SRCIP profile statement provides the same result as specifying the TCPSTACKSOURCEVIPA parameter for implicit bind scenarios, and also applies to applications that issue a bind to the INADDR_ANY or in6addr_any IP address.

8. SOURCEVIPA: Static VIPA address from the HOME list (IPv4 interface defined with the LINK statement) or from the SOURCEVIPAINTERFACE parameter (IPv6 or IPv4 interface defined with the INTERFACE statement)

   All of the following conditions must be met:

   - SOURCEVIPA is enabled on IPCONFIG or IPCONFIG6.
   - SOURCEVIPA is not disabled for the socket.
   - Either the socket is not yet bound, or the socket is bound to the INADDR_ANY or in6addr_any IP address.

   If these conditions are met, TCP/IP determines the interface over which the initial packet will be sent.

   - For an IPv4 packet being sent over an interface defined with the LINK statement, TCP/IP does the following:
     a. Locates that interface in the HOME list.
     b. Searches backward in the HOME list for a static VIPA.
     c. If a static VIPA is found in the HOME list, TCP/IP uses the first static VIPA found as the source IP address.
   - For an IPv4 packet being sent over an interface defined with the INTERFACE statement, TCP/IP does the following:
     a. Determines whether a SOURCEVIPAINTERFACE parameter was specified for the selected interface.
     b. If a SOURCEVIPAINTERFACE parameter was specified, TCP/IP uses the address of the VIPA interface that is referenced by the SOURCEVIPAINTERFACE parameter.
   - For an IPv6 packet, TCP/IP does the following:
     a. Determines whether a SOURCEVIPAINTERFACE parameter was specified for the selected interface.
     b. If a SOURCEVIPAINTERFACE parameter was specified, TCP/IP uses the default source address selection algorithm to select one of the addresses configured for the VIPA interface that is referenced by the SOURCEVIPAINTERFACE parameter. For information about the default source address selection algorithm, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

9. HOME IP address of the link over which the packet is sent

   For an IPv4 packet, TCP/IP uses the HOME IP address of the link over which the initial packet is sent.

For an IPv6 packet, TCP/IP uses the default source address selection algorithm to select one of the addresses configured for the interface over which the initial packet is sent. For information about the default source address selection algorithm, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

Setting up physical characteristics in PROFILE.TCPIP

Figure 34 on page 227 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. Figure 34 on page 227 includes the portion of the sample that shows how to set up physical characteristics. This sample can be copied from SEZAINST(SAMPPROF). Following Figure 34 on page 227, several of the statements that are used to set up physical characteristics in PROFILE.TCPIP are described.

```
; ====================================================================
; Network interface definitions
; ====================================================================
;
; DEVICE: Defines name (and sometimes device number) for various types
;   of network interfaces for IPv4 only
; LINK: Defines a network interface to be associated with a particular
;   device.  For IPv4 only.
; INTERFACE: Defines an IPv6 interface, or an IPv4 OSA-Express QDIO
;   ethernet interface.
; VIPADYNAMIC: Defines IPv4 and IPv6 dynamic virtual interfaces
;
; --------------------------------------------------------------------
; DEVICE and LINK statements
; --------------------------------------------------------------------
;
; DEVICE and LINK for CTC devices
;
;DEVICE  CTC1    CTC  D00  AUTORESTART
;LINK    CTCD00  CTC  0  CTC1
;
; DEVICE and LINK for HYPERchannel A220 devices:
;
;DEVICE  HCH1    HCH  E00  AUTORESTART
;LINK    HCHE00  HCH  1  HCH1
;
; DEVICE and LINK for LAN Channel Station and OSA devices:
;   DEVICE: Defines name and hexadecimal device number for an IBM 8232
;     LAN channel station (LCS) device, and IBM 3172 Interconnect
;     Controller, an IBM 2216 Multiaccess Connector Model 400,
;     an IBM FDDI, Ethernet, or Token Ring OSA, or an IBM ATM OSA-2
;     in LAN emulation mode
;   LINK: Defines a network interface link associated with an LCS
;     device; may be for Ethernet Network, Token-Ring Network or
;     PC Network, or FDDI.
;
;   Example: LCS1 is a 3172 model 1 with a Token Ring and Ethernet
;    adapter
;
;DEVICE  LCS1  LCS  BA0  AUTORESTART
;LINK    TR1   IBMTR  0  LCS1
;LINK    ETH1  ETHERNET  1  LCS1
;
;   Example: LCS2 is a 3172 model 2 with a FDDI adapter
;
;DEVICE  LCS2   LCS  BE0  AUTORESTART
;LINK    FDDI1  FDDI  0  LCS2
;
; DEVICE and LINK for MPCIPA QDIO Devices:
;
;   Example: MPCIPA1 is an OSA-Express QDIO Ethernet feature
```

```
;
;DEVICE  MPCIPA1     MPCIPA  NONROUTER AUTORESTART
;LINK    MPCIPALINK1 IPAQENET  MPCIPA1
;
;   Example: MPCIPA2 is an OSA-Express QDIO Ethernet feature
;   configured as the PRIMARY router
;
;DEVICE  MPCIPA2     MPCIPA  PRIROUTER AUTORESTART
;LINK    MPCIPALINK2 IPAQENET  MPCIPA2
;
; DEVICE and LINK for HiperSockets CHPID FE
;
;DEVICE  IUTIQDFE      MPCIPA    AUTORESTART
;LINK    HIPERSOCKFE4  IPAQIDIO  IUTIQDFE

; VIPADYNAMIC statement for dynamic virtual (DVIPA) interfaces
; ------------------------------------------------------------------------
;
; The VIPADYNAMIC statement provides the following functions:
;   - Define dynamic virtual (DVIPA) interfaces on a stack.
;   - Define sysplex distribution of TCP connections using DVIPAs.
;   - Define a stack as a backup for DVIPAs.
;   - Define the IP address range for creating DVIPAs by use of IOCTL
;     or Bind requests.
;   - Define routes over interfaces other than dynamic XCF, to be
;     used for the forwarding of DVIPA packets by sysplex
;     distributor.
;
; VIPADYNAMIC
;
;   Define two IPV4 dynamic VIPAs on this stack:
;   VIPADEFINE 255.255.255.192 201.2.10.11 201.2.10.12
;
;   Define two IPv6 dynamic VIPAs on this stack:
;   VIPADEFINE DVIPA1 1::1
;   VIPADEFINE DVIPA2 2::2
;
;   Define this stack as backup for these dynamic VIPAs and,
;   define the DVIPAs on this stack if they are not
;   already active elsewhere in the sysplex:
;   VIPABACKUP  200 MOVEABLE IMMEDIATE 255.255.255.192 9.67.240.02
;   VIPABACKUP  V6DVIPA1 MOVEABLE IMMEDIATE 2000::9:67:240:2
;
;   Define Sysplex Distributor statements for these dynamic VIPAs:
;   VIPADISTRIBUTE SYSPLEXPORTS 201.2.10.11 PORT 4011 DESTIP ALL
;   VIPADISTRIBUTE TIMEDAFF 200 201.2.10.12 PORT 4012 DESTIP ALL
;   VIPADISTRIBUTE DISTMETHOD ROUNDROBIN DVIPA1       DESTIP ALL
;   VIPADISTRIBUTE SYSPLEXPORTS DVIPA2      PORT 4013 DESTIP ALL
;   VIPADISTRIBUTE
;     DISTMETHOD SERVERWLM  9.67.240.02 PORT 10000  DESTIP ALL
;   VIPADISTRIBUTE
;     DISTMETHOD SERVERWLM PROCXCOST ZIIP 2 ZAAP 2 ILWEIGHTING 2
;     OPTLOCAL 1  SYSPLEXPORTS
;     V6DVIPA1 PORT 10000  DESTIP ALL
;
;   Define this stack as backup for dynamic VIPAs on
;   other TCP/IP stacks:
;   VIPABACKUP 100             201.2.10.13 201.2.10.14
;   VIPABACKUP  80             201.2.10.21 201.2.10.22
;   VIPABACKUP  60             201.2.10.31 201.2.10.33
;   VIPABACKUP  40             201.2.10.32 201.2.10.34
;
;   Define two dynamic VIPA ranges on this stack:
;   VIPARANGE DEFINE 255.255.255.192 201.2.10.192
;   VIPARANGE V6RANGE1 3::1/100
;
```

```
;   Define alternative routes to dynamic XCF routes, for forwarding of
;   DVIPA packets by sysplex distributor
;   VIPAROUTE DEFINE 201.1.10.20     9.67.213.81
;   VIPAROUTE DEFINE 2001::251:00002 50C9:C2D4:0:1:9:67:215:66

```

Figure 34. Example of physical characteristics in PROFILE.TCPIP

Following are descriptions of several of the statements shown in Figure 34 that are used to set up physical characteristics in PROFILE.TCPIP. For more information about any of these statements, or information on statements not described, see *z/OS Communications Server: IP Configuration Reference*. For information specific to IPv6 support, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

DEVICE and LINK

Use DEVICE and LINK statements to define each IPv4 network interface to the TCPIP address space. See *z/OS Communications Server: IP Configuration Reference* for more details about the various network interfaces supported by TCP/IP.

ATM Use the ATM DEVICE and LINK statements to define connectivity to an ATM network. These statements allow for connectivity in either ATM native mode over an ATM virtual circuit (VC) or in ATM LAN Emulation mode.

For ATM native mode, the VC can be either a permanent virtual circuit (PVC) or a switched virtual circuit (SVC). To define a PVC, use the ATMPVC statement. To define SVCs, use the ATMLIS statement to define the ATM logical IP subnet (LIS). Also, for SVCs, use the ATMARPSV statement to define the ATMARP server that will resolve ATMARP requests within the LIS. For ATM LAN emulation mode, the ATM DEVICE and LINK definitions allow you to retrieve SNMP network management data for the device. In this mode, you need to define the device as an LCS.

CDLC The DEVICE CDLC describes the interface between the TCP/IP address space and the 3745/46 devices used.

CLAW Use CLAW DEVICE for RISC System/6000 and SP2.

CTC Use the CTC DEVICE and LINK statements to define connectivity to another z/OS using channel-to-channel.

HYPERchannel A220 DEVICE and LINK

Use the HCH DEVICE and LINK statements to define connectivity via the HYPERchannel A220 adapter.

LAN Channel Station (LCS) DEVICE and LINK

Use the LCS DEVICE and LINK statements to define connectivity to a token-ring, FDDI, or Ethernet LAN. LCS devices can have more than one adapter. Therefore, you can have more than one LINK statement for an LCS DEVICE statement.

In configurations where multiple LCS and/or MPCIPA links onto the same LAN are defined, if the interface targeted by the ARP Request is inactive, one of the other active interfaces on the LAN will automatically take over responsibility for answering ARPs on behalf of the inactive interface. In this way, fault tolerance is achievable on the LAN without requiring a dynamic routing protocol.

TCP/IP supports ARP for VIPAs. In a flat network (one in which traffic flows directly between two endpoints without an intermediate router) using static routing with multiple interfaces onto the same LAN, you can achieve fault tolerance by defining a VIPA in the same subnet as the physical interfaces on the LAN. If a static route specifies a VIPA as the next hop IP address, the host or router will send an ARP for the VIPA. TCP/IP will reply to the ARP with the MAC address of one of the active physical interfaces on that LAN.

MPCIPA

Use the MPCIPA DEVICE and LINK statements to define either of the following:

- LAN connectivity with the OSA-Express feature using the Queued Direct I/O (QDIO) interface

  Tip: You can also use the INTERFACE statement to define an IPv4 interface for OSA-Express QDIO Ethernet, which combines the definitions of the DEVICE, LINK, and HOME statements into a single statement.
- HiperSockets connectivity

For the OSA-Express QDIO interface, the MPCIPA device name must be the PORT name of the TRLE definition of the QDIO interface as described in *z/OS Communications Server: SNA Resource Definition Reference*. Device specifications for the type of IP routing supported are also specified on the MPCIPA DEVICE statement. These are also described in *z/OS Communications Server: SNA Resource Definition Reference*.

In configurations where multiple LCS and/or MPCIPA links onto the same LAN are defined, if the interface targeted by the ARP Request is inactive, one of the other active interfaces on the LAN will automatically take over responsibility for answering ARPs on behalf of the inactive interface. In this way, fault tolerance is achievable on the LAN without requiring a dynamic routing protocol.

TCP/IP supports ARP for VIPAs. In a flat network (one in which traffic flows directly between two endpoints without an intermediate router) using static routing with multiple interfaces onto the same LAN, you can achieve fault tolerance by defining a VIPA in the same subnet as the physical interfaces on the LAN. If a static route specifies a VIPA as the next hop IP address, the host or router will send an ARP for the VIPA. TCP/IP will reply to the ARP with the MAC address of one of the active physical interfaces on that LAN.

Use the IPCONFIG DYNAMICXCF statement to cause TCP/IP to automatically define and activate HiperSockets connectivity between each pair of TCP/IP stacks that is in the same CPC in the same z/OS sysplex.

MPCOSA
The MPCOSA DEVICE statements define the MPC OSA Ethernet and FDDI devices.

MPCPTP

MPCPTP can be used to define any of the following:

- A connection to another host over a series of CTCs (in this case, the device name must be the name of a VTAM TRLE).
- An XCF connection to another TCP/IP in the same z/OS sysplex. For an XCF connection, the device name must be the CP name or SSCP name of the target VTAM on the other side of the XCF connection, and the VTAM ISTLSXCF major node must be active to start the device.
- An IUTSAMEH connection (with no need for any I/O devices) to another TCP/IP on the same z/OS system or to VTAM for Enterprise Extender. For an IUTSAMEH connection, the device name must be the reserved name IUTSAMEH. VTAM automatically activates the IUTSAMEH TRLE.

Use the IPCONFIG DYNAMICXCF statement to cause TCP/IP to automatically define and activate XCF connectivity between each pair of TCP/IP stacks in the same sysplex and IUTSAMEH connectivity between multiple TCP/IP stacks on the same z/OS.

SNAIUCV and SNALU62
Use SNAIUCV DEVICE to specify the interface to use for SNA LU0 traffic to the SNALINK started procedures. For example, use this to define the interface between the TCP/IP address space and the SNALINK address space that is using a 3745 running NCPRoute. Similarly, the DEVICE SNALU62 statement defines the interface between the TCP/IP address space and the address space using SNA LU6.2. See *z/OS Communications Server: IP Configuration Reference* for information about how to define multiple LU6.2 connections within the same TCP/IP address space.

VIRTUAL
Use VIRTUAL DEVICE to define a static virtual IP address (VIPA) interface.

The static virtual device requires DEVICE and LINK statements to define a device that is always started, can never be stopped, can be known within the network, yet requires no physical adapters. It is very useful to define VIPAs so that if a physical adapter loses its connection to the network, application traffic using the failed physical adapter can be rerouted over another interface to the network. To the network, the VIPA address appears to be one hop away from the TCP/IP address spaces. The network sends and receives datagrams to and from the physical interfaces to get to the VIPA address. For more information about VIPA, see Chapter 7, “Virtual IP Addressing,” on page 351.

X.25 The DEVICE X25DEV defines the interface between the TCP/IP address space and the address space of the X.25 NPSI server.

INTERFACE (IPv4)

Use the INTERFACE statement to define IPv4 OSA-Express QDIO interfaces (instead of using MPCIPA DEVICE and LINK statements).

IPAQENET

Use the IPAQENET INTERFACE statement to define IPv4 LAN connectivity through the OSA-Express feature using QDIO.

INTERFACE (IPv6)

Use INTERFACE statements to define each IPv6 network interface to the TCPIP address space. See *z/OS Communications Server: IP Configuration Reference* for more details about the various network interfaces supported by TCP/IP.

IPAQENET6

Use the IPAQENET6 INTERFACE statement to define IPv6 LAN connectivity through the OSA-Express feature using QDIO.

IPAQIDIO6

Use the IPAQIDIO6 INTERFACE statement to define HiperSockets IPv6 connectivity.

Use the IPCONFIG6 DYNAMICXCF statement to cause TCP/IP to automatically define and activate HiperSockets IPv6 connectivity between each pair of TCP/IP stacks that is in the same CPC in the same z/OS sysplex.

MPCPTP6

Use the MPCPTP6 INTERFACE statement to define any of the following IPv6 connections:

- A connection to another host using ESCON channel-to-channel adapters.
- An XCF connection to another TCP/IP in the same z/OS sysplex.
- An IUTSAMEH connection (with no need for any I/O devices) to another TCP/IP on the same z/OS system or to VTAM for Enterprise Extender.

Use the IPCONFIG6 DYNAMICXCF statement to cause TCP/IP to automatically define and activate XCF connectivity between each pair of TCP/IP stacks in the same sysplex and IUTSAMEH connectivity between multiple TCP/IP stacks on the same z/OS.

VIRTUAL6

Use the VIRTUAL6 INTERFACE statement to define IPv6 static VIPAs.

VIPADYNAMIC

Use the VIPADYNAMIC block statement to define dynamic virtual IP address (DVIPA) interfaces. For more information about DVIPA interfaces, see Chapter 7, “Virtual IP Addressing,” on page 351.

TRANSLATE

Use TRANSLATE to indicate which LINK has specified network addresses for use as a static ARP table. The first TRANSLATE statement in a configuration data set replaces the entire ARP cache. Subsequent TRANSLATE statements add to the table. If you are using OSPF routing (OMPROUTE), see Chapter 6, “Routing,” on page 255 for more information about requirements for the TRANSLATE statement.

HOME

HOME lists the IP addresses and their associated LINK adapter. The first HOME statement within a configuration data set replaces the existing HOME list. If subsequent HOME statements are found within a configuration data set, add entries to the list.

Guideline: The order of the HOME list is important if IPCONFIG SOURCEVIPA is specified. For more information, see "Source IP address selection" on page 218. For more information about the HOME statement and for precautions when either the VIPA address or a physical adapter used as a source for the VIPA has an IP address that is the network address, see *z/OS Communications Server: IP Configuration Reference*.

PRIMARYINTERFACE

Use PRIMARYINTERFACE to specify which interface should be designated as the default local host for use by the GETHOSTID() function. If PRIMARYINTERFACE is not used, the first IP address in the HOME list becomes the default local host address.

BEGINROUTES

Use the BEGINROUTES statement to add static routes to the IP route table.

After an interface has a DEVICE, LINK, and HOME statement, or an INTERFACE statement, it can be started with the START statement or the VARY TCPIP,,START command.

Devices that support ARP offload

Certain devices provide an ARP offload function that offloads all ARP processing to the adapter. The function provided by the adapter impacts the ability of TCP/IP to display ARP cache information or ARP counter statistics for these devices.

Note: ARP processing is relevant only for IPv4 LAN interfaces.

The following devices provide an ARP offload function and provide ARP cache data or ARP counters to TCP/IP.

- MPCIPA (OSA-Express Gigabit Ethernet) with a minimum required microcode level of [MCL] 401
- All other OSA-Express features in QDIO mode

Note: If multiple TCP/IP instances are sharing the device, the ARP data will represent all TCP/IP instances using the device. This information is provided to TCP/IP every 30 seconds from the device.

The following devices provide an ARP offload function and do not provide any ARP cache data or ARP counters to TCP/IP:

- MPCOSA (OSA-2 Fast Ethernet, FDDI)
- MPCIPA (OSA-Express Gigabit Ethernet) with a microcode level earlier than [MCL] 401

Note: For IPv6 LAN interfaces, TCP/IP performs all the neighbor discovery processing, maintains the neighbor cache, and provides the ability to display neighbor cache information.

Interface-layer fault-tolerance for local area networks (interface-takeover function)

The TCP/IP stack in the z/OS Communications Server provides transparent fault-tolerance for failed (or stopped) IPv4 devices or IPv6 interfaces, when the

stack is configured with redundant connectivity onto a LAN. This support is provided by the z/OS Communications Server interface-takeover function, and applies to IPv4 MPCIPA and LCS device types and to the IPv6 IPAQENET6 interface type.

At device or interface startup time, TCP/IP dynamically learns of redundant connectivity onto the LAN, and uses this information to select suitable backups in the case of a future failure of the device or interface. This support makes use of ARP flows (for IPv4 devices) or neighbor discovery flows (for IPv6 interfaces), so upon failure (or stop) of a device or interface, TCP/IP immediately notifies stations on the LAN that the original IPv4 or IPv6 address is now reachable through the backup's link-layer (MAC) address. Users targeting the original IP address will see no outage due to the failure, and will be unaware that any failure occurred.

Since this support is built upon ARP or neighbor discovery flows, no dynamic routing protocol in the IP layer is required to achieve this fault tolerance. To enable this support, you only need to configure redundancy onto the LAN:

- You need redundant LAN adapters.
- For IPv4, you must configure and activate multiple LINKs onto the LAN.
- For IPv6, you need to configure and start multiple INTERFACEs onto the LAN.

Restriction: An IPv4 device cannot back up an IPv6 interface, and an IPv6 interface cannot back up an IPv4 device.

Rule: If static routing is used, there needs to be a static route to the LAN subnet over each interface onto the LAN. There also needs to be a default route and routes to destinations not directly attached to the LAN over each interface.

The interface-layer fault-tolerance feature can be used in conjunction with VIPA addresses, where applications can target the VIPA address, and any failure of the real LAN hardware is handled by the interface-takeover function. This differs from traditional VIPA usage, where dynamic routing protocols are required to route around real hardware failures.

IPv6 considerations: Stateless autoconfiguration and duplicate address detection

IPv6 provides the capability of autoconfiguring addresses for an interface by using information provided by IPv6 routers. Descriptions of this function can be found in RFC 2461 and RFC 2462. The term *autoconfigured IP address* is used here to mean an IP address that is created as a result of information received from a router advertisement. z/OS TCP/IP allows autoconfiguration if no IP addresses are defined on the profile INTERFACE statement using the IPADDR keyword. If the INTERFACE statement contains IPADDR definitions, this indicates that the installation is defining its own IP addresses and autoconfiguration is not desired. The term *manually configured addresses* is used here to describe the addresses that are defined using the IPADDR keyword.

TCP creates an autoconfigured IP address for an interface if all three of the following conditions are met:

- The interface is active.
- A valid router advertisement containing prefix information with the autonomous flag on is received over the interface.
- No manually configured home addresses are defined for the interface at the time the router advertisement is received.

The IP address that is created is formed by appending the interface ID generated by the stack to the prefix supplied by the router advertisement. Autoconfigured IP addresses can be identified in the Netstat HOME/-h report by the `Autoconfigured` flag. For more information on the interface ID generated by the stack, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

An autoconfigured IP address exists until one of the following occurs:

- The valid lifetime specified by the most recent router advertisement expires. When the valid lifetime expires, the autoconfigured address is removed. Existing connections using this address are terminated when subsequent activity occurs on the connection. The router advertisement that contains the valid lifetime for the autoconfigured address can also specify a preferred lifetime. The preferred lifetime indicates that the IP address can be freely used. When the preferred lifetime expires, the autoconfigured address is considered deprecated. The deprecated state indicates that another IP address should be used if available and provides a transition period before the valid lifetime expires. A deprecated IP address can be identified in the Netstat HOME/-h report by the `deprecated` flag.
- The installation activates a profile that contains a manually configured IP address on the same interface as the autoconfigured IP address (that is, the INTERFACE statement contains the ADDADDR keyword). If this occurs, any autoconfigured IP addresses on that interface are deleted and existing connections using this address are terminated when subsequent activity occurs on the connection. The manually configured addresses are added and duplicate address detection for the newly added IP addresses initiated, if applicable.

Duplicate address detection is the process described in RFC 2462 which verifies that IPv6 home addresses are unique on the local link before assigning them to an interface. Duplicate address detection is performed on all IPv6 IPAQENET6 home addresses, whether they are manually configured or autogenerated, unless the INTERFACE statement specifies DUPADDRDET 0. Duplicate address detection is not done for LOOPBACK6 or VIRTUAL6 addresses. The duplicate address detection process sends a multicast neighbor solicitation and waits a period of time to see if another neighbor indicates that the address is in use. By default, only one neighbor solicitation is sent and the length of time waited is approximately one second. If no neighbor responds in that interval, the address is considered unique and the interface will start using it. The number of neighbor solicitations sent by duplicate address detection can be modified by the DUPADDRDET keyword on the INTERFACE statement. The duration of the wait interval (awaiting a response from a neighbor already using the address) can be modified by information obtained from routers on the attached network.

Duplicate address detection occurs when the interface is started. Unless the INTERFACE statement indicated duplicate address detection is to be bypassed, IPv6 manually configured addresses are unavailable until the interface is started and duplicate address detection completes without finding another node on the local link with the same address. Prior to activation of the interface, manually configured addresses are shown in the Netstat HOME/-h report as unavailable with the reason `DUPLICATE ADDRESS DETECTION PENDING`. While the duplicated address detection is actively in progress for an address, the Netstat HOME/-h report shows the address as unavailable with the reason `DUPLICATE ADDRESS DETECTION IN PROGRESS`. If another neighbor indicates the address is in use during the duplicate address detection process, message EZZ9780I is issued and the address is not made available to the interface. If the address that was found to be

in use is a manually configured address, the address appears in the Netstat HOME/-h report as unavailable with the reason DUPLICATE ADDRESS DETECTED.

A link-local address is required to activate a QDIO IPv6 interface and will be generated automatically by the stack. The link-local address is generated using the link-local prefix and the interface ID. If the link-local address generated from the interface ID is determined to be a duplicate, the interface is not activated if:

- Autoconfigured addresses are allowed.
- A manually configured home address specifying only the prefix was specified on the INTERFACE statement. In such a case, the interface ID needs to be used to form the complete link-local address, and since the interface ID has been found to be in use on the network, the formed link-local address cannot be used.

If duplicate address detection fails on the link-local address and only fully configured manual addresses were specified on the INTERFACE statement, up to two attempts are made to create a unique link local address using a randomly generated value instead of the interface ID. If duplicate address detection succeeds using the randomly generated link-local address, message EZZ9784I is issued indicating the generated address and the interface is activated.

Setting up reserved port number definitions in PROFILE.TCPIP

Figure 35 on page 236 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. This sample can be copied from SEZAINST(SAMPPROF). Figure 35 on page 236 includes the portion of the sample that shows how to set up reserved port number definitions. Descriptions for the statements follow Figure 35 on page 236.

;
; --------------------------------------------------------------------
;
; PORT: Reserves a port for specified job names
;
;   - A port that is not reserved in this list can be used by any user.
;     If you have TCP/IP hosts in your network that reserve ports
;     in the range 1-1023 for privileged applications, you should
;     reserve them here to prevent users from using them.
;     The RESTRICTLOWPORTS option on TCPCONFIG and UDPCONFIG will also
;     prevent unauthorized applications from accessing unreserved
;     ports in the 1-1023 range.
;
;   - A PORT statement with the optional keyword SAF followed by a
;     1-8 character name can be used to reserve a PORT and control
```

```
;     access to the PORT with a security product such as RACF.
;     For port access control, the full resource name for the security
;     product authorization check is constructed as follows:
;     EZB.PORTACCESS.sysname.tcpname.safname
;     where:
;       EZB.PORTACCESS is a constant
;       sysname is the MVS system name (substitute your sysname)
;       tcpname is the TCPIP jobname (substitute your jobname)
;       safname is the 1-8 character name following the SAF keyword
;
;     When PORT access control is used, the TCP/IP application
;     requiring access to the reserved PORT must be running under a
;     USERID that is authorized to the resource. The resources
;     are defined in the SERVAUTH class.
;
;     For an example of how the SAF keyword can be used to enhance
;     security, see the definition below for the FTP data PORT 20
;     with the SAF keyword. This definition reserves TCP PORT 20 for
;     any jobname (the *) but requires that the FTP user be permitted
;     by the security product to the resource:
;     EZB.PORTACCESS.sysname.tcpname.FTPDATA in the SERVAUTH class.
;
;   - The BIND keyword is used to force a generic server (one that
;     binds to the IPv4 INADDR_ANY address, or the IPv6 unspecified
;     address, in6addr_any) to bind to the specific IP address that
;     is specified following the BIND keyword. This capability could
;     be used, for example, to allow z/OS UNIX telnet and telnet
;     3270 servers to both bind to TCP port 23.
;     The IP address that follows bind must be in IPv4 (dotted
;     decimal) or IPv6 (colon-hexadecimal) format and may be
;     any valid address for the host including VIPA and dynamic
;     VIPA addresses.
;
;   The special jobname of OMVS indicates that the PORT is reserved
;   for any application with the exception of those that use the Pascal
;   API.
;
;   The special jobname of * indicates that the PORT is reserved
;   for any application, including Pascal API socket applications.
;   Jobname may be specified as a prefix of zero to seven characters
;   ending in *.
;
;   The special jobname of RESERVED indicates that the PORT is
;   blocked. It will not be available to any application.
;
;   GUIDELINE: When IPSECURITY is enabled, UDP ports 500 and 4500
;   should either be reserved for IKED (if it is in use) or should
;   be marked RESERVED.
;
;   TIP:  The PORT statement can also be used to control application
;   access to unreserved ports by configuring PORT entries where the
;   port number is replaced by the keyword UNRSV.

```

Figure 35. Example of reserved port number definitions

Following are descriptions of the statements shown in Figure 35 on page 236. For more information about any of these statements, see *z/OS Communications Server: IP Configuration Reference*. For information specific to IPv6 support, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

AUTOLOG

Use AUTOLOG to list the procedure names that should start when the TCPIP address space starts. It is also used to supply a timeout value for detecting hung procedures at TCP/IP initialization time. The timeout value is the time TCP/IP should allow for a procedure to come down when, at startup, it is still active and TCP/IP is attempting to AUTOLOG the procedure again. A hung procedure is active to MVS, but is not listening on the socket that is reserved for it via the PORT statement. When AUTOLOG detects a hung task, TCP/IP checks every 10 seconds (until the timeout value has expired) to see if the procedure has come down. If the procedure comes down during one of these 10 second intervals, it is restarted. If the procedure is still active when the time interval specified by the timeout value expires, then TCP/IP cancels and restarts the procedure.

The AUTOLOG statement shown in Figure 35 on page 236 has a timeout value of five minutes.

In the first AUTOLOG statement the FTP Server shows FTPD JOBNAME FTPD1. This means when the TCPIP address space starts, the FTPD procedure will be started via the MVS START FTPD command. Because FTPD forks a child process that actually listens on PORT 21, the autolog task verifies that FTPD1 is listening on port 21.

Similarly, when the TCPIP address space starts, the autolog task starts the remaining 10 tasks.

Unless the tasks in the AUTOLOG list are in the PORT reservation list, the autolog task does not check for hung tasks every five minutes.

Notes:

1. If you run multiple TCP/IP address spaces, ensure that the second address space AUTOLOG list does not cancel the procedures of the first. In those cases, an installation might require different procedure names for the servers for each address space. For more information about multiple stacks, see "Port management overview" on page 50.
2. You can use the AUTOLOG statement to automatically start generic servers in a single stack environment, but you should be careful using the AUTOLOG statement to start generic servers in a multiple stack environment. Instead, you could use an operations automation software package (IBM and other vendors provide these) to start generic servers automatically. For a list of generic servers provided by TCP/IP, see "Generic servers in a CINET environment" on page 53.

For those procedures that require parameters to be used on the MVS START command, there is a PARMSTRING option.

You should delay the start of AUTOLOG procedures that require AT-TLS services by specifying the optional DELAYSTART parameter with the TTLS subparameter on the AUTOLOG entry for the procedure. If you specify this parameter and subparameter, the procedure will start after the Policy Agent has installed the AT-TLS policy and AT-TLS services are available.

You should delay the start of AUTOLOG procedures that bind to a dynamic VIPA by specifying the optional DELAYSTART parameter with the DVIPA subparameter on the AUTOLOG entry for the procedure. If you

specify this parameter and subparameter, the procedure will not start until the TCP/IP stack has joined the sysplex group and processed the dynamic VIPA configuration.

For a procedure that will bind to a dynamic VIPA and that requires AT-TLS services, you should specify DELAYSTART DVIPA TTLS. When more than one DELAYSTART subparameter is specified, all of the processing steps defined for those subparameters must complete before the procedure is started.

For more information, see *z/OS Communications Server: IP Configuration Reference*.

PORT Use the PORT statement to do the following:

- Reserve ports for different jobs and optionally limit access to these ports by user ID
- Control application access to unreserved ports

Reserving particular ports:

Use PORT to reserve ports for different jobs and to prevent rogue applications from taking ports intended for specific servers, such as port 21, which is needed by FTP. For each port entry, the port number, protocol, and procedure name are specified. The first port entry shows port 7 UDP reserved for the miscellaneous echo server for procedure MISCSERV. Similarly, port 7 of TCP is also reserved for the same server. In this example, six ports are reserved for the miscellaneous server.

NOAUTOLOG can be specified, as in the port 20 TCP * in Figure 35 on page 236. In this way, the port is reserved for an OMVS forked task so that the FTP server can fork tasks to port 20 as each FTP user logs in.

Use the DELAYACKS and NODELAYACKS options to allow an installation to delay their acknowledgments so they can be combined with data to be sent to foreign hosts. Unless a performance reason is needed, DELAYACKS should be used to delay the transmission of acknowledgments.

Use the SHAREPORT parameter or the SHAREPORTWLM parameter when reserving a port to be shared across multiple TCP listeners. This is not valid for UDP. To understand how these PORT statement parameters are used, see *z/OS Communications Server: IP Configuration Reference*. Use the Netstat ALL/-A report to determine whether port sharing is being used for a TCP listener. If port sharing is being used, this report indicates which type is being used.

Typically, reserving a port for a specific job name is sufficient. If the port must instead be reserved for a specific user ID or a set of user IDs, use the SAF keyword to specify the name of a SAF resource to be associated with the port. The user ID associated with the application that attempts to bind to the port must be permitted to the SAF resource.

The BIND keyword is used to force a generic server (one that binds to INADDR_ANY or in6addr_any) to bind to the specific IP address that is specified following the BIND keyword. This capability could be used, for example, to allow the z/OS UNIX Telnet and TN3270E Telnet servers to both bind to TCP port 23 on different IP addresses. The IP address that follows BIND can be any valid address for the host, including VIPA and dynamic VIPA addresses. The address supplied can be either an IPv4 address (in dotted-decimal format) or an IPv6 address (in colon-hexadecimal format). IPv4-mapped IPv6 addresses and

IPv4-compatible IPv6 addresses are not supported. For multiple servers to bind to the same port with this function, the IP address for each server must be unique.

RESERVED indicates that the port is not available for use by any user.

Controlling access to unreserved ports:

You can also use the PORT statement to control application access to unreserved ports by configuring one or more PORT statements in which the port number is replaced by the keyword UNRSV. The UNRSV keyword refers to any unreserved port (any port number that has not been reserved by a PORT or PORTRANGE statement). If you configure the RESTRICTLOWPORTS parameter on the TCPCONFIG or UDPCONFIG profile statement, PORT UNRSV statements for the corresponding protocol control access only to unreserved ports above port 1023. If you do not configure the RESTRICTLOWPORTS parameter, PORT UNRSV statements control access to all unreserved ports in the range 1 - 65 535. The type of access that is controlled by the PORT UNRSV statement is specified (explicitly or by default) by the WHENBIND or WHENLISTEN keywords.

If you configure one or more PORT UNRSV statements for a protocol, access is unconditionally denied to any application that explicitly binds to an unreserved port and that does not match the protocol and job name on any of the configured PORT UNRSV statements. Applications that explicitly bind to an unreserved port and that do match the protocol and job name on a PORT UNRSV statement are allowed to access the unreserved port, unless the access is restricted by the SAF or DENY keywords. If the SAF keyword is specified, the user ID associated with the application that attempts to access the port must be permitted to the specified SAF resource. If the DENY keyword is specified, access is unconditionally denied.

For UDP sockets, the access permission is checked when an unreserved port is specified on an explicit bind. The WHENBIND keyword is the only access option that is allowed for UDP ports.

For TCP sockets, access can be controlled when an unreserved port is specified on an explicit bind (WHENBIND) or when a listen is issued on a user-specified port that was not reserved for the application (WHENLISTEN).

For more information about controlling access to unreserved ports, see "Port access control" on page 116. For more information about the PORT statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

PORTRANGE

PORTRANGE is a statement used to reserve a range of ports for specified job names.

SACONFIG

SACONFIG is the statement used to configure the information about the SNMP TCP/IP subagent. The AGENT keyword on this statement is used to specify the port number to be used when the TCP/IP subagent connects to the SNMP agent. Omission of this statement causes TCPIP to assume the default value of SACONFIG ENABLED COMMUNITY public AGENT 161. For more information on the SACONFIG profile statement, see *z/OS Communications Server: IP Configuration Reference*.

Setting up the System Authorization Facility server access authorization class (optional)

The TCP/IP address space uses the server access authorization (SERVAUTH) class of the System Authorization Facility (SAF) to protect TCP/IP resources from unauthorized access. The use of SERVAUTH may be optional and is available in degrees so that installations can pick and choose the access needed. Installations may be able to choose to use one, all, or none of the protections provided by SERVAUTH. The customization described here is completely optional when using the IBM security product RACF. Non-IBM security products might require customization. A template of the commands and all other SAF commands appears in SEZAINST(EZARACF). See Chapter 3, "Security," on page 109 for more detailed information.

Configuring the local host table (optional)

You can set up the local host table to support local host name resolution. If you use the local host table for this purpose, your socket applications will only be able to resolve names and IP addresses that appear in your local host table.

If you need to resolve host names outside your local area, you can configure the resolver to use a domain name server (see the NSINTERADDR statement). If you use a domain name server, you do not need to set up any host definitions in your resolver configuration, but you may still do so.

If you have configured your resolver to use a name server, it will always try to do so, unless your TCP/IP C/C++ API applications were written with a RESOLVE_VIA_LOOKUP symbol in the source code. You can also configure the resolver to only use a local host table by specifying LOOKUP LOCAL in the TCPIP.DATA configuration file. For both cases, all name resolution calls will always use a local host table. This is probably not a technique you will see for standard socket applications, but it may be a technique you could find useful for when you develop your own socket applications or for testing changes before they are placed in your name server.

It might be a good idea to have a local host table available for the resolver to use if the name server is not reachable. If the name server does not respond to name resolution requests, the resolver tries to use the local host table. If the name server is reachable but returns a negative reply for a name resolution request, the resolver tries to resolve the name using the local host table, if such a file is present.

Assume you try to resolve the host name *friendly* and your DOMAINORIGIN is *my.house.com*, the resolver sends a query to the name server for *friendly.my.house.com*. If the name server returns a negative reply (the name is not registered), the resolver looks into the local host table for an entry of *friendly.my.house.com* and, if not found, for an entry of *friendly*.

Due to the flexibility of the Domain Name System, it is recommended you use a domain name server. If you set up a small TCP/IP network, the simplicity of the local host table approach might be preferable.

The following types of local host table can be used:

- HOSTS.LOCAL

  HOSTS.LOCAL is only used for IPv4 requests.
- /etc/hosts

/etc/hosts is only used for IPv4 requests.

- ETC.IPNODES and /etc/ipnodes

  ETC.IPNODES and /etc/ipnodes can be used for IPv6 requests, and for IPv4 requests when COMMONSEARCH is coded in the resolver setup statements.

Creating HOSTS.LOCAL site host table

The site host table is generated from the *hlq*.HOSTS.LOCAL data set. This data set contains descriptions of local host entries in the HOSTS format. HOSTS.LOCAL can only contain IPv4 addresses. A sample HOSTS.LOCAL data set is created during installation. This information describes how to update the sample *hlq*.HOSTS.LOCAL data set and use it to generate the two data sets, *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO, which function as your site table.

HOST entries

One line of the *hlq*.HOSTS.LOCAL data set is used for each distinct host and ends with four colons (::::). The maximum length of the line is 512 characters. Each host can have multiple IP addresses and multiple names. The line for each host has three essential fields, separated by colons. These fields are:

- The keyword *HOST*
- A list of IP addresses, separated by commas, for that host. You can specify a maximum of six IP addresses per HOST entry.
- A list of fully qualified names, separated by commas, for that host. You can specify a maximum of 20 host names per HOST entry. Only the first six host names per host entry are used in the *hlq*.HOSTS.ADDRINFO data set. All host names are used in the *hlq*.HOSTS.SITEINFO data set.

For example, if you have two local hosts, LOCAL1 (IP addresses 192.6.77.4 and 192.8.4.1) and LOCAL2 (with an alias LOCALB and IP address 192.6.77.2), append the following lines to the *hlq*.HOSTS.LOCAL data set:

```
HOST : 192.6.77.4, 192.8.4.1 : LOCAL1 ::::
HOST : 192.6.77.2 : LOCAL2, LOCALB ::::
```

Notes:

1. The maximum length for a host allowed in the HOST tables is 24 characters.
2. If the HOST entry has more than the maximum of 6 IP addresses for one host name or more than 20 host names for a single IP address, the MAKESITE command will complete successfully with no error message issued.

NET and GATEWAY entries

The NET and GATEWAY statements are not used by TCP/IP for z/OS applications. However, some socket calls require the NET entries. If your programs do not need the NET and GATEWAY statements, delete them before invoking MAKESITE.

Sample HOSTS.LOCAL data set (HOSTS): Following is the sample HOSTS.LOCAL data set provided in SEZAINST(HOSTS):

```
; HOSTS.LOCAL
; -----------
; COPYRIGHT = NONE.
;
; The format of this file is documented in RFC 952, "DoD Internet
; Host Table Specification".
;
; The format for entries is:
```

```
;
; NET : ADDR : NETNAME :
; GATEWAY : ADDR, ALT-ADDR : HOSTNM : CPUTYPE : OPSYS : PROTOCOLS :
; HOST : ADDR, ALT-ADDR : HOSTNM, NICKNM : CPUTYPE : OPSYS : PROTOCOLS :
;
; Where:
;   ADDR, ALT-ADDR = IP address in decimal, e.g., 26.0.0.73
;   HOSTNM, NICKNM = the fully qualified host name and any nicknames
;   CPUTYPE = machine type (PDP-11/70, VAX-11/780, IBM-3090, C/30, etc.)
;   OPSYS = operating system (UNIX, TOPS20, TENEX, VM/SP, etc.)
;   PROTOCOLS = transport/service (TCP/TELNET,TCP/FTP, etc.)
;   : (colon) = field delimiter
;   :: (2 colons) = null field
; *** CPUTYPE, OPSYS, and PROTOCOLS are optional fields.
;
;   MAKESITE does not allow continuation lines, as described in
;   note 2 of the section "GRAMMATICAL HOST TABLE SPECIFICATION"
;   in RFC 952.  Entries should be specified on a single line of
;   up to a maximum of 512 characters per line.
;
;
; Note:  The NET and GATEWAY statements are not used by the TCP/IP for
;        MVS applications.  However, some socket calls require the NET
;        entries.  For better performance, if your programs do not need
;        the NET and GATEWAY statements, delete them before running
;        the MAKESITE program.
;
;
HOST : 9.67.43.100 : NAMESERVER ::::
HOST : 9.67.43.126 : RALEIGH ::::
HOST : 129.34.128.245, 129.34.128.246 : YORKTOWN, WATSON ::::
;
NET  : 9.67.43.0 : RALEIGH.IBM.COM :
;
GATEWAY : 129.34.0.0 : YORKTOWN-GATEWAY ::::
;
```

Using MAKESITE

Because many servers and commands allocate *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO, it is important not to overwrite or delete these data sets while TCP/IP is running. To avoid disrupting any active users, use an *HLQ*=parm that is different than your active *hlq*. This allows you to swap names (by renaming the old HOSTS data sets and then renaming the new HOSTS data sets) without starting and stopping TCP/IP.

Use MAKESITE as a TSO command or in a batch job to generate new *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO data sets. The parameters are the same for either a TSO command or a batch job invocation of MAKESITE. See *z/OS Communications Server: IP System Administrator's Commands* for more information.

After you make changes to your *hlq*.HOSTS.LOCAL data set, you must generate and install new *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO data sets.

Guidelines: Use ETC.IPNODES (in the style of etc/ipnodes) as the preferred alternative to the generated local hosts tables from MAKESITE for the following reasons:

- No imposed 24 character restriction on host names.

- No imposed restriction on the first eight characters of the host names having to be unique. However, there are certain applications that require the first eight characters to be unique, such as Network Job Entry (NJE).
- Closely resembles that of other TCP/IP platforms, and eliminates the MAKESITE requirement of file post-processing.
- Allows configuration of both IPv4 and IPv6 addresses.
- Only one file is managed for the system, and that all the APIs can utilize the same single file. The COMMONSEARCH statement in the resolver setup file can be used to reduce IPv6 and IPv4 searching to a single search order, as well as to reduce the z/OS UNIX and native MVS environments to a single search order.

For more information on the use of IPNODES by the resolver to locate IPv4 and IPv6 addresses and sitenames, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

For the search orders used in locating the local host tables, see "Configuration files for TCP/IP applications" on page 30. For a description of the use of IPNODES by the resolver to locate IPv4 and IPv6 addresses and sitenames when the resolver setup statement COMMONSEARCH is specified, see "IPv6/common search order" on page 767 and "IPv6/common search order" on page 772.

Creating /etc/hosts

The /etc/hosts file can be defined as follows:

- The maximum line length is 256 characters. If a line is greater than 256 characters, it is truncated to 256 characters and processed. If trace resolver is active, a warning message is issued.
- The line starts with an IP address, followed by a blank, followed by host names. Host names are separated by one or more blanks.
- Only IPv4 addresses are supported.
- Each IP address can have up to 35 host names. A host name can have up to 35 IP addresses.
- The values for the host name must conform to the following:
  - Maximum of 128 characters.
  - Must contain one or more tokens separated by a period.
  - Each token must be at least 1 character and less than 64 characters.
  - First character in each token must be a letter (A-Z or a-z) or number (0-9).
- A comment is indicated by the # or ; character.

For the search orders used in locating /etc/hosts, see "Configuration files for TCP/IP applications" on page 30.

Creating ETC.IPNODES and /etc/ipnodes

The ETC.IPNODES and /etc/ipnodes file can be defined as follows:

- z/OS UNIX files can reside in any directory. The maximum line length supported is 256 characters. If a line is greater than 256 characters, it is truncated to 256 characters and processed. If trace resolver is active, a warning message is issued. If you need more than 256 characters for the IP address and the associated host names, you can code additional lines with the same IP address as follows:

```
Address1 Hostname1
Address1 Hostname2
Address1 Hostname3
```

- MVS data sets must be partitioned organization (PO) or sequential (PS), RECFM=F or RECFM=FB, a logical record length (LRECL) between 56 and 256, and have any valid blocksize (BLKSIZE) for fixed block.
- It can contain IPv4 and IPv6 addresses, but not IPv4 mapped addresses. Each IP address can have up to 35 host names. A host name can have up to 35 IP addresses.
- The values for the host name must conform to the following:
  - Maximum of 128 characters.
  - Must contain one or more tokens separated by a period.
  - Each token must be at least 1 character and less than 64 characters.
  - First character in each token must be a letter (A-Z or a-z) or number (0-9).
- A comment is indicated by the # or ; character.

The sample IPNODES file provided by z/OS Communications Server follows. It can be found as member EZBREIPN (alias IPNODES) in SEZAINST.

```
;
;  IBM z/OS Communications Server
;  SMP/E distribution name: EZBREIPN
;
;  5694-A01 (C) Copyright IBM Corp. 2002.
;  Licensed Materials - Property of IBM
;
;  Function: Sample ETC.IPNODES file
;
;  The file contains the Internet Protocol (IP) host names
;  and addresses for the local host and other hosts in the
;  Internet network.
;  This file is used to resolve a name into an address (that is, to
;  translate a host name into its Internet address) or resolve
;  an address into a name.
;
;  Comments begin with a # or ; character and continue until the
;  end of the line.
;
;  The following statement defines the Internet Protocol (IP) name
;  and address of the local host and specifies the names and
;  addresses of remote hosts. The maximum line length support is
;  256 characters
;
;  Entries in the hosts file have the following format:
;
;  Address HostName
;
;  Address HostName1 HostName2 HostName3 ..... HostName35
;
;
;  Address: is an IP address, it can be IPV4 or IPV6 address.
;           Note: IPv4-mapped IPv6 address is not allowed.
;
;  HostName: the length of the hostname is up to 128 characters,
;            and each IP address can have up to 35 hostnames.
;
;
   9.67.43.100 NAMESERVER
   9.67.43.126 RALEIGH
   9.67.43.222 HOSTNAME1.RALEIGH.IBM.COM
```

```
   129.34.128.245 YORKTOWN WATSON
   1::2 TESTIPV6ADDRESS1
   1:2:3:4:5:6:7:8 TESTIPV6ADDRESS2
;
```

For the search orders used in locating ETC.IPNODES and /etc/ipnodes, see "Configuration files for TCP/IP applications" on page 30.

Verifying your configuration

At this point, your configuration files have been updated.

To verify a configuration, start the TCP/IP address space and ensure that you see the following message:

```
EZB6473I TCP/IP STACK FUNCTIONS INITIALIZATION COMPLETE
```

If the message is not displayed, the messages issued by the TCP/IP address space should describe why TCP/IP did not start.

Verifying TCPIP.DATA statement values in the native MVS environment

To display which TCPIP.DATA statement values are being used and where they are being obtained from, use trace resolver output. You can obtain trace resolver output at your TSO screen by issuing the following TSO commands:

```
alloc f(systcpt) dsn(*)
READY
netstat up
READY
free f(systcpt)
READY
```

Tip: When directing trace resolver output to a TSO terminal, define the screen size to be only 80 columns wide. Otherwise, trace output is difficult to read.

For further information on the trace resolver facility and interpreting its output, see *z/OS Communications Server: IP Diagnosis Guide*.

Verifying TCPIP.DATA statement values in the z/OS UNIX environment

To display which TCPIP.DATA statement values are being used and where they are being obtained from, use trace resolver output. You can obtain trace resolver output by issuing the following z/OS UNIX shell commands:

```
export RESOLVER_TRACE=stdout
netstat -u
set -A RESOLVER_TRACE
```

For further information on the trace resolver facility and interpreting its output, see *z/OS Communications Server: IP Diagnosis Guide*.

Verifying PROFILE.TCPIP

You can use the following commands to verify many configuration values that are specified in the TCP/IP profile:

- Netstat commands

You can use the Netstat DEvlinks/**-d** command to verify the physical network and hardware definitions. You can use the Netstat CONFIG/**-f** command to verify operating characteristics.

- DISPLAY TCPIP,,OSAINFO command

  You can use this command to verify that the OSA-Express QDIO configuration was successfully accepted by the OSA-Express QDIO feature. The command output is a view from the OSA-Express QDIO feature of the data subchannel device for the interface.

For information about the syntax and output of these commands, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying interfaces with Ping and Traceroute

The Ping and Traceroute commands can be used in the TSO and z/OS UNIX environments to verify adapters or interfaces attached to the z/OS host. For information about the syntax and output of the commands, see *z/OS Communications Server: IP System Administrator's Commands*.

Given that your PROFILE.TCPIP file contains the interfaces of your installation and that the TCPIP.DATA file contains the correct TCPIPJOBNAME, the TCPIP address space is configured and you can go on to configuring routes, servers, and so on.

Verifying local name resolution with TESTSITE

Use the TESTSITE command to verify that the *hlq*.HOSTS.ADDRINFO and *hlq*.HOSTS.SITEINFO data sets can correctly resolve the name of a host, gateway, or net. For more information on the TESTSITE command, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying PROFILE.TCPIP and TCPIP.DATA using HOMETEST

Use the HOMETEST command to verify the HOSTNAME, DOMAINORIGIN, SEARCH, and NSINTERADDR TCPIP.DATA statements. HOMETEST will use the resolver to obtain the IP addresses assigned to the HOSTNAME and compare them to the HOME list specified in PROFILE.TCPIP. A warning message will be issued if any HOSTNAME IP addresses are missing from the HOME list.

Activate TRACE RESOLVER if you would like detailed information on how the HOSTNAME is resolved to IP addresses. The information will also include what TCPIP.DATA data set names were used. This can be done by issuing the following TSO command before running HOMETEST. The detailed information will be displayed on your TSO screen.

```
allocate dd(systcpt) da(*)
```

Issue the following TSO command after HOMETEST to turn off TRACE RESOLVER output.

```
free dd(systcpt)
```

If you do not have TRACE RESOLVER turned on before running HOMETEST, the following is displayed:

```
hometest

Running IBM MVS TCP/IP CS V1R6 TCP/IP Configuration Tester

FTP.DATA file not found. Using hardcoded default values.
```

```
TCP Host Name is: MVS026

Using Name Server to Resolve MVS026
The following IP addresses correspond to TCP Host Name: MVS026
9.67.113.58

The following IP addresses are the HOME IP addresses defined in PROFILE.TCPIP:
9.67.113.58
127.0.0.1

All IP addresses for MVS026 are in the HOME list!

Hometest was successful - all Tests Passed!
```

Verifying your X Window System installation (Optional)

Note: You cannot verify your X Window System until after routing and DNS setup.

Support is provided for two versions of the X Window System and the corresponding Motif. The current support, provided as part of the base IP support in z/OS Communications Server, is for X Window System Version 11 Release 6 and Motif Version 1.2. Support for X Window System Version 11 Release 4 and Motif Version 1.1 is available as feature HIP614X.

Verifying the X Window X11R4 System installation

X Window X11R4 System is installed with the other target libraries. The macro or headers go into the target library data set SEZACMAC. To verify the installation of the X Window System:

1. Specify your workstation IP address by adding a record (such as the following) to your XWINDOWS.DISPLAY data set.

   ```
   royal.csc.ibm.com:0.0
   ```

   In this example, `royal.csc.ibm.com:0.0` is the name of the host running the X Window System server.

   Note: No leading blanks are allowed in this record.
2. On the workstation running the X Window System server, issue an XHOST command specifying the name of your MVS system.
3. Run the program with the XSAMP1 command.

Verifying the X Window X11R6 System installation

To verify the installation of the X Window X11R6 System:

1. Ensure that a host (the workstation) with an X Window System server that supports X11R6 is properly configured and reachable by the MVS system. From the workstation, use Telnet to access the MVS system, and open a z/OS UNIX shell on the MVS system.
2. From the z/OS UNIX shell, export the DISPLAY environment variable using either the network name or the qualified IP address of the workstation as shown in the following example:

   ```
   export DISPLAY=royal.csc.ibm.com:0.0
   ```

   In this example, *royal.csc.ibm.com* is the name of the workstation running the X Window System server. The display is indicated by *:0.0*, and is specified this way in almost all cases.

3. Authorize the MVS system to access the workstation by executing the XHOST command, and specify either the name of the MVS system or a plus sign (+) as shown in the following example.

   ```
   xhost +
   ```

   Note: The + option turns off security for this workstation and allows any X client to display here.

4. The sample X clients are shipped in the directory */usr/lpp/tcpip/X11R6/Xamples/demos*. Change into this directory. There are four sample program directories, xsamp1, xsamp2, xsamp3, and pexsamp. Change to the xsamp1 directory. Verify that there are files named Makefile and xsamp1.c, and then execute the following command:

   ```
   make
   ```

5. Execute the program using the following command:

   ```
   xsamp1
   ```

6. The z/OS UNIX shell should block as another window is opened. Verify the workstation is displaying a new window. The xsamp1 client displays a blank window for 60 seconds and then exits, taking its window with it. The z/OS UNIX shell should no longer be blocked.

Customizing TCP/IP messages

The messages for every application provided by TCP/IP are compiled and linked with the application and reside in an internal message repository. Some of the applications also store their messages in message catalogs or message data sets. You can modify these message catalogs or message data sets to translate the messages to another language or to customize them for your installation.

Customizing message catalogs

Applications in Table 14 use message catalogs that are created by using the **gencat** utility. The message catalogs are installed in the /usr/lpp/tcpip/lib/nls/msg/C/ directory in the z/OS UNIX file system.

Table 14. TCP/IP message catalogs

Application	Message catalogs
Autolog TCP/IP configuration	cfmsg.cat
Bind 9 name server	ns9.cat RESMSG.cat
Communications Server SMTP (CSSMTP) application	ezamlcat.cat ezamlrpy.cat
Digital Certificate Access Server (DCAS)	dcasm.cat
Defense Manager daemon (DMD)	dmdmsg.cat
Load Balancing Advisor (LBA) Automated domain name registration (ADNR)	lcadvm.cat
FTP client FTP server	ftpdmsg.cat ftpdrply.cat

Table 14. TCP/IP message catalogs (continued)

Application	Message catalogs
z/OS UNIX **host** command z/OS UNIX **hostname** command z/OS UNIX **domainname** command z/OS UNIX **dnsdomainname** command	ezahomsg.cat ezaitmsg.cat
IKE daemon(IKED)	ike_log.cat
z/OS UNIX **ipsec** command	ipsecmsg.cat
MODDVIPA utility	xfdvpm.cat
TSO NETSTAT command z/OS UNIX **netstat**/**onetstat** command DISPLAY TCPIP,,NETSTAT operator command	netmsg.cat netmsg6.cat
SNMP Network SLAPM2 subagent (nslapm2)	pagtsmsg.cat
z/OS UNIX **nssctl** command	nssctlmsg.cat

Traffic regulation manager daemon (TRMD)	trmdm.cat
z/OS UNIX **trmdstat** command	trmdstat.cat
XWindows X11R4 Motif V1.1	Mrm12.cat Uil12.cat xm12.cat X11R6.cat
XWindows X11R6 Motif V1.2	Mrm21.cat xm21.cat Uil21.cat X11R66.cat

Message format

Use the z/OS UNIX **dspcat** command to display the message text from a message catalog. The messages are in the following format:

```
index_num "message text"
```

The *index_num* value is the identifier that the application uses to access the message text.

The *message_text* value might include conversion characters for the variable fields that are converted when the message is printed or displayed and control characters that affect the message format. The conversion characters start with a percent sign (%) and the control characters start with a backslash (\). These are all standard notations for the C language print function. The messages might also contain comments, which start with /* and end with */.

In the following simulated message, the control character \n forces a new line to print. The string variables %1$s, %2$s, and %3$s are converted in the order that they are passed from the application.

```
1 "EZZ2350I MVS TCP/IP NETSTAT %1$s       TCPIP Name: %2$s        %3$s\n"
```

Rules for modifying messages

The general rule for customizing or translating messages is to only change the text portion of the message.

- Do not change the *index_num* identifier. This part of the message has a specific meaning. If you change it, the application might not function correctly.
- Do not change the conversion characters for the variables. These characters indicate that the application is passing data, the type of data that the application is passing, and the appropriate way to display or print this data. For example, do not change or delete %1$s and %2$d in the following message:

  ```
  475 "EZA1644I Recfm: %1$s  lrecl: %2$d\n"
  ```

  If you change or delete the conversion characters, results are unpredictable.
- You can reorder the sequence of variables within a message when the variables are defined by conversion characters with the format %*n*$, where *n* is an integer. For example, you can reverse the conversion characters when translating the following message:

  ```
  Before:
  480 "EZY9999I Command %1$s received from user %2$s\n"

  After:
  480 "EZY9999I Utilisador %2$s envio instrucion %1$s\n"
  ```

  The result would be `EZY9999I Utilisador MANNY envio instrucion FTP` instead of `EZY9999I Command FTP received from user MANNY`.

  You cannot reorder the sequence of variables in the following message:

  ```
  EZY9999I Command $s received from user $s
  ```

Steps for creating a modified message catalog

Before you begin: Review the following information:

- "Message format" on page 250
- "Rules for modifying messages" on page 250

You also need to know the following:

- The commands indicated in these steps are z/OS UNIX commands; perform all of these steps from the z/OS UNIX shell.
- These steps use a message catalog called sample.cat, and assume that the application code and catalog are at the correct levels. If you customize a catalog, IBM Service personnel might require that you use the shipped level of the catalog to recreate and diagnose a reported problem.

Perform the following steps to create a modified message catalog:

1. Copy the current z/OS UNIX catalog to a backup file to ensure that you have a copy of the original catalog.

   ```
   cp  /usr/lpp/tcpip/lib/nls/msg/C/sample.cat  /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup
   ```

2. Using the z/OS UNIX **dspcat** command, convert the editable backup catalog that you just copied.

   ```
   dspcat -t -g  /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup  > /tmp/sample.cat.copy
   ```

   The file sample.cat.copy is the file that you will update to preserve the timestamp and customize the messages.

3. Change the first line in the catalog from a comment to a z/OS UNIX **gencat** command $timestamp directive.

   This enables the original timestamp to be imbedded in the new catalog when the catalog is built. In some cases, when an application opens a message catalog, it checks the timestamp at the top of the catalog to ensure that it matches the application timestamp. If the timestamps are different, the

application does not use the message catalog. You must ensure that the new message catalog contains the timestamp from the original message catalog by performing the following steps:

a. Edit the file to be updated.

```
oedit /tmp/sample.cat.copy
```

b. Change the first line comment to add a **gencat** command $timestamp directive to preserve the timestamp when the directory is built. The first line in the file is similar to the following line:

```
The time stamp of catalog /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup is: 2010 095 20:30 UTC
```

Replace the leading text on the line with the $timestamp directive as follows:

```
$timestamp 2010 095 20:30 UTC
```

If you omit this step and the original line is left unchanged in the catalog, when you attempt to generate a catalog from this file, you will see a message similar to the following message:

```
FSUM5108 gencat: Invalid message number.
```

c. Save the file.

4. Update the catalog (/tmp/sample.cat.copy) with any local modifications and save the file.

5. Build a new and customized catalog by using the z/OS UNIX **gencat** command.

```
gencat   /tmp/sample.cat   /tmp/sample.cat.copy
```

The correct response is the following message:

```
FSUM5105 gencat: Message catalog generated normally.
```

Tip: Verify that your changes are correct before invoking the **gencat** command. Some errors cause the **gencat** command to fail, but other errors might not be apparent until the message is displayed.

6. Browse the new catalog and verify that the timestamp from Step 3 matches what is in the file.

```
obrowse /tmp/sample.cat
```

The first record contains the time stamp (*yyyy ddd hh:mm* UTC). For example:

```
...2010 095 20:30 UTC
```

7. Replace the z/OS UNIX catalog, which is shipped with the release, with the updated catalog that you created in Step 5.

```
cp  /tmp/sample.cat /usr/lpp/tcpip/lib/nls/msg/C/sample.cat
```

For more information about the **dspcat** and **gencat** utilities, see *z/OS UNIX System Services Command Reference*.

Customizing message data sets

The following table shows the servers that have external messages, the DD statement used, and the name of the message data set delivered with the system:

Server	DD statement	Data set
NCPROUTE	//MESSAGE	SEZAINST(EZBNRMSG)
SNMP Query Engine	//MSSNMPMS	SEZAINST(MSSNMP)

Server	DD statement	Data set
MISC Server	//MSMISCSR	SEZAINST(MSMISCSR)

The procedures for these servers have a special DD statement that point to the external message data set. If you are going to override the internal messages and use external customized messages, you need to remove the comment from the appropriate DD statement and ensure it points to the correct data set.

Message text

The message text might include conversion characters for the variable fields that are converted when the message is printed or displayed, and control characters that affect the message format. The conversion characters start with a percent sign (%) and the control characters start with a backslash (\). These are all standard notations for the C language print function. The messages might also contain comments which start with `/*` and end with `*/`.

In the following simulated message, the control character `\n` forces a new line to print and the string variables, represented by `%s`, are converted in the order they are passed from the program.

```
9999 I "Command %s received from user %s\n"
```

Message format

Figure 36 explains the syntax for TCP/IP message IDs on the host:

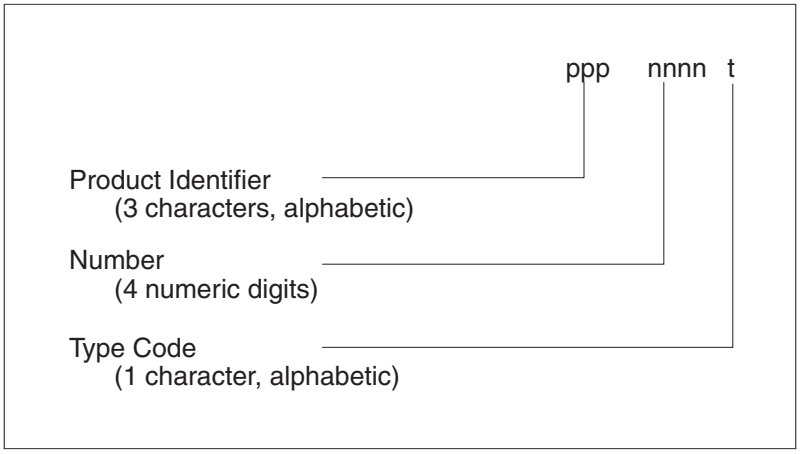

Figure 36. Syntax for TCP/IP message IDs

The ***product identifiers*** (ppp) for TCP/IP are EZA, EZB, EZD, EZY, EZZ, and SNM. The ***number*** (nnnn) indicates a unique 4-digit numeric value assigned to the message by product. The ***type code*** (t) indicates the severity assigned to the message.

Rules for customizing the messages

The general rule for customizing or translating messages is to only change the text portion of the message.

- Do not change the MARGIN, PRODUCT, and COMPONENT definitions at the top of the data set. These are required definitions for the program. For example, these entries at the top of the MISC server message data set should not be changed:

  ```
  MARGINS(1,72)
  PRODUCT EZA
  COMPONENT MSC
  ```

- Do not change the message numbers and the severity code. These parts of the message have specific meaning; if you change them the program may not work correctly.
- Do not change the conversion characters. These indicate that the program is passing data, the type of data it is passing, and the appropriate way to display or print this data. For example, do not change or delete %s and %d in the following message:

  ```
  4059 I "Connecting to agent %s on DPI port %d\n"
  ```

- You can reorder the variables that are passed in the message. For example, you can reverse the order of the two string variables that are passed when translating a message by specifying the new order of the arguments in parentheses following the message text:

  Before: `9999 I "Command %s received from user %s\n"`

  After: `9999 I "Utilisador %s envio instrucion %s\n"(2, 1)`

  The result would be `EZY9999I Utilisador MANNY envio instrucion FTP` instead of `EZY9999I Command FTP received from user MANNY`.
- Watch for any program parameters or keywords that might be in the message text. In most cases, you should not translate them.

  For example, in the following message, `'active'` is a keyword used in the gateway definition and should not be translated:

  ```
  3974 E   "First two elements must be 'active' for active gateway\n"
  ```

Chapter 6. Routing

This information explains the steps required to configure your TCP/IP stack for dynamic, static, or policy-based routing, and explains how to verify the configuration. The contents of this topic are based on the assumption that you understand your entire network configuration.

After reading this information, you should be able to do the following:

- Configure dynamic, static, or policy-based routing
- Use the Ping command to ping a remote host by IP address
- Use the Traceroute command to determine the path that will be taken to reach a particular destination using static or dynamic routing
- Use the Netstat command to display a TCP/IP stack's routing information
- Use DISPLAY commands to display dynamic routing information

Recommendation: The definition or modification of an installation's routing configuration should not be performed without a complete understanding of the entire network design.

Routing terminology

"General terms" describes some of the more common IP routing-related terms and concepts. If you need more detailed information, see *Routing in the Internet* by Christian Huitema.

General terms

Autonomous system (AS)
A group of routers exchanging routing information through a common routing protocol. A single AS can represent a large number of IP networks.

Dynamic routes
IP layer routing table entries that are dynamically managed and can automatically change in response to network topology changes. For IPv4, these routes are managed by a routing daemon. For IPv6, these routes can be managed by a routing daemon, and they can also be learned by listening to router advertisement messages received from routers as part of the router discovery protocol.

Exterior Gateway Protocol (EGP)
A routing protocol spoken by routers belonging to different autonomous systems when those routers are configured to share routing information between autonomous systems. This topic does not discuss exterior gateway routing.

Interior Gateway Protocol (IGP)
A routing protocol spoken by routers belonging to the same autonomous system. Each AS has a single IGP. A separate AS within a network can be running a different IGP.

Main route table
An IPv4 or IPv6 route table that is populated using static routes and dynamic routes. These route tables have the name EZBMAIN. A TCP/IP stack has one main IPv4 route table and one main IPv6 route table. In the

absence of policy-based routing, the IPv4 main route table contains all of the routes used by a TCP/IP stack when making IPv4 routing decisions. When policy-based routing is in use, policies can be configured to use the IPv4 main route table in IPv4 routing decisions when no route is found in a policy-based route table.

Policy-based route table
An IPv4 route table that is configured for use by policy-based routing. A TCP/IP stack can have zero or more policy-based route tables. A policy-based route table can be defined using a flat file that is parsed by the Policy Agent, or using the IBM Configuration Assistant for z/OS Communications Server. A policy-based route table definition can contain static routes, dynamic routing parameters for controlling the scope of routes added to the table by OMPROUTE, or both. Policy rules and actions can then be defined to indicate that, for given types of traffic, the TCP/IP stack should use specific sets of route tables when making routing decisions.

Policy-based routing (PBR)
A technique used to make routing decisions based on policies defined by the network administrator. Policy-based routing selects a route for outbound traffic from a set of policy-based route tables, and optionally the main route table, according to the policy defined for the traffic.

Replaceable static routes
IPv4 static routes that can be replaced by OMPROUTE, or IPv6 static routes that can be replaced by OMPROUTE or by routes learned by listening to router advertisement messages received from routers as part of the router discovery protocol.

Router
A device or host that interprets protocols at the IP layer and forwards datagrams on a path towards their correct destination.

Routing
The process used in an IP network to deliver a datagram to the correct destination.

Routing daemon
A server process that manages the IP route table.

Static routes
IP layer routing table entries that are manually configured (using the BEGINROUTES or GATEWAY configuration statements) and do not change automatically in response to network topology changes, except when:

- The change is due to an ICMP redirect (if not disabled).
- A dynamic routing protocol learns a route to a destination configured as a replaceable static route.

Interior Gateway Protocols

An interior gateway protocol (IGP) is a dynamic route update protocol used between routers that run on TCP/IP hosts within a single autonomous system. The routers use this protocol to exchange information about IP routes.

Some of the more common interior gateway protocols are:

Routing Information Protocol (RIP)
RIP uses a distance vector algorithm to calculate the best path to a

destination based on the number of hops in the path. RIP has several limitations. Some of the limitations which exist in RIP Version 1 are resolved by RIP Version 2.

RIP Version 2

RIP Version 2 extends RIP Version 1. Among the improvements are support for multicasting and variable subnetting. Variable subnetting allows the division of networks into variable size subnets. For example, one route can represent addresses from 9.1.1.0 through 9.1.1.255 (the 9.1.1.0/255.255.255.0 subnet) while another can represent addresses from 9.2.0.0 through 9.2.255.255 (the 9.2.0.0/255.255.0.0 subnet).

IPv6 RIP

IPv6 RIP uses the same distance vector algorithm used by RIP to calculate the best path to a destination. It is intended to allow routers to exchange information for computing routes through an IPv6-based network.

Open Shortest Path First (OSPF)

OSPF uses a link state or shortest path first algorithm. OSPF's most significant advantage compared to RIP is the reduced time needed to converge after a network change. In general, OSPF is more complicated to configure than RIP and might not be suitable for small networks.

IPv6 OSPF

IPv6 OSPF also uses a link state or shortest path first algorithm to calculate the best path to a destination. IPv6 OSPF has the same advantages and more complicated configuration compared to IPv6 RIP, like OSPF compared to RIP.

Table 15. Interior Gateway Protocol characteristics

Feature	RIP-1	RIP-2	IPv6 RIP	OSPF	IPv6 OSPF
Algorithm	Distance vector	Distance vector	Distance vector	Shortest path first	Shortest path first
Network load (1)	High	High	High	Low	Low
CPU processing requirement (1)	Low	Low	Low	High	High
IP network design restrictions	Many	Some	Some	Virtually none	Virtually none
Convergence time	Up to 180 seconds	Up to 180 seconds	Up to 180 seconds	Low	Low
Multicast supported (2)	No	Yes	Yes	Yes	Yes
Multiple equal-cost routes	No (3)	No(3)	No(3)	Yes	Yes

Table 15. Interior Gateway Protocol characteristics (continued)

Feature	RIP-1	RIP-2	IPv6 RIP	OSPF	IPv6 OSPF

Notes:

1. Depends on network size and stability.
2. Multicast saves CPU cycles on hosts that are not interested in certain periodic updates, such as OSPF link state advertisements or RIP-2 routing table updates. Multicast frames are filtered out either in the device driver or directly on the interface card if this host has not joined the specific multicast group.
3. RIP in OMPROUTE allows multiple equal-cost routes only for directly connected destinations over redundant interfaces. See "Using static routing with OMPROUTE" on page 345.

Route selection algorithm

Whether static, dynamic, or policy-based routing is used, the algorithm used by the IP layer to select a route from a route table is the same. Route selection occurs in the following order:

1. If a route exists to the destination address (a host route), it is chosen.
2. If no host route exists to the destination address, the route chosen depends upon the version of IP being used:
   - For IPv4:
     a. If subnet, network, or supernetwork routes exist to the destination, the route with the most specific network mask (the mask with the most bits on) is chosen.
     b. If the destination is a multicast destination and a multicast default route exists, that route is chosen.
   - For IPv6, if prefix routes exist to the destination, the route with the most specific prefix is chosen.
3. Default routes are chosen when no other route exists to a destination.

Multiple equal-cost routes are allowed for static, dynamic, and policy-based routing. Table 15 on page 257 and "Multiple equal-cost routes" on page 276 provide additional information about the use of multiple equal-cost routes.

In the absence of policy-based routing, the IP layer routes traffic by searching the main route table for the most specific route known, using the selection order described. If policy-based routing is being used, the IP layer routes traffic according to the policy defined for the traffic. For more information about how the IP layer routes traffic when policy-based routing is being used, see "Policy-based routing" on page 337.

The sample network

Figure 37 on page 259 and Figure 38 on page 260 show network diagrams that depict a sample network. This sample network is used in the following topics as the configuration of static, dynamic, and policy-based routing is described:

- "IPv4 static routing" on page 260
- "IPv6 static routing" on page 263
- "IPv4 dynamic routing using OMPROUTE" on page 267
- "IPv6 dynamic routing using OMPROUTE" on page 271
- "Policy-based routing" on page 337

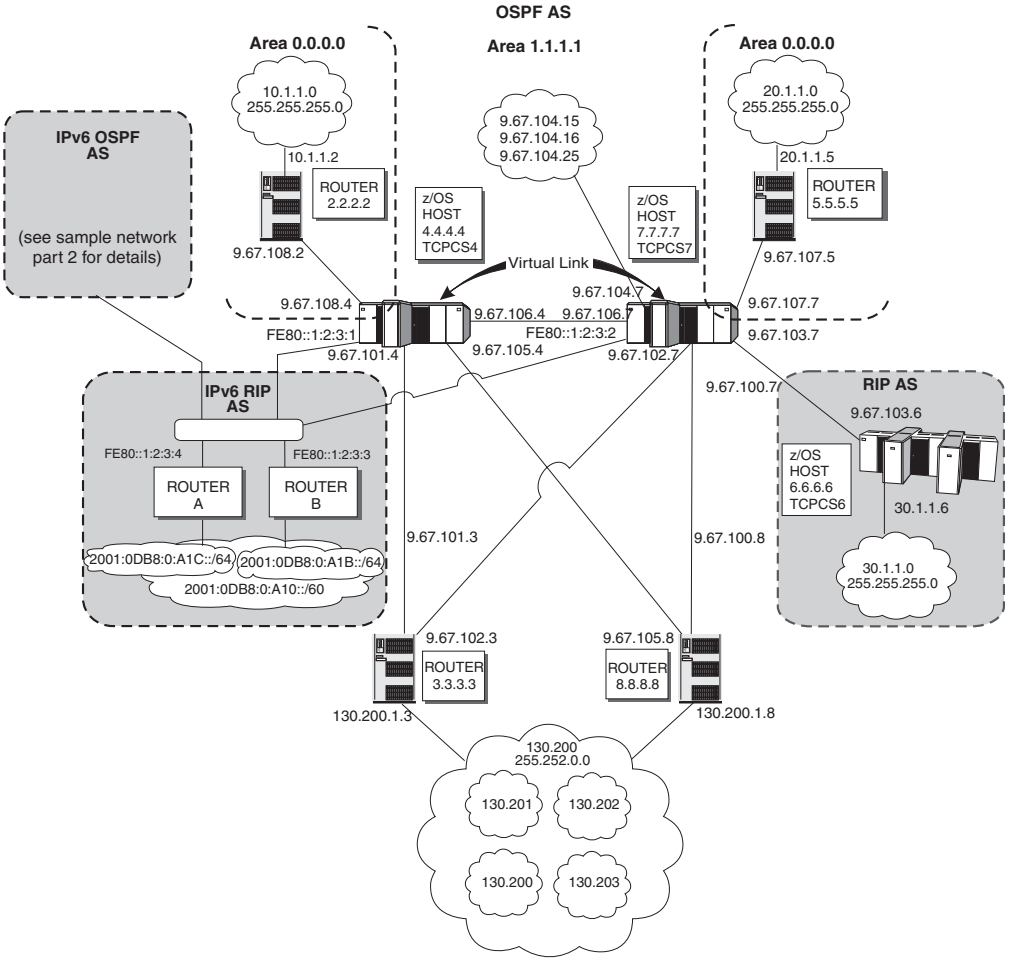

Figure 37. Sample network part 1

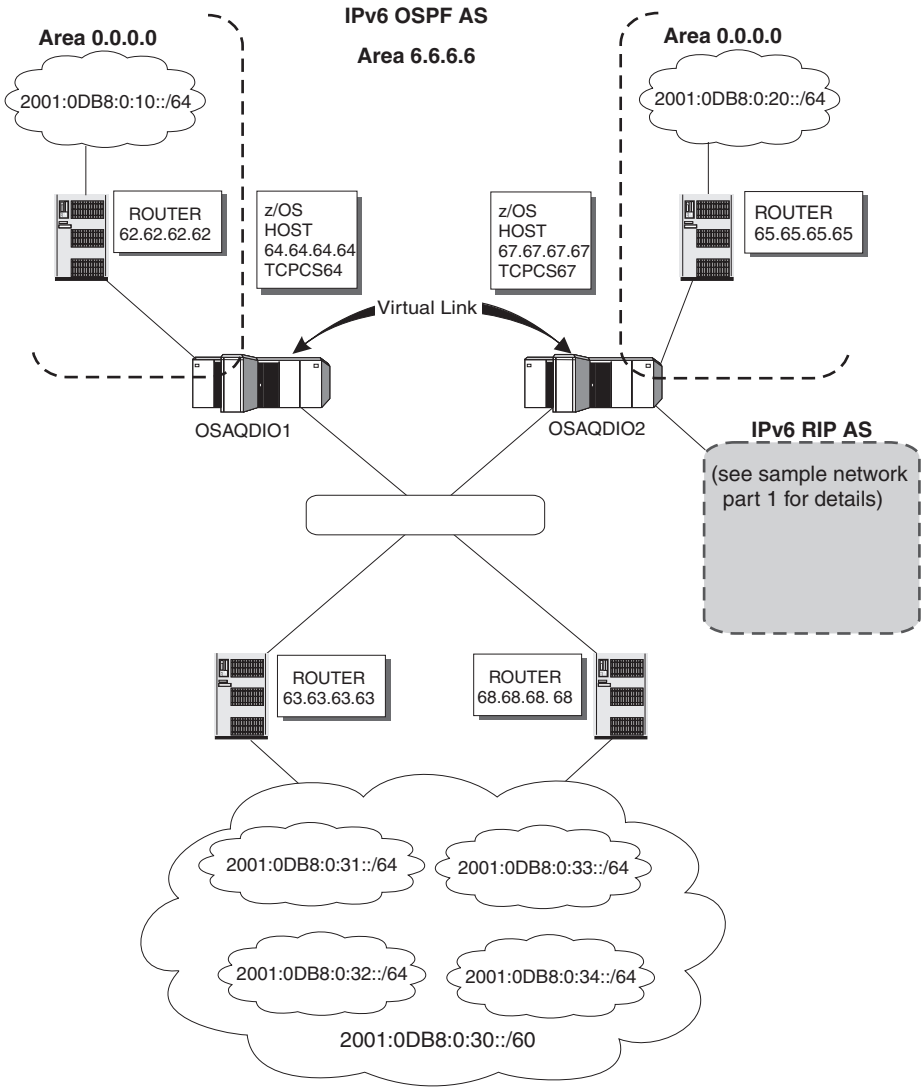

Figure 38. Sample network part 2, IPv6 OSPF AS

In this sample network, TCPCS4 and TCPCS7 are both performing as OSPF area border routers between OSPF areas 0.0.0.0 and 1.1.1.1. TCPCS64 and TCPCS67 are both performing as OSPF area border routers between IPv6 OSPF areas 0.0.0.0 and 6.6.6.6. TCPCS7 is performing as an AS boundary router between the OSPF AS and the RIP AS. TCPCS67 is performing as an AS boundary router between the IPv6 OSPF AS and the IPv6 RIP AS. TCPCS4 and TCPCS7 have interfaces to both the IPv4 network and the IPv6 network.

IPv4 static routing

Static routing requires that routes are configured manually for each router or destination; this is a significant reason system administrators avoid this technique if given a choice. Static routing has the disadvantage that network reachability is not dependent on the state of the network itself. If a destination is down or unreachable over that statically configured route, the static routes remain in the routing table, and traffic continues to be sent toward that destination without success.

To minimize network administrator tasks, configuration of static routes is to be avoided, especially in a large network. However, certain circumstances make static routing more appropriate. For example, static routes can be used:

- To define a default route or a route that is not being advertised within a network using a dynamic routing protocol
- To replace exterior gateway protocols when trying to avoid:
  - The cost of routing protocol traffic between ASs
  - Complex routing policies
- In conjunction with a routing daemon to provide backup routes when the daemon cannot find a dynamic route to the destination. In this case, the static route must be configured as replaceable.

If static routing is used, only the PROFILE.TCPIP data set has to be updated with either the BEGINROUTES or GATEWAY statements. The BEGINROUTES statement is recommended to define static routes due to its ease of use and additional functionality. Additionally, if static routes are to be replaceable by OMPROUTE, the BEGINROUTES configuration statement must be used. GATEWAY does not support definition of replaceable static routes, and a static route defined on a GATEWAY statement will not be replaceable by a routing daemon.

The only ways to modify static routes are:

- Replace the routing table using the VARY TCPIP,,OBEYFILE command
- Use incoming ICMP Redirect packets
- Use ICMP Must Fragment packets
- If a static route is defined on a BEGINROUTES statement as being replaceable, it can be replaced if a dynamic route is discovered by OMPROUTE. This is the only way that a static route can be replaced by a dynamic route.

For more information on the VARY TCPIP,,OBEYFILE command, see *z/OS Communications Server: IP System Administrator's Commands*. For more information on the IPCONFIG statement, and the IGNOREREDIRECTS and PATHMTUDISC parameters for the IPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

Note that the first BEGINROUTES or GATEWAY statement in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, replaces all static routes in the TCP/IP stack routing table (including those destination addresses specified in the BSDROUTINGPARMS section of the PROFILE.TCPIP). Subsequent statements within the same data set append to the routing table. Also, both BEGINROUTES and GATEWAY statements cannot be used within the same data set.

Every interface must have an IP address to transmit or receive packets. Along with the IP address, each interface must have a subnet mask associated with it for routing purposes. The combination of the address and mask will yield the subnet that the interface belongs to and also determines the broadcast address for the interfaces. For interfaces not involved in dynamic routing, the subnet mask can be specified in one of the following ways:

- On the BSDROUTINGPARMS statement in PROFILE.TCPIP (required if running NCPROUTE).
- On the INTERFACE statement in the OMPROUTE configuration file, if running OMPROUTE. Also, if running OMPROUTE, OMPROUTE will always override the stack's BSDROUTINGPARMS and set the subnet mask for every interface it is aware of, even if you did not code the interface to OMPROUTE. Therefore, it

is highly recommended that you either specify every interface to OMPROUTE with the correct subnet mask, or configure OMPROUTE to ignore undefined interfaces.

If you do not specify the subnet mask by one of these methods, the subnet mask is determined by the stack using the stack routing table. Specifying the subnet mask rather than letting it default is highly recommended.

For point-to-point links, such as CTC and CLAW, a destination address is used to document the other end of a point-to-point connection. For interfaces not involved in dynamic routing, this can be specified in one of the following ways:

- On the BSDROUTINGPARMS statement in PROFILE.TCPIP.
- On the INTERFACE statement in the OMPROUTE configuration file, if running OMPROUTE. Also, if running OMPROUTE, OMPROUTE will always override the stack's BSDROUTINGPARMS and set the destination address for every point-to-point link it is aware of, even if you did not code the interface to OMPROUTE. Therefore, it is highly recommended that you either specify every interface to OMPROUTE with the correct destination address, or configure OMPROUTE to ignore undefined interfaces.

If you do not specify the destination address by one of these methods, the stack determines the address by using the stack routing table. Specifying the destination address rather then letting it default is highly recommended.

Tip: You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

Replaceable static routes: Because replaceable static routes are intended to be last-resort routes, TCP/IP attempts to use them only if no dynamic routes to the destination are available.

If a non-replaceable static route fails validation, even if the reason for the failure is transient like gateway unreachable, the definition for the non-replaceable static route is discarded. However, if a replaceable static route fails validation for a transient reason, the definition of the route is retained. When there are no dynamic routes to the destination, TCP/IP periodically retries to add the replaceable static route to the routing table. Because of these periodic retries multiple EZZ4333I messages may be seen. Retries will be performed no more often than every 30 seconds, and only as long as there are no active routes to the destination in the routing table, and only if at least one new route has been added to the routing table since the last retry. Retries are terminated as soon as a valid route to the destination is installed into the routing table, whether it is dynamic, static, or replaceable static.

For a discussion of things to consider when using IPv4 static routing and OMPROUTE together on the same TCP/IP stack, see "Using static routing with OMPROUTE" on page 345.

IPv6 static routing

Static routing requires that routes are configured manually for each router or destination; this is a significant reason system administrators avoid this technique if given a choice. Static routing has the disadvantage that network reachability is not dependent on the state of the network itself. If a destination is down, or unreachable through a statically configured route, the static routes remain in the routing table and traffic continues to be sent toward that destination without success.

To minimize network administrator tasks, configuration of static routes is to be avoided, especially in a large network. However, certain circumstances make static routing more appropriate. For example, static routes can be used:

- To define a route that will not be learned dynamically from OMPROUTE or from router advertisements received from routers as part of the router discovery protocol
- In conjunction with dynamic routes to provide backup routes when a dynamic route to the destination cannot be found. In this case, the static route must be configured as replaceable.

If static routing is used, only the PROFILE.TCPIP data set has to be updated with BEGINROUTES statements. The only ways to modify static routes are:

- Replace the routing table using the VARY TCPIP,,OBEYFILE command
- Use incoming ICMPv6 redirect packets
- If a static route is defined on a BEGINROUTES statement as being replaceable, it can be replaced by a dynamic route

Note that the first BEGINROUTES statement in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, replaces all static routes in the TCP/IP stack routing table. Subsequent statements within the same data set append to the routing table.

Rule: If you use static routes and want to honor ICMPv6 redirect messages (that is, you do not code IPCONFIG6 IGNOREREDIRECTS), then you must code the first hop address using the link-local address of the router. This is required since all redirect messages are sent using the router's link-local address, and if the source address of the redirect message does not match the address of the first hop in the routing table, the redirect message will be ignored.

For more information on the VARY TCPIP,,OBEYFILE command, see *z/OS Communications Server: IP System Administrator's Commands*. For more information on the IPCONFIG6 statement, and the IGNOREREDIRECTS parameter on the IPCONFIG6 statement, see *z/OS Communications Server: IP Configuration Reference*.

Tip: You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

Replaceable static routes: Since replaceable static routes are intended to be last-resort routes, TCP/IP only attempts to use them if no dynamic routes to a destination are available. If a non-replaceable static route fails validation, even if the reason for the failure is transient (for example, gateway unreachable), the

definition for the non-replaceable static route is discarded. However, if a replaceable static route fails validation for a transient reason, the definition of the route is retained. When there are no dynamic routes to the destination, TCP/IP periodically retries to add the replaceable static route to the routing table. Because of these periodic retries, multiple EZZ4348I messages might be seen. Retries are performed at the most every 30 seconds, as long as there are no active routes to the destination in the routing table and at least one new route has been added to the routing table since the last retry. Retries are terminated as soon as a valid route to the destination is installed into the routing table, whether it is a dynamic, static, or replaceable static route.

For a discussion of things to consider when using IPv6 static routing and IPv6 router advertisements together on the same TCP/IP stack, see "Using IPv6 static routing with router advertisements" on page 346. For a discussion of things to consider when using IPv6 static routing and OMPROUTE together on the same TCP/IP stack, see "Using static routing with OMPROUTE" on page 345.

Static routing configuration examples

The following topics illustrate static routing configuration examples.

z/OS TCPCS4

Static route statements for z/OS TCPCS4

```
BEGINRoutes ;first BEGINRoutes in the profile
;
;Network/mask                 FirstHop      LinkName         PacketSize
Route 9.67.106.0/24           =             CTC4TO7          MTU 1500       ;route1
Route 9.67.105.0/24           =             CTC4TO8          MTU 1500       ;route2
Route 9.67.101.0/24           =             CTC4TO3          MTU 1500       ;route3
Route 9.67.108.0/24           =             CTC4TO2          MTU 1500       ;route4

Route 2001:0DB8:0:A1C::/64    FE80::1:2:3:4 OSAQDIO46        MTU 5000 REPL  ;route18
Route DEFAULT6                FE80::1:2:3:4 OSAQDIO46        MTU 5000 REPL  ;route19
EndRoutes
;
```

Notes:

1. In the BEGINROUTES block, the netmask can be specified by a /xx. This number, denoted by xx, represents the number of significant bits in the netmask. For example:

   ```
   /16 = 16 significant bits = 11111111 11111111 00000000 00000000 = 255.255.0.0
   ```

   For IPv6, you must specify the prefix length of the route using the /xxx notation.
2. For direct routes, use an equals symbol (=) for the first hop.

BSDROUTINGPARMS statements for z/OS TCPCS4

```
BSDRoutingParms TRUE ; Shown only for completeness
; Linkname    MTU    Metric    Subnet Mask     Dest Address

  EndBSDRoutingParms
;
```

The sample configuration has an IPv4 supernet route for 130.200.0.0. An IPv4 supernet route means that the netmask for the route is smaller than the class netmask. In this case, 130.200.0.0 is a class B address. The default netmask for class B is 255.255.0.0. The netmask used for this sample is 255.252.0.0, which is less than 255.255.0.0, hence making this a supernet route. In routing, the stack prefers a route that has the most bits in common. Therefore, the stack chooses a route in the following order:

1. If a route exists to the destination address (a host route), it is chosen.
2. At this point, the route chosen depends upon the version of IP being used:
   - For IPv4:

a. If subnet, network, or supernetwork routes exist to the destination, the route with the most specific network mask (the mask with the most bits on) is chosen.
b. If the destination is a multicast destination and a multicast default route exists, that route is chosen.

- For IPv6, if prefix routes exist to the destination, the route with the most specific prefix is chosen.

3. Default routes are chosen when no other route exists to a destination.

For example, for TCPCS4 (and when trying to reach 130.200.0.0), route12 in the list is used, which is the supernet route 130.200.0.0 with mask 255.252.0.0. If applying the mask of that route, 255.252.0.0, to the destination IP address, 130.200.0.0, the result is 130.200.0.0, which is the IP address of this route. Now, when trying to reach destination 130.203.5.2, the stack would use route13 in the list, which is a network route for 130.203.00 with mask 255.255.0.0. If applying the mask of that route, 255.255.0.0, to the destination IP address, 130.203.5.2, the result is 130.203.00, which is the IP address of this route.

For TCPCS4, route7 and route8 are examples of equal cost multipath routes to get to 9.67.103.0 subnet. This means that TCPCS4 has two different routes to get to this destination. If IPCONFIG MULTIPATH is not enabled, then only route7 will be used as long as it is active. This is because the stack chooses the first route and ignores route8. If route7 becomes inactive, then the stack will switch and use route8. If MULTIPATH is enabled, then the stack will use both routes according to the MULTIPATH specification.

In the preceding example, all of the IPv4 links have a subnet mask of 255.255.255.0 because this is what is specified for the links in the BSDROUTINGPARMS. Therefore, to determine the broadcast addresses for link CTC4TO3, AND the IP Address, 9.67.101.4, and the subnet mask, 255.255.255.0, to yield the subnet for this link, 9.67.101.0. Then, OR the subnet, 9.67.101.0, with the complement of the subnet mask, 0.0.0.255. This determines that the broadcast address for this link is 9.67.101.255.

For TCPCS4, route15 and route16 would be selected to reach host FE80::1:2:3:3 and host FE80::1:2:3:4 respectively. Route17 and route18 would be selected to reach any IPv6 address that had the first 64 bits of 2001:0DB8:0:A1B and 2001:0DB8:0:A1C respectively. Route19 would be selected for any other IPv6 destination.

Rules:

1. All IPv4 IP addresses must follow Classless Inter-Domain Routing (CIDR) convention that requires the actual mask to be one or more on-bits followed by zero or more off-bits. On-bits cannot be followed by off-bits followed by on-bits. Therefore, a mask of 255.255.254.0 is valid (an actual mask of FFFFE00), but a mask of 255.255.253.0 is not valid (an actual mask of FFFFD00) because 253 is 11111101.
2. VIPA links or VIPA interfaces are not allowed on BEGINROUTES statements.
3. DEFAULT and DEFAULT6 routes are always indirect routes and therefore must always have a first hop address specified.

IPv4 dynamic routing using OMPROUTE

Daemon is a UNIX term for a background server process, and daemons are used for dynamic routing. For z/OS Communications Server IP, there is a multiprotocol routing daemon available. For IPv4, OMPROUTE supports the RIP Version 1, RIP Version 2, and OSPF routing protocols. You can send RIP Version 1 or RIP Version 2, but not both at the same time on a single interface. However, you can configure a RIP interface to receive both versions.

Guideline: If OROUTED was used in a prior release and the RIP protocol is still the preferred dynamic routing method in your host configuration, use OMPROUTE to provide RIP support.

For IPv4, OMPROUTE implements the OSPF protocol described in RFC 1583 (*OSPF Version 2*), the OSPF subagent protocol described in RFC 1850 (*OSPF Version 2 Management Information Base*), and the RIP protocols described in RFC 1058 (*Routing Information Protocol*) and in RFC 1723 (*RIP Version 2 - Carrying Additional Information*). It provides an alternative to the static TCP/IP gateway definitions. The MVS host running with OMPROUTE becomes an active OSPF or RIP router in a TCP/IP network. Either or both of these routing protocols can be used to dynamically maintain the host routing table. For example, OMPROUTE can detect when a route is created, is temporarily unavailable, or if a more efficient route exists. If both OSPF and RIP protocols are used simultaneously, OSPF routes will be preferred over RIP routes to the same destination.

Tip: You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

Open Shortest Path First

Open Shortest Path First (OSPF) is classified as an Interior Gateway Protocol (IGP). This means that it distributes routing information between routers belonging to a single autonomous system (AS), a group of routers all using a common routing protocol. The OSPF protocol is based on link-state or shortest path first (SPF) technology. It has been designed expressly for the TCP/IP Internet environment, including explicit support for IP subnetting and the tagging of externally derived routing information.

OSPF performs the following tasks:

Multiple routes
Provides support for up to 16 equal-cost routes.

Authentication
Provides for the authentication of routing updates.

IP multicast
Uses IP multicast when sending or receiving the updates.

Allows network grouping
Allows sets of networks to be grouped together. Such a grouping is called an area. The topology of an area is hidden from the rest of the autonomous system. This method of hiding information enables a significant reduction in routing traffic. Also, routing within the area is determined only by the

area's own topology, lending the area protection from bad routing data. An area is a generalization of an IP subnetted network.

IP subnet configuration
Enables the flexible configuration of IP subnets. Each route distributed by OSPF has a destination and mask. Two different subnets of the same IP network number may have different sizes (that is, different masks). This is commonly referred to as variable length subnetting. A packet is routed to the best (longest or most specific) match. Host routes are considered to be subnets whose masks are all ones (0xFFFFFFFF).

Authenticate OSPF protocol exchanges
Can be configured such that all OSPF protocol exchanges are authenticated. This means that only trusted routers can participate in the autonomous system's routing. A single authentication scheme is configured for each physical link. This enables some links to use authentication while others do not.

OSPF is a dynamic routing protocol. It quickly detects topological changes in the AS (such as router interface failures) and calculates new loop-free routes after a period of convergence. This period of convergence is short and involves a minimum of routing traffic as compared to the RIP protocol.

In a link-state routing protocol, each router maintains a database describing the autonomous system's topology. Each individual piece of this database is a particular router's local state (for example, the router's usable interfaces and reachable neighbors). The router distributes its local state throughout the autonomous system by flooding.

To generate routes, all routers run the exact same algorithm, in parallel. From the topological database, each router constructs a tree of shortest paths with itself as root. This shortest-path tree gives the route to each destination in the autonomous system. Externally derived routing information (for example, routes learned from the RIP protocol) appears on the tree as leaves. When multiple equal-cost routes to a destination exist, the routes (up to 16) are added to the TCP/IP stack's route table. The TCP/IP stack uses these equal-cost routes according to the multipath setting configured for the route table. “Multiple equal-cost routes” on page 276 provides additional information about the multipath setting configured for a route table and the use of multiple equal-cost routes.

Externally derived routing data (for example, routes learned from the RIP protocol) is passed transparently throughout the autonomous system. This externally derived data is kept separate from the OSPF protocol's link state data. Each external route can also be tagged by the advertising router, but not by OMPROUTE, enabling the passing of additional information between routers on the boundaries of the autonomous system. OMPROUTE does pass tags created by others. For information on configuring OSPF, see “Steps for configuring OSPF and RIP (IPv4 and IPv6)” on page 288.

Routing Information Protocol

Routing Information Protocol (RIP) is an Interior Gateway Protocol (IGP) designed to manage a relatively small network. RIP is based on the Bellman-Ford or the distance-vector algorithm. RIP has many limitations and is not suitable for every TCP/IP environment. Before using the RIP function in OMPROUTE, read RFCs 1058 and 1723 to decide if RIP can be used to manage the routing tables of your

network. For more information about RFCs 1058 and 1723, see Appendix G, "Related protocol specifications," on page 1555.

RIP uses the number of hops, or hop count, to determine the best possible route to a host or network. The term hop count is also referred to as the metric. In RIP, a hop count of 16 means infinity, or that the destination cannot be reached. This limits the longest path in the network that can be managed by RIP to 15 gateways.

A RIP router broadcasts routing information to its directly connected networks every 30 seconds. It receives updates from neighboring RIP routers every 30 seconds and uses the information contained in these updates to maintain the routing table. If an update has not been received from a neighboring RIP router in 180 seconds, a RIP router assumes that the neighboring RIP router is down, sets all routes through that router to a metric of 16 (infinity), and stops using those routes when routing IP packets. If an update has still not been received from the neighboring RIP router after another 120 seconds, the RIP router deletes from the routing table all of the routes through that neighboring RIP router.

RIP Version 2 is an extension of RIP Version 1 and provides the following features:

Route Tags
The route tags are used to separate *internal* RIP routes (routes for networks within the RIP routing domain) from *external* RIP routes, which may have been imported from an EGP (external gateway protocol) or another IGP. OMPROUTE does not generate route tags, but preserves them in received routes and readvertises them when necessary.

Variable subnetting support
Variable length subnet masks are included in routing information so that dynamically added routes to destinations outside subnetworks or networks can be reached.

Immediate next hop for shorter paths
Next hop IP addresses, whenever applicable, are included in the routing information to eliminate packets being routed through extra hops in the network.

Multicasting to reduce load on hosts
IP multicast address 224.0.0.9, reserved for RIP Version 2 packets, is used to reduce unnecessary load on hosts which are not listening for RIP Version 2 messages. This support is dependent on interfaces that are multicast-capable.

Authentication for routing update security
Authentication keys can be configured for inclusion in outgoing RIP Version 2 packets. Incoming RIP Version 2 packets are checked against the configured keys.

Configuration switches for RIP Version 1 and RIP Version 2 packets
Configuration parameters allow for controlling which version of RIP packets are to be sent or received over each interface.

Supernetting support
The supernetting feature is part of Classless InterDomain Routing (CIDR). Supernetting provides a way to combine multiple network routes into fewer supernet routes, thus reducing the number of routes in the routing table and in advertisements.

For configuration information for RIP, see "Steps for configuring OSPF and RIP (IPv4 and IPv6)" on page 288.

IPv6 dynamic routing using router discovery

Enabling IPv6 router discovery in z/OS Communications Server requires no additional z/OS Communications Server configuration. All that is needed is at least one IPv6 interface that is defined and started, and at least one adjacent router through that interface that is configured for IPv6 router discovery. If these things exist, then z/OS Communications Server begins receiving router advertisements from the adjacent routers. Depending on the configuration in the adjacent routers, the following types of routes can be learned from the received router advertisements:

- Default route for which the originator of the router advertisement is the next hop
- Indirect routes to prefixes for which the originator of the router advertisement is the next hop
- Direct routes (no next hop) to prefixes that reside on the link shared by z/OS Communications Server and the originator of the router advertisement

If there are non-replaceable static routes to the same destinations as those in the router advertisements, then the routes that are learned from the router advertisements are not added to the stack routing table.

Multiple routes from router advertisements

Multiple default routes and multiple prefix routes to a single prefix might be learned through router advertisements. If an adjacent router resides on a link onto which z/OS Communications Server TCP/IP has multiple IPv6 interfaces, multiple routes are learned for each route in the router advertisement from the adjacent router (one route through each interface onto the link). Default routes and indirect routes to a prefix might be learned from the router advertisements that are originated by multiple adjacent routers.

When multiple direct prefix routes to a single prefix are learned, all of the routes are installed in the stack route table.

When multiple default routes or multiple indirect prefix routes to a single prefix are learned, the following information is used by the stack to determine the subset of the routes that are installed in the stack route table:

- The reachability of the advertising routers
- The status (active or inactive) of the associated interfaces
- The preference values (high, medium, or low) that are advertised for the routes in the router advertisements. This value enables the originator of the router advertisement to indicate whether it should be preferred over other routers as the next hop for the route.

The routes with the highest preference value are installed in the route table; however, routes that were learned from routers that are reachable over active interfaces take priority, regardless of preference value.

When multiple default routes or multiple prefix routes to a single prefix are installed in the stack route table, TCP/IP uses those routes according to the setting of the MULTIPATH parameter on the IPCONFIG6 statement.

IPv6 dynamic routing using OMPROUTE

For IPv6, OMPROUTE implements the IPv6 RIP protocol described in RFC 2080 (*RIPng for IPv6*) and the IPv6 OSPF protocol described in RFC 2740 (*OSPF for IPv6*). It provides an alternative to the static TCP/IP gateway definitions. The MVS host running with OMPROUTE becomes an active OSPF or RIP router in a TCP/IP network. Either or both of these routing protocols can be used to dynamically maintain the host IPv6 routing table. For example, OMPROUTE can detect when a route is created, is temporarily unavailable, or if a more efficient route exists. If both IPv6 OSPF and IPv6 RIP protocols are used simultaneously, IPv6 OSPF routes will be preferred over IPv6 RIP routes to the same destination.

Tip: You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

IPv6 OSPF protocol

IPv6 OSPF is classified as an Interior Gateway Protocol (IGP). This means that it distributes routing information between routers belonging to a single autonomous system (AS), a group of routers all using a common routing protocol. The IPv6 OSPF protocol is based on link-state or shortest path first (SPF) technology.

IPv6 OSPF is a dynamic routing protocol. It quickly detects topological changes in the AS (such as router interface failures) and calculates new loop-free routes after a period of convergence. This period of convergence is short and involves a minimum of routing traffic as compared to the IPv6 RIP protocol. However, it does generally require more CPU resources on participating routers.

In IPv6 OSPF, sets of networks can be placed together in groups called areas. The topology of an area is hidden from the rest of the AS. This method of hiding information enables a significant reduction in routing traffic. Also, routing within the area is determined only by the area's own topology, lending the area protection from bad routing data.

Each IPv6 OSPF router maintains a database describing the autonomous system's topology. Each individual piece of this database is a particular router's local state (for example, the router's usable interfaces and reachable neighbors). The router distributes its local state information by flooding. The routing information in an area is summarized and advertised into adjacent areas, allowing for the generation of interarea routes. This summarization and advertising of routing information between areas is the responsibility of the routers that reside on the border between areas (called area border routers).

To generate routes, all routers run the exact same algorithm, in parallel. From the topological database, each router constructs a tree of shortest paths with itself as root. This shortest-path tree gives the route to each destination in the autonomous system. Externally derived routing information (for example, routes learned from the IPv6 RIP protocol) appears on the tree as leaves. When multiple equal-cost routes to a destination exist, the routes (up to 16) are added to the TCP/IP stack's route table. The TCP/IP stack uses these equal-cost routes according to the multipath setting configured for the route table. "Multiple equal-cost routes" on page 276

page 276 provides additional information about the multipath setting configured for a route table and the use of multiple equal-cost routes.

Externally derived routing data is passed transparently throughout the autonomous system. This externally derived data is kept separate from the IPv6 OSPF protocol's link state data. Each external route can also be tagged by the advertising router, but not by OMPROUTE, enabling the passing of additional information between routers on the boundaries of the autonomous system. OMPROUTE does pass tags created by others. For information on configuring IPv6 OSPF, see "Steps for configuring OSPF and RIP (IPv4 and IPv6)" on page 288.

IPv6 RIP protocol

IPv6 RIP is an Interior Gateway Protocol (IGP) designed to manage a relatively small network. IPv6 RIP is based on the Bellman-Ford or the distance-vector algorithm. IPv6 RIP has limitations and is not suited for every TCP/IP environment. Before using the IPv6 RIP function in OMPROUTE, read RFC 2080 to decide if RIP can be used to manage the IPv6 routing tables of your network. For more information about RFC 2080, see Appendix G, "Related protocol specifications," on page 1555.

IPv6 RIP uses the number of hops, or hop count, to determine the best possible route to a host or network. The term hop count is also referred to as the metric. In IPv6 RIP, a hop count of 16 means infinity, or that the destination cannot be reached. This limits the longest path in the network that can be managed by IPv6 RIP to 15 gateways.

A IPv6 RIP router broadcasts routing information to its directly connected networks every 30 seconds. It receives updates from neighboring IPv6 RIP routers every 30 seconds and uses the information contained in these updates to maintain the IPv6 routing table. If an IPv6 RIP update has not been received from a neighboring router in 180 seconds, an IPv6 RIP router assumes that the neighboring router is down, sets all IPv6 RIP routes through that router to a metric of 16 (infinity), and stops using those routes when routing IP packets. If an update has still not been received from the neighboring router after another 120 seconds, the IPv6 RIP router deletes from the IPv6 routing table all of the IPv6 RIP routes through that neighboring router.

Next hop IP addresses, whenever applicable, are included in IPv6 RIP updates to eliminate packets being routed through extra hops in the network. IPv6 multicast address FF02::9, reserved for IPv6 RIP packets, is used to reduce unnecessary load on hosts that are not listening for IPv6 RIP messages.

For configuration information for IPv6 RIP, see "Steps for configuring OSPF and RIP (IPv4 and IPv6)" on page 288.

OMPROUTE configuration

This topic includes items to consider when configuring OMPROUTE, and the steps to use to configure OMPROUTE.

Run-time environment

OMPROUTE is a z/OS UNIX application, and it requires a z/OS UNIX file system to operate. It can be started from an MVS started procedure, from the z/OS shell, or from AUTOLOG (see step 2 on page 278 for restrictions on using AUTOLOG to

start OMPROUTE). OMPROUTE must be started by a RACF-authorized user ID, and it must reside in an APF authorized library.

OMPROUTE uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and syslogd are used for major events such as initialization, termination, and error conditions. CTRACE is used for tracing the receipt and transmission of OSPF/RIP packets and communications between OMPROUTE and the TCP/IP stack. In addition, OMPROUTE can be configured to use CTRACE for detailed tracing and debugging. STDOUT is used for detailed tracing and debugging.

When syslogd is active and /dev/console is defined in the syslog.conf file, OMPROUTE logging messages are directed to syslogd and to the MVS console. If syslogd is active and /dev/console is not defined, OMPROUTE logging messages are directed to syslogd only.

When syslogd is inactive, OMPROUTE logging messages are directed to the OMPROUTE JES joblog and to the MVS console.

If OMPROUTE tracing or debugging is enabled, the output can be directed to STDOUT, the JES joblog, or OMPROUTE CTRACE. Additionally, the logging messages (that is, interface initialization messages) can be found in syslogd, provided it is active at the time of tracing or debugging. Syslogd directs urgent OMPROUTE messages to the MVS console.

Tip: If you enable OMPROUTE tracing without syslogd active, large amounts of data can be written to the console.

OMPROUTE uses a standard message catalog. The message catalog must be in the z/OS UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

Configuration of OMPROUTE is accomplished using an OMPROUTE configuration file. For details on the statements in the OMPROUTE configuration file, see *z/OS Communications Server: IP Configuration Reference*.

Display of OMPROUTE information is performed using the DISPLAY or MODIFY command. Modification of OMPROUTE information is performed using the MODIFY command. For details on OMPROUTE's DISPLAY and MODIFY commands, see *z/OS Communications Server: IP System Administrator's Commands*.

Language Environment run-time considerations

When starting OMPROUTE from a started or cataloged procedure, it is usually recommended that OMPROUTE be started directly from the SEZALOAD data set using PGM=OMPROUTE. However, there is a situation where it might be desirable to start OMPROUTE using BPXBATCH.

When OMPROUTE is started using PGM=OMPROUTE, the STDENV DD card, if used, is passed directly to the OMPROUTE program. The Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS= environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM= parameter and the options must be specified before any OMPROUTE options. However, the PARM= statement allows a maximum of 100 characters. If the desired Language

Environment run-time options plus OMPROUTE parameters exceeds 100 characters, consideration should be given to using BPXBATCH to start OMPROUTE. When PGM=BPXBATCH is used, the Language Environment environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

OMPROUTE tuning considerations

It might be desirable to tune OMPROUTE's storage usage when running in complex network environments or when running with traces enabled for long periods of time. To determine if tuning is necessary, use the Language Environment run-time options RPTSTG and RPTOPTS. For information on these options and the reports they generate, see z/OS Language Environment documentation.

Multiple TCP/IP stacks

A one-to-one relationship exists between an instance of OMPROUTE and a stack. OSPF, RIP, IPv6 OSPF, and IPv6 RIP support on multiple stacks requires multiple instances of OMPROUTE.

TCP/IP stack routing table management

OMPROUTE's job is limited to the management of the TCP/IP stack routing table. OMPROUTE is not involved in the actual routing decisions made by the TCP/IP stack when routing a packet to its destination.

If IPv4 interfaces are defined in the OMPROUTE configuration file as OSPF or RIP interfaces, all IPv4 dynamic routes are deleted from the stack's IPv4 routing table upon initialization of OMPROUTE. If IPv6 interfaces are defined in the OMPROUTE configuration file as OSPF or RIP interfaces, all IPv6 dynamic routes, excluding those dynamic routes learned through IPv6 router discovery, are deleted from the stack's IPv6 routing table upon initialization of OMPROUTE. OMPROUTE then repopulates the stack routing tables that it cleared, using information learned through the routing protocols.

IPv4 Internet Control Message Protocol (ICMP) redirects are ignored when OMPROUTE is active and there are IPv4 interfaces configured to OMPROUTE as RIP or OSPF interfaces. IPv6 ICMP redirects are ignored when OMPROUTE is active and there are IPv6 interfaces configured to OMPROUTE as RIP or OSPF interfaces.

OMPROUTE does not make use of the BSDROUTINGPARMS statement. Instead, the IPv4 Maximum Transmission Unit (MTU), subnet mask, and destination address parameters are configured using the OSPF_INTERFACE, RIP_INTERFACE, and INTERFACE statements in the OMPROUTE configuration file. The MTU for IPv6 interfaces is learned from the TCP/IP stack and therefore is not a parameter on the IPV6_OSPF_INTERFACE, IPV6_RIP_INTERFACE, and IPV6_INTERFACE statements.

Result: The Netstat DEvlinks/-d report displays these parameters under the heading `Routing Parameters`, even though the BSDROUTINGPARMS statement is not defined.

Using RIP, IPv6 RIP, OSPF, and IPv6 OSPF with OMPROUTE

When OMPROUTE is initialized, it uses the OMPROUTE configuration file to determine which routing protocols will be enabled. If at least one OSPF interface is

configured, the OSPF protocol is enabled. If at least one RIP interface is configured, RIP is enabled. If at least one IPv6 RIP interface is configured, IPv6 RIP is enabled. If at least one IPv6 OSPF interface is configured, IPv6 OSPF is enabled. If OMPROUTE is started with no interfaces defined for a particular protocol, that protocol is disabled until one of the following occurs:

- OMPROUTE is stopped and restarted with a configuration file containing at least one interface of the specific type.
- OMPROUTE is dynamically reconfigured using the MODIFY command with a configuration file containing at least one interface of the specific type.

When OMPROUTE is configured for both the OSPF and RIP protocols (either IPv4 or IPv6), routes that are learned through the OSPF protocol take precedence over routes learned through the RIP protocol.

The OSPF and RIP protocols are communicated over IPv4 interfaces that are defined with the OSPF_INTERFACE and RIP_INTERFACE configuration statements, respectively. An IPv4 interface involved in the communication of neither the RIP nor the OSPF protocol should be configured to OMPROUTE with the INTERFACE configuration statement, unless Ignore_Undefined_Interfaces=YES is coded on the Global_Options configuration statement. OMPROUTE supports a maximum of 255 real, physical, IPv4 interfaces (that is, interfaces on which data can actually be sent and received). There is no theoretical limit on how many VIPAs can be configured, though there are practical limits imposed by network design. For special VIPA considerations, see step 4 on page 292.

The IPv6 OSPF and IPv6 RIP protocols are communicated over IPv6 interfaces that are defined with the IPV6_OSPF_INTERFACE and IPV6_RIP_INTERFACE configuration statements, respectively. An IPv6 interface not involved in the communication of the IPv6 OSPF or IPv6 RIP protocol can be configured to OMPROUTE with the IPV6_INTERFACE configuration statement. If default values are acceptable and you do not need to define additional prefixes to an IPv6 interface not involved in the communication of the IPv6 OSPF or IPv6 RIP protocol, it is not necessary to configure the interface to OMPROUTE at all. OMPROUTE will learn about the interface and its MTU value from the stack and use default values for other parameters. This is different from IPv4, where all interfaces should be configured to prevent OMPROUTE from using default values for MTU size and subnet mask, unless Global_Options is coded with Ignore_Undefined_Interfaces=YES.

OMPROUTE allows for the generation of multiple, equal-cost routes to a destination. For OSPF and IPv6 OSPF, up to 16 multiple equal-cost routes are allowed. For RIP and IPv6 RIP, multiple equal-cost routes are supported only to directly connected destinations over redundant interfaces.

Token-ring multicast

If OMPROUTE will be communicating through the OSPF or RIP Version 2 protocol over a token ring media, and there will be routers attached to that token ring that are not listening (at the DLC layer) for the token ring multicast MAC address 0xC000.0004.0000, the following TRANSLATE statement is required in the PROFILE.TCPIP:

```
TRANSLATE 224.0.0.0 IBMTR FFFFFFFFFFFF linkname
```

Without this statement, OSPF and RIP Version 2 multicast packets are discarded at the DLC layer by those routers that are not listening for the token ring multicast MAC address.

Restriction: The TRANSLATE statement cannot be used for OSA devices in QDIO mode.

Virtual IP addresses

OMPROUTE is enhanced with virtual IP addressing (VIPA) to handle network interface failures by switching to alternate paths. The VIPA routes are included in the OSPF, RIP, IPv6 OSPF, and IPv6 RIP advertisements to adjacent routers. Adjacent routers learn about VIPA routes from the advertisements and can use them to reach the destinations at the MVS host.

Service policy

If service policy is going to be used to restrict access to neighbors on point-to-multipoint interfaces (for example MPCPTP interfaces including XCF and IUTSAMEH connections) for temporary intervals, those neighbors must be explicitly defined on the OSPF_INTERFACE or RIP_INTERFACE statement. Otherwise, OMPROUTE might not be able to communicate with those neighbors when the access restriction expires.

Multiple equal-cost routes

When the TCP/IP main route table is used to route traffic, multiple routes exist in the TCP/IP main route table for a destination, and the IPCONFIG MULTIPATH or IPCONFIG6 MULTIPATH statement is specified in PROFILE.TCPIP, outbound traffic for that destination is spread across all of the routes. The same is true when a policy-based route table is used to route traffic, multiple routes exist in the policy-based route table for a destination, and the Multipath parameter on the RouteTable policy statement indicates that multipath support should be provided for the policy-based route table. This traffic spreading is done on either a packet-basis or connection-basis, depending on the type of multipath support configured. For information on configuring different types of multipath support using the IPCONFIG and IPCONFIG6 statements, and the RouteTable policy statement, see *z/OS Communications Server: IP Configuration Reference*.

When OMPROUTE is being used to provide dynamic routing for a TCP/IP stack, multiple routes to the same destination can be dynamically added to a TCP/IP stack route table, based upon the routing information learned from other routers. These multiple routes will be added when the route calculation for each has resulted in the same route cost value. No more than 16 equal-cost routes will be added for each destination. For RIP and IPv6 RIP, multiple equal-cost routes will be added only to directly-connected destinations over redundant interfaces. The RIP and IPv6 RIP protocols will generate no more than one indirect route to a destination.

Table 16. Multipath route limitations

Multipath route type	Static (BEGINROUTES and policy-defined)	OMPROUTE (OSPF and IPv6 OSPF)	OMPROUTE (RIP and IPv6 RIP)
Direct host	Yes (no limit)	Yes (up to 16)	No
Indirect host	Yes (no limit)	Yes (up to 16)	No
Direct network	Yes (no limit)	Yes (up to 16)	Yes (up to 16 for redundant interfaces)
Indirect network	Yes (no limit)	Yes (up to 16)	No
Default (indirect)	Yes (no limit)	Yes (up to 16)	No

Guidelines:

- If more equal-cost multipath routes are needed in the main IPv4 route table than can be provided by an IPv4 dynamic routing protocol, you can configure static routes using the GATEWAY or BEGINROUTES statements.
- If more equal-cost multipath routes are needed in the main IPv6 route table than can be provided by an IPv6 dynamic routing protocol, you can configure static routes using the BEGINROUTES statement.
- If more equal-cost multipath routes are needed in a policy-based route table than can be provided by a dynamic routing protocol, you can configure static routes using the RouteTable policy statement.

Sysplex autonomics

If you enable sysplex autonomics, it is very important that you ensure that the WLM policy for the OMPROUTE address space receives sufficient resources in relationship to other work being managed on the system. Under high load conditions it is possible that OMPROUTE, if not properly classified, can trigger an autonomic response from the TCP/IP stack it has an affinity with, resulting in the TCP/IP address space removing itself from the sysplex group. It is recommended that the TCP/IP and OMPROUTE address spaces be placed in the SYSSTC service classification. Classification in another service class will leave the system vulnerable to a sysplex distributor outage. For further information on sysplex autonomics, see "Sysplex problem detection and recovery" on page 449.

Steps for configuring OMPROUTE

The steps to configure OMPROUTE are:

1. Create the OMPROUTE configuration file.
2. Reserve the ports, and ensure loopback availability.
3. Update the resolver configuration file.
4. Update the OMPROUTE cataloged procedure.
5. Specify the RIP UDP port numbers in the SERVICES file or data set (if using the RIP or IPv6 RIP protocol).
6. RACF authorize user IDs for starting OMPROUTE.
7. Start syslogd.
8. Update the OMPROUTE environment variables (optional).
9. Create static routes (optional).
10. Configure OSPF authentication (optional, if using the IPv4 OSPF protocol).

Tip: If policy-based routing is used on the TCP/IP stack and the routing policy is configured with dynamic routing parameters, you do not need to provide additional configuration to OMPROUTE for dynamic routing support to be provided for the policy-based route tables. The dynamic routing parameters specified in the routing policy are provided to OMPROUTE by the TCP/IP stack to control the scope of dynamic routes computed by OMPROUTE. For a description of this function, see "Policy-based routing" on page 337.

Result: If policy-based routing is used on the TCP/IP stack and a route table is configured to the Policy Agent with no dynamic routing parameters, OMPROUTE has no knowledge of that route table. For example, the route table does not appear in the display of OMPROUTE route tables.

Following are the details for the steps to configure OMPROUTE.

1. Create the OMPROUTE configuration file.

   The OMPROUTE configuration file provides information about the host's routing capabilities and TCP/IP interfaces. For more detail about the contents of this file, see "Steps for configuring OSPF and RIP (IPv4 and IPv6)" on page 288. The following is the search order used by OMPROUTE to locate the configuration data set or file:

   a. DD:OMPCFG
   b. If the environment variable, OMPROUTE_FILE, has been defined, OMPROUTE uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data. The syntax for an MVS data set name is //'*mvs.dataset.name*'. The syntax for a z/OS UNIX file name is */dir/subdir/file.name*.
   c. /etc/omproute.conf
   d. *hlq*.ETC.OMPROUTE.CONF

   Tip: If you are configuring a complex environment, you can use the following OMPROUTE configuration file features:

   - Group related statements into separate files and use the INCLUDE statement to include them in your OMPROUTE configuration.
   - Use MVS system symbols (such as &SYSCLONE, &SYSNAME, and &SYSPLEX). This feature reduces the number of OMPROUTE configuration files that must be maintained in a multisystem environment.

   A sample configuration file is provided in SEZAINST(EZAORCFG). The configuration files for TCPCS4, TCPCS6, TCPCS7, and TCPCS64 in the sample network are shown in "Sample OMPROUTE configuration files" on page 333. For a description of the syntax rules for the OMPROUTE configuration file, as well as details on each of the configuration statements, see *z/OS Communications Server: IP Configuration Reference*.

---

2. Reserve the ports.

   RIP protocol

   If the RIP protocol of OMPROUTE is going to be used, UDP port 520 should be reserved for OMPROUTE. If the IPv6 RIP protocol of OMPROUTE is going to be used, UDP port 521 should be reserved for OMPROUTE. This is done by adding the name of the member containing the OMPROUTE cataloged procedure to the PORT statement in PROFILE.TCPIP:

   ```
   PORT
       520 UDP OMPROUTE
       521 UDP OMPROUTE
   ```

   If you want to be able to start OMPROUTE from the z/OS shell, use the special name OMVS as follows:

   ```
   PORT
       520 UDP OMVS
       521 UDP OMVS
   ```

   Autolog considerations for OMPROUTE when using the OSPF protocol

   If a procedure in the AUTOLOG list also has a PORT statement reserving a TCP or UDP port but does not have a listening connection on that port, TCP/IP periodically attempts to cancel that procedure and start it again.

   Therefore, if OMPROUTE is being started with AUTOLOG and only the OSPF or IPv6 OSPF protocol is being used (no RIP or IPv6 RIP protocol,

so no listening connection on the RIP or IPv6 RIP UDP port), it is important to do one of the following:

- Ensure that the RIP UDP port (520) and the IPv6 RIP UDP port (521) are not reserved by the PORT statement in the PROFILE.TCPIP.
- Add the NOAUTOLOG parameter to the PORT statement in the PROFILE.TCPIP. For example,

```
PORT
 520 UDP OMPROUTE NOAUTOLOG
 521 UDP OMPROUTE NOAUTOLOG
```

Tip: When using only the OSPF or IPv6 OSPF protocol, the auto-start feature of AUTOLOG can be used as described. However, the monitoring and auto-restart features of AUTOLOG are unavailable due to AUTOLOG's dependence on listening to a TCP or UDP connection, which does not exist with OSPF and IPv6 OSPF.

If you fail to take one of these actions, OMPROUTE will be periodically canceled and restarted by TCP/IP.

---

3. Update the resolver configuration file.

   The resolver configuration file contains keywords (DATASETPREFIX and TCPIPjobname) used by OMPROUTE. The value assigned to DATASETPREFIX will determine the high-level qualifier (*hlq*). The *hlq* is used in the search order for the OMPROUTE configuration file. If no DATASETPREFIX keyword is found, a default of TCPIP is used. The value assigned to TCPIPjobname will be used as the name of the TCP/IP stack with which OMPROUTE establishes a connection.

   For a description of the search order used by the resolver to locate the resolver configuration file, see "Resolver configuration files" on page 759.

---

4. Update the OMPROUTE cataloged procedure.

   If OMPROUTE is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(OMPROUTE) to your system or recognized PROCLIB. Specify OMPROUTE parameters and change the data set names to suit your local configuration.

//OMPROUTE PROC
//OMPROUTE EXEC PGM=OMPROUTE,REGION=10M,TIME=NOLIMIT,
// PARM=('POSIX(ON)',
//       'ENVAR("_CEE_ENVFILE=DD:STDENV")/')
//*
//* Example of start parameters to OMPROUTE:
//*
//* PARM=('POSIX(ON)',
```

```
//*       'ENVAR("_CEE_ENVFILE=DD:STDENV")/-t1 -6t1')
//*
//*        Provide environment variables to run with the
//*        desired stack and configuration.  As an example,
//*        the file specified by STDENV could have these
//*        five lines in it:
//*
//*           RESOLVER_CONFIG=//'SYS1.TCPPARMS(TCPDATA2)'
//*           OMPROUTE_FILE=/u/usernnn/config.tcpcs2
//*           OMPROUTE_DEBUG_FILE=/tmp/logs/omproute.debug
//*           OMPROUTE_IPV6_DEBUG_FILE=/tmp/logs/omprout6.debug
//*           OMPROUTE_DEBUG_FILE_CONTROL=1000,5
//*
//*        For information on the above environment variables,
//*        refer to the IP CONFIGURATION GUIDE.
//*
//STDENV   DD PATH='/u/usernnn/envcs2',
//         PATHOPTS=(ORDONLY)
//*
//*        The stdout stream may be redirected to a HFS file as
//*        shown below.
//*        The PATHOPTS OTRUNC option will clear the stdout file
//*        every time OMPROUTE is started.  If you want to retain
//*        previous stdout information, change it to OAPPEND.
//*
//SYSPRINT DD SYSOUT=*
//*SYSPRINT DD PATH='/tmp/omproute.stdout',
//*            PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//*            PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
//*
//*        The stderr stream may be redirected to a HFS file as
//*        shown below.
//*        The PATHOPTS OTRUNC option will clear the stderr file
//*        every time OMPROUTE is started.  If you want to retain
//*        previous stderr information, change it to OAPPEND.
//*
//SYSOUT   DD SYSOUT=*
//*SYSOUT   DD PATH='/tmp/omproute.stderr',
//*            PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//*            PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
//*
//CEEDUMP  DD SYSOUT=*,DCB=(RECFM=FB,LRECL=132,BLKSIZE=132)
```

---

5. Specify the RIP UDP port numbers in the SERVICES file or data set (if using the RIP or IPv6 RIP protocol).

   The services file contains the relationship between services and port numbers as described in *z/OS Communications Server: IP Configuration Reference*. The portion of the services file relevant to OMPROUTE is:

   ```
   route           520/udp         router omproute
   route           521/udp         ipv6rip ripng
   ```

   The file must exist for the RIP and IPv6 RIP protocols of OMPROUTE to operate.

   For a description of the search order used to locate the services file, see "Configuration files for TCP/IP applications" on page 30.

---

6. RACF authorize user IDs for starting OMPROUTE.

To reduce risk of an unauthorized user starting OMPROUTE and affecting the contents of the routing table, users who start OMPROUTE must be RACF-authorized to the entity MVS.ROUTEMGR.OMPROUTE and require a UID of zero. To RACF-authorize, the following commands must be entered from a RACF user ID, substituting the authorized user ID on the ID(userid) parameter. The commands in this example are taken from SEZAINST(EZARACF).

```
RDEFINE OPERCMDS (MVS.ROUTEMGR.OMPROUTE) UACC(NONE)
PERMIT MVS.ROUTEMGR.OMPROUTE ACCESS(CONTROL) CLASS(OPERCMDS) ID(userid)
SETROPTS RACLIST(OPERCMDS) REFRESH
```

Rule: OMPROUTE requires UID=0 for correct installation, configuration, and operation.

---

7. Start syslogd.

   To write only the urgent OMPROUTE messages to the z/OS console, syslogd should be running while OMPROUTE is running. Syslogd sends the non-urgent messages to the z/OS UNIX file system message log.

---

8. Update the OMPROUTE environment variables (optional).

   The following environment variables are used by OMPROUTE and can be tailored to a particular installation:

   RESOLVER_CONFIG
   The RESOLVER_CONFIG variable is used by OMPROUTE to locate the resolver configuration file. For more information on OMPROUTE's use of the resolver configuration file, see step 3 on page 279. For more information about the RESOLVER_CONFIG environment variable, see "Setting z/OS XL C/C++ environment variables for configuration files" on page 763.

   OMPROUTE_FILE
   The OMPROUTE_FILE variable is used by OMPROUTE in the search order for the OMPROUTE configuration file. For details on the search order used for locating this configuration file, see step 1 on page 278.

   OMPROUTE_OPTIONS
   The OMPROUTE_OPTIONS variable is used by OMPROUTE to set various controls for OMPROUTE processing. Currently only the hello_hi option is supported. The syntax of this variable is:

   ```
   OMPROUTE_OPTIONS=hello_hi
   ```

   Specifying OMPROUTE_OPTIONS=hello_hi changes the way OMPROUTE processes the IPv4 OSPF hello packets. These packets are then given a higher priority than other updates and processed by the first available OMPROUTE task ahead of other received IPv4 OSPF packets. Prior to specifying this parameter, customers must be aware of the impact to their network of processing hello packets out of the received order sequence.

   Tips:

   a. Specifying OMPROUTE_OPTIONS=hello_hi only helps to keep adjacencies up when OMPROUTE is running and getting flooded with protocol packets. It does not provide any help for the case

when adjacencies are not staying up because OMPROUTE is not getting enough cycles (that is, swapped out or running in too low a priority).

b. IPv6 OSPF always gives hello packets higher priority than other IPv6 OSPF traffic, so this option is not necessary for IPv6 OSPF.

OMPROUTE_DEBUG_FILE

The OMPROUTE_DEBUG_FILE variable is used by OMPROUTE to override the debug output destination for IPv4 dynamic routing protocols and for processing common to both IPv4 and IPv6 routing protocols.

Tip: When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is active, debug output is written to CTRACE and not to the destination specified by this variable.

For more information on using this environment variable, see "OMPROUTE parameters" on page 285.

OMPROUTE_DEBUG_FILE_CONTROL

The OMPROUTE_DEBUG_FILE_CONTROL variable is used by OMPROUTE to control the size and quantity of trace files created when the OMPROUTE_DEBUG_FILE or OMPROUTE_IPV6_DEBUG_FILE variable is specified. The syntax of this variable is:

```
OMPROUTE_DEBUG_FILE_CONTROL=<size of file>,<num of files>
```

The default values for <size of file> and <num of files> are 200 (KB) and 5 respectively. In general, these values are sufficient for most installations.

If OMPROUTE_DEBUG_FILE and OMPROUTE_IPV6_DEBUG_FILE are both specified with different output destinations, the values specified on the OMPROUTE_DEBUG_FILE_CONTROL variable will apply to both the IPv4 debug files and the IPv6 debug files. The total number of files created in this environment would be <num of files> multiplied by 2.

OMPROUTE_IPV6_DEBUG_FILE

The OMPROUTE_IPV6_DEBUG_FILE variable is used by OMPROUTE to override the debug output destination for IPv6 dynamic routing protocols.

Tip: When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is active, debug output is written to CTRACE and not to the destination specified by this variable.

For more information on using this environment variable, see "OMPROUTE parameters" on page 285.

OMPROUTE_CTRACE_MEMBER

The OMPROUTE_CTRACE_MEMBER variable is used by OMPROUTE to specify the name of the parmlib member containing CTRACE default settings. If not specified, the default value is CTIORA00. Use this environment variable to set different CTRACE options and buffer sizes for multiple OMPROUTE instances.

---

9. Create static routes (optional).

OMPROUTE does not use the environment variable GATEWAYS_FILE to initialize static routes. To create IPv4 static routes, use the BEGINROUTES or GATEWAY statement in PROFILE.TCPIP. To create IPv6 static routes, use the BEGINROUTES statement in PROFILE.TCPIP. For information on the syntax of the GATEWAY and BEGINROUTES statements, see *z/OS Communications Server: IP Configuration Reference*.

During initialization, OMPROUTE learns of static routes by reading the internal routing table set up by TCP/IP. If static routes are changed during execution by VARY TCPIP,,OBEYFILE command processing, OMPROUTE is dynamically notified of the changes by TCP/IP. OMPROUTE will advertise active static routes to other routers if allowed by configuration (for example, the IMPORT_STATIC_ROUTES parameter of the AS_BOUNDARY_ROUTING or IPV6_AS_BOUNDARY_ROUTING configuration statements).

Static routes can be defined as replaceable or nonreplaceable, with nonreplaceable being the default.

A nonreplaceable static route cannot be replaced or modified by OMPROUTE, even if a better dynamic route can be learned and even if the static route is not actually available (but a static route that is not available will not be advertised by OMPROUTE). Because of this, the use of nonreplaceable static routes with OMPROUTE is not recommended unless it is to provide routing over an interface over which no routing protocol is being communicated.

A replaceable static route will be replaced by OMPROUTE if it dynamically learns a route to the destination. Any dynamically learned route will be considered more desirable than a replaceable static route. A replaceable static route should be considered as a last resort route, to be used by TCP/IP when no dynamic route to a destination can be found.

For detailed information, see "Using static routing with OMPROUTE" on page 345.

---

10. Configure OSPF authentication (optional, if using the IPv4 OSPF protocol).

    OMPROUTE supports defining the IPv4 OSPF authentication type by area or by interface. By default, all interfaces attached to an area use the type of authentication defined for that area on the AREA configuration statement, unless overridden on the OSPF_INTERFACE configuration statement. The values of authentication keys must be defined on OSPF_INTERFACE statements in any case. All routers which could become neighbors of each other must use the same authentication type and key, or OSPF communication between the routers will not be possible.

    Virtual links behave similarly to interfaces for authentication purposes. By default, a virtual link uses the same type of authentication that is specified for the backbone area unless overridden on the VIRTUAL_LINK configuration statement. When the authentication type is not NONE, the value of the authentication key must be specified on the VIRTUAL_LINK configuration statement. There is no requirement for a virtual link to have the same authentication key value as its underlying real interface.

    OSPF authentication does not protect the contents of an OSPF packet. These packets are not encrypted. However, it does provide verification that the packet is genuine.

    Tip: Unlike IPv4 OSPF, IPv6 OSPF does not provide its own, protocol-layer authentication. It relies instead on authentication provided by IPv6 IPSec.

    There are two methods of IPv4 OSPF authentication, password and MD5 cryptographic.

Password authentication is very basic: an 8-byte password is appended to all OSPF packets and sent in the clear with the rest of the packet. If the sent password matches that defined by the packet receiver, the packet is accepted.

MD5 authentication is more sophisticated. The combination of the OSPF packet and the MD5 key is summarized into a 16-byte message digest, which is appended to the packet and sent. The keys are never sent, only the message digests. The receiver then attempts to re-create the message digest from the combination of its defined key and the OSPF packet. If the digest is successfully re-created, the packet is accepted; otherwise it is rejected. MD5 authentication also contains a monotonic increasing counter to protect against replay attacks.

If MD5 cryptographic authentication is being used, a 16-byte MD5 key must be defined on the OSPF_INTERFACE configuration statement. This key is defined as a hexadecimal string and may be obtained in several ways. One method for obtaining MD5 keys is provided in the pwtokey utility, which converts a password into an MD5 key. This UNIX System Services utility implements the algorithm defined in RFC 3414, *User-based Security Model (USM) for version 3 of the Simple Network Management Protocol (SNMPv3)*. Since OSPF does not support localization of keys, it is only necessary to provide a password to this utility to generate a single, 16-byte key. If multiple sites have this utility, MD5 keys can easily be generated from passwords, which are easier to remember and communicate than 16-byte hexadecimal strings.

Starting and controlling OMPROUTE

After the necessary RACF authorization has been defined (see step 6 on page 280), OMPROUTE can be started from an MVS procedure, from the z/OS shell, or from AUTOLOG.

- You can start OMPROUTE from the MVS operators console by starting the OMPROUTE start procedure. A sample start procedure is provided with the product in SEZAINST(OMPROUTE).
- You can start OMPROUTE from the z/OS shell by starting OMVS and then issuing the OMPROUTE command and, optionally, any parameters. For information on parameters, see "OMPROUTE parameters" on page 285.
- You can use the AUTOLOG statement to start OMPROUTE automatically during TCP/IP initialization. Insert the name of the OMPROUTE start procedure in the AUTOLOG statement of the PROFILE.TCPIP data set.

```
AUTOLOG
  OMPROUTE
ENDAUTOLOG
```

Note: For special considerations when using AUTOLOG to start OMPROUTE with the OSPF or IPv6 OSPF protocol, see step 2 on page 278.

In a Common INET environment, OMPROUTE will attempt to connect to a stack whose name is determined by the TCPIPjobname keyword from the resolver configuration data set or file. In configurations with multiple stacks, a copy of OMPROUTE must be started for each stack that requires OMPROUTE services. To associate OMPROUTE with a particular stack, use the environment variable RESOLVER_CONFIG to point to the data set or file that defines the unique TCPIPjobname.

When running from an MVS procedure, the environment variables can be set by using the STDENV DD statement in the OMPROUTE procedure. For information concerning the environment variables used by OMPROUTE, see step 8 on page 281.

OMPROUTE parameters

OMPROUTE accepts five command line parameters, which govern tracing and debug information. OMPROUTE's trace and debug information is written to stdout with three exceptions:

- When OMPROUTE is started with no tracing, and then a MODIFY command is issued to enable tracing. In this case, by default, the output destination is the file omproute_debug in the current temporary directory (the default is /tmp).
- When the debug output destination has been overridden with the use of an environment variable (OMPROUTE_DEBUG_FILE or OMPROUTE_IPV6_DEBUG_FILE).

  Rule: OMPROUTE_DEBUG_FILE and OMPROUTE_IPV6_DEBUG_FILE can specify only a z/OS UNIX file. To have debug information go into an MVS data set, instead of coding these environment variables, use the SYSPRINT DD card to redirect stdout to the desired MVS data set.
- When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is enabled. In this case, the output is sent to the CTRACE facility.

If OMPROUTE is to be started from an MVS procedure, add your parameters to PARM=() in the OMPROUTE cataloged procedure. For example:

```
//* PARM=('POSIX(ON)',
//*       'ENVAR("_CEE_ENVFILE=DD:STDENV")/-t1 -6t1')
//*
```

If OMPROUTE is to be started from a z/OS shell command line, enter the parameters on the command line.

For either method of starting OMPROUTE, parameters can be specified in mixed case.

Note: The -t*n*, -d*n*, -6t*n*, -6d*n*, and -s*n* parameters affect OMPROUTE performance. If you use these parameters, you might need to increase the Dead_Router_Interval value on OSPF interfaces to prevent neighbor adjacencies from collapsing. If this becomes necessary, you will also need to modify other routers since the Dead_Router_Interval value must be the same for all routers attached to a common network.

The -tn and -6tn command line parameters

The -t*n* parameter specifies the external tracing level for OMPROUTE initialization and IPv4 routing protocols, where *n* is a supported trace level. The -6t*n* parameter specifies the external tracing level for IPv6 routing protocols, where *n* is a supported trace level. The -t*n* and -6t*n* traces are intended for customers, testers, service, or developers, and provide information on the operation of the routing application. These options can be used for many purposes, such as debugging a configuration, education on the operation of the routing application, verification of test cases, and so on. The following levels are supported:

1 Informational messages

2 Formatted packet trace

These option levels are cumulative—level 2 includes level 1. For example, -t2 provides formatted packet trace and informational messages.

The -dn, -6dn, and -sn command line parameters

These options specify the internal debugging levels. They are intended for service and provide internal debugging information needed for debugging problems. Use of these parameters can significantly impact performance and are not recommended unless needed to debug a problem. For more information about the use of these parameters, see *z/OS Communications Server: IP Diagnosis Guide*.

Controlling OMPROUTE

You can control OMPROUTE from the operator's console using the MODIFY command. The syntax of the MODIFY command can be found in *z/OS Communications Server: IP System Administrator's Commands*. MODIFY commands are available to perform the following functions:

- "Stopping OMPROUTE"
- "Rereading the configuration file" on page 287
- "Enabling or disabling the OMPROUTE subagent" on page 287
- "Changing the cost of OSPF links" on page 287
- "Controlling OMPROUTE tracing and debugging" on page 288

Stopping OMPROUTE

OMPROUTE can be stopped in several ways:

- From MVS, issue STOP <procname> or MODIFY <procname>,KILL.

  If OMPROUTE was started from a cataloged procedure, procname is the member name of that procedure. If OMPROUTE was started from the z/OS shell, procname is useridX, where X is the sequence number set by the system. To determine the sequence number, from the SDSF LOG window on TSO, issue /D OMVS,U=userid. This will show the programs running under this user ID. The procname can also be set using the environment variable _BPX_JOBNAME and then starting OMPROUTE in the shell background.
- From a z/OS shell superuser ID, issue the kill command to the process ID (PID) associated with OMPROUTE. To determine the PID, use one of the following methods:
  - From the MVS console, issue D OMVS,U=userid, or issue /D OMVS,U=userid at the SDSF LOG window on TSO (where userid is the user ID that started omproute from the shell).
  - Issue the **ps -ef** command from the z/OS shell.
  - Record the PID when you start OMPROUTE.

For information on the environment variable _BPX_JOBNAME, see *z/OS UNIX System Services Planning*. For information on the D OMVS,U=userid command, see *z/OS MVS System Commands*.

Tip: When OMPROUTE is taken down, it should be kept down for at least 3 times the largest dead router interval of any IPv4 OSPF interfaces using MD5 authentication. The same applies to routers adjacent to interfaces using MD5 authentication. Do not stop and start OMPROUTE without waiting for this required time interval.

Rereading the configuration file

The MODIFY *procname*,RECONFIG command is used to reread the OMPROUTE configuration file. This command accepts and applies only statements of the following types that have been added to the configuration file since the last time the file was read:

- OSPF_INTERFACE
- RIP_INTERFACE
- INTERFACE
- IPV6_OSPF_INTERFACE
- IPV6_OSPF (ROUTERID parameter only)
- IPV6_RIP_INTERFACE
- IPV6_INTERFACE

These configuration statements must be reread from the configuration file using the MODIFY *procname*,RECONFIG command before the interfaces to which they refer are defined to the TCP/IP stack. If you have coded GLOBAL_OPTIONS IGNORE_UNDEFINED_INTERFACES=YES in your OMPROUTE configuration file, you can use OMPROUTE reconfiguration to add a definition for an interface that has already been configured in the stack but ignored by OMPROUTE. However, OMPROUTE does not associate the interface with the new definition until the interface has been deleted from the stack and re-added.

Restriction: The IPV6_OSPF statement (ROUTERID parameter only) is recognized by this command only if there is no existing IPv6 OSPF router ID value set in OMPROUTE. This command cannot be used to change the value of an existing IPv6 OSPF router ID.

Enabling or disabling the OMPROUTE subagent

Use the MODIFY <procname>,ROUTESA=ENABLE command or the MODIFY <procname>,ROUTESA=DISABLE command to enable or disable the OMPROUTE subagent.

Rule: To change any other value on the ROUTESA_CONFIG statement, the OMPROUTE application must be recycled.

The OMPROUTE subagent implements RFC 1850, *OSPF Version 2 Management Information Base*, for the OSPF protocol. The ROUTESA_CONFIG statement is used in the OMPROUTE configuration file to configure the OMPROUTE subagent. For details on ROUTESA_CONFIG, see *z/OS Communications Server: IP Configuration Reference*.

Changing the cost of OSPF links

The cost of an OSPF interface can be dynamically changed using the MODIFY <procname>,OSPF,WEIGHT,NAME=<if_name>,COST=<cost> command. The cost of an IPv6 OSPF interface can be dynamically changed using the MODIFY <procname>,IPV6OSPF,WEIGHT,NAME=<if_name>,COST=<cost> command. This new cost is flooded quickly throughout the OSPF routing domain, and modifies the routing immediately.

The cost of the interface reverts to its configured value whenever OMPROUTE is restarted. To make the cost change permanent, you must change the appropriate OSPF_INTERFACE or IPV6_OSPF_INTERFACE statement in the configuration file.

Controlling OMPROUTE tracing and debugging

The following commands are used to start, stop, or change the level of OMPROUTE tracing and debugging:

- MODIFY <procname>,TRACE=n : for OMPROUTE tracing for initialization and IPv4 routing protocols; n can be 0–2.
- MODIFY <procname>,DEBUG=n : for OMPROUTE debugging for initialization and IPv4 routing protocols; n can be 0–4.
- MODIFY <procname>,SADEBUG=n : for OMPROUTE subagent debugging; n can be 0 or 1.
- MODIFY <procname>,TRACE6=n : for OMPROUTE tracing for IPv6 routing protocols; n can be 0–2.
- MODIFY <procname>,DEBUG6=n : for OMPROUTE debugging for IPv6 routing protocols; n can be 0–4.

Tip: Use of OMPROUTE tracing and debugging affects OMPROUTE performance and might require increasing the Dead_Router_Interval on OSPF interfaces to keep neighbor adjacencies from collapsing.

Steps for configuring OSPF and RIP (IPv4 and IPv6)

The steps for configuring OSPF and RIP are:

1. Set the OSPF router ID, if the OSPF protocol is used.
2. Define OSPF areas, if the OSPF protocol is used.
3. Limit information exchange between OSPF areas, if the OSPF protocol is used.
4. Define IPv4 interfaces, if the IPv4 OSPF or IPv4 RIP protocol is used.
5. Define IPv6 interfaces, if the IPv6 OSPF or IPv6 RIP protocol is used.
6. Define interface costs (OSPF_INTERFACE, RIP_INTERFACE, IPV6_OSPF_INTERFACE, and IPV6_RIP_INTERFACE).
7. Configure virtual links, if the OSPF protocol is used.
8. Manage high-cost links, if the OSPF protocol is used.
9. Define RIP filters, if the RIP protocol is used.
10. Define route precedence in a multiprotocol environment, if the OSPF protocol is used.

Tip: If policy-based routing is used on the TCP/IP stack and the routing policy is configured with dynamic routing parameters, you do not need to provide additional configuration to OMPROUTE for dynamic routing support to be provided for the policy-based route tables. The dynamic routing parameters specified in the routing policy are provided to OMPROUTE by the TCP/IP stack to control the scope of dynamic routes computed by OMPROUTE. For a description of this function, see "Policy-based routing" on page 337.

Following are the detailed steps to configure OSPF and RIP (IPv4 and IPv6).

1. Set the OSPF router ID, if the OSPF protocol is used.

   Every router in an OSPF autonomous system must be assigned a unique router ID.

   IPv4 OSPF

   The ROUTERID parameter of the OSPF configuration statement should be coded within the OMPROUTE configuration file to assign the router ID. The value must be the IP address of one of the OSPF_INTERFACEs defined in the OMPROUTE configuration file. If the ROUTERID

parameter of the OSPF configuration statement is not coded, OMPROUTE chooses the IP address from one of the OSPF_INTERFACE statements as the router ID. Because dynamic VIPAs (DVIPAs) can move between z/OS hosts within a sysplex, the router ID should be the IP address of a physical interface or a static VIPA, but not a dynamic VIPA. For more information about the rules and guidelines for the ROUTERID parameter of the OSPF statement, see *z/OS Communications Server: IP Configuration Reference*.

In the example network shown in Figure 37 on page 259, the router ID is set to the static VIPA address that represents each OMPROUTE router. TCPCS4 has ROUTERID=4.4.4.4, and TCPCS7 has ROUTERID=7.7.7.7.

IPv6 OSPF

The ROUTERID parameter of the IPV6_OSPF configuration statement is coded within the OMPROUTE configuration file to assign the IPv6 OSPF router ID. This router ID is any IPv4-style dotted-decimal value except for 0.0.0.0, with care taken to assure its uniqueness across routers within the IPv6 autonomous system. If the ROUTERID parameter of the IPV6_OSPF configuration statement is not coded and the IPv4 OSPF protocol is also being used, OMPROUTE will use the IPv4 OSPF router ID as the IPv6 OSPF router ID. If the IPv4 OSPF protocol is not being used, the ROUTERID parameter of the IPV6_OSPF statement must be specified. For more information about the rules and guidelines for the ROUTERID parameter of the IPV6_OSPF statement, see *z/OS Communications Server: IP Configuration Reference*.

In the example network shown in Figure 38 on page 260, the ROUTERID parameter of the IPV6_OSPF statement on TCPCS64 will be explicitly configured using ROUTERID=64.64.64.64.

---

2. Define OSPF areas, if the OSPF protocol is used.

   The sample network shown in Figure 37 on page 259 and Figure 38 on page 260 depicts an IPv4 network and an IPv6 network, both divided using two methods. The first division is between IP subnetworks within the OSPF autonomous system (AS) and IP subnetworks external to the OSPF AS (those within the RIP AS). The subnetworks included within each OSPF AS are further subdivided into regions called areas. OSPF areas are collections of contiguous IP subnetworks. The function of areas is to reduce the OSPF overhead required to compute routes to destinations in different areas. Overhead is reduced because less information is exchanged and stored by routers and because fewer CPU cycles are required for a less complex route table calculation.

   Every OSPF AS that will have multiple areas must have at least a backbone area. The backbone is always identified by area number 0.0.0.0. For networks with multiple areas, the backbone provides a core that connects the areas. Unlike other areas, the backbone's subnets can be physically separate. In this case, logical connectivity of the backbone is maintained by configuring virtual links between backbone routers across intervening non-backbone areas. See step 7 on page 305 for more information on this subject.

   Routers that attach to more than one area function as area border routers. All area border routers are part of the backbone, so they must either attach directly to a backbone IP subnet or be connected to another backbone router over a virtual link.

   The information and algorithms used by OSPF to calculate routes vary according to whether the destination is within the same area, in a different

area within the OSPF AS, or external to the OSPF AS. Every router maintains a database of all links within its area. A shortest path first algorithm is used to calculate the best routes to destinations within the area from this database. Routes between areas are calculated from summary advertisements originated by area border routers for destinations located in other areas of the OSPF AS. External routes (for example, routes to destinations that lie within a RIP AS) are calculated from AS external advertisements originated by AS boundary routers and flooded throughout the OSPF AS.

IPv4 OSPF

Use the AREA configuration statement to define the areas to which a router attaches. If you do not use the AREA statement, the default is that all OSPF interfaces attach to the backbone area. In the sample network, TCPCS4 and TCPCS7 are both area border routers belonging to both the backbone area (0.0.0.0) and area 1.1.1.1.

```
AREA
  Area_Number=0.0.0.0;

AREA
  Area_Number=1.1.1.1;
```

IPv6 OSPF

Use the IPV6_AREA configuration statement to define the areas to which a router attaches. If you do not use the IPV6_AREA statement, the default is that all IPv6 OSPF interfaces attach to the backbone area. In the sample network, TCPCS64 and TCPCS67 are area border routers belonging to both the backbone area (0.0.0.0) and area 6.6.6.6.

```
IPV6_AREA
   Area_Number=0.0.0.0;
IPV6_AREA
   Area_Number=6.6.6.6;
```

---

3. Limit information exchange between OSPF areas, if the OSPF protocol is used.

   When area border routers are configured, the OSPF route information that crosses the area boundary can be controlled using configuration statements. For recommendations regarding the usefulness of multiple areas in the z/OS CS environment, see "Minimizing the routing responsibility of z/OS Communications Server" on page 309.

   One option is to define an area as a stub area. AS external advertisements are never flooded into stub areas. In addition, the origination into the stub area of summary advertisements for interarea routes can be suppressed, creating what is commonly known as a totally stubby area.

   Destinations external to the stub area are still reachable due to the area border routers advertising default routes into stub areas. Traffic within the stub area for unknown destinations is forwarded to the area border router (using the default route). It is acceptable for routers within the area to use a default route for traffic destined outside the AS. The border router uses its more complete routing information to forward the traffic on an appropriate path toward its destination.

   The following requirements must be met for an area to be defined as a stub area:

   - No virtual links are configured through the area to maintain backbone connectivity.

- No routers within the area are AS boundary routers (OSPF routers that advertise routes from external sources as AS external advertisements).

  Tip: Static routes and RIP routes are AS external.

Another option is to use IP address ranges to limit the number of summary advertisements originated out of an area. In IPv4, a range is defined by an IP address and an address mask. Destinations are considered to fall within the range if the destination address and the range IP address match after the range mask has been applied to both addresses. In IPv6, a range is defined by an IP address prefix and a prefix length, and destinations are considered to fall within the range if a destination address and a range IP address match for the length of the range's prefix.

When a range is configured for an area at an area border router, the border router suppresses summary advertisements for destinations within that area that fall within the range. The suppressed advertisements would have been originated into the other areas to which the border router attaches. Instead, the area border router may originate a single summary advertisement for the range or no advertisement at all, depending on the option chosen with the configuration statement.

Rules:

a. If the range is not advertised, there will be no interarea routes for any destination that falls within the range.

b. Ranges cannot be used for areas through which virtual links are configured to maintain backbone connectivity.

   IPv4 OSPF

   The following statement configures an OSPF area as a stub area. The Import_Summaries=No parameter will result in the suppression of summary advertisements for interarea routes into the stub area, creating a totally stubby area:

```
AREA
  Area_Number=2.2.2.2
  Stub_area=Yes
  Import_Summaries=No;
```

   In the sample network shown in Figure 37 on page 259, the following RANGE statement could be configured on TCPCS7 to prevent TCPCS7 from advertising destinations in the 9.67.101.0 subnet into the backbone area (Area 0.0.0.0):

```
RANGE
   IP_Address=9.67.101.0
   Subnet_Mask=255.255.255.0
   Area_Number=1.1.1.1
   Advertise=No;
```

   IPv6 OSPF

   The following statement configures an IPv6 OSPF area as a stub area. The Import_Summaries=No parameter will result in the suppression of summary advertisements for interarea routes into the stub area, creating a totally stubby area:

```
IPV6_AREA
   Area_Number=1.1.1.1
   Stub_area=Yes
   Import_Prefixes=No;
```

   In the sample network, the following IPV6_RANGE statement could be configured on TCPCS67 to cause TCPCS67 to advertise all destinations in the 2001:0DB8:0:31::/64 prefix into the backbone area (Area 0.0.0.0) as a single route to the 2001:0DB8:0:31::/64 prefix:

```
IPV6_RANGE
   Prefix=2001:0DB8:0:31::/64
   Area_Number=6.6.6.6
   Advertise=Yes;
```

4. Define IPv4 interfaces, if the IPv4 OSPF or IPv4 RIP protocol is used.

   Each interface in use by the stack should be defined to OMPROUTE using an OSPF_INTERFACE, RIP_INTERFACE, or INTERFACE statement. This topic describes the differences between interface types that you should consider when configuring interfaces to OMPROUTE. In general, use the following guidelines:

   - An interface over which the OSPF protocol is communicated with other routers must be configured with the OSPF_INTERFACE statement.
   - An interface over which the RIP protocol is communicated with other routers must be configured with the RIP_INTERFACE statement.
   - Either all other interfaces should be configured with the INTERFACE statement, or OMPROUTE should be configured to ignore undefined interfaces using the IGNORE_UNDEFINED_INTERFACES parameter of the GLOBAL_OPTIONS statement in the OMPROUTE configuration file. It is important that one or the other be done.

     If OMPROUTE is not configured to ignore undefined interfaces, it configures stack interfaces that are not defined to OMPROUTE with default values. These values might not be desirable. For example, the class mask will be used as the subnet mask and 576 will be used as the MTU value. Furthermore, OMPROUTE overrides stack values with its default values. To prevent this from happening, either configure every interface, even those that are not using RIP or OSPF, or configure OMPROUTE to ignore undefined interfaces.

   A VIPA interface is an exception to these guidelines and is discussed in more detail in this step.

   z/OS Communications Server enforces RFC rules against using either a subnetwork's broadcast or network address as a host address. (An address that has all ones in the host portion is a subnet broadcast address. An address that has all zeros in the host portion is the subnet's network address.) Therefore, the subnet_mask on an OSPF_INTERFACE, RIP_INTERFACE, or INTERFACE statement should have enough zero bits such that no home address in that subnet has all zeros or all ones in the host portion of the address. For example if a subnet has two home addresses 10.1.1.1 and 10.1.1.2, the subnet mask must have zeros in at least two bits; for example, 255.255.255.252. However, if a subnet has four home addresses 10.1.1.1, 10.1.1.2, 10.1.1.3, and 10.1.1.4, the subnet mask must have zeros in at least three bits; for example, 255.255.255.248. In this case, there could be up to 6 home addresses in that subnet (10.1.1.1 through 10.1.1.6). In general, if a subnet mask has n zero bits, then there can be up to ((2**n)-2) home addresses in that subnet. This limit applies even if the home addresses are configured on different TCP/IP stacks.

   Rules:

   a. OMPROUTE supports a maximum of 255 real, physical, IPv4 interfaces (that is, interfaces on which data can actually be sent and received). There is no theoretical limit on how many VIPAs can be configured, though there are practical limits imposed by network design.
   b. RIP version 1 uses broadcast and RIP version 2 uses multicast. RIP version 1 will not run on a medium that supports multicast but not

broadcast, which is the default QDIO configuration. To configure the OSA-Express feature operating in QDIO mode (for example, gigabit Ethernet) to send and receive broadcast packets, use the IPBCAST parameter on the LINK statement in your TCP/IP profile. The OSA-Express microcode level must support broadcast to use this parameter. Some levels of OSA-Express microcode support multicasting but not broadcasting. In this case, RIP version 2, which relies on multicast, is recommended over RIP version 1, which relies on broadcast.

Configuring multi-access parallel interfaces

Whenever configuring multi-access parallel interfaces (primary and backup redundant interfaces having IP addresses in the same network) for OMPROUTE (OSPF), use the Parallel_OSPF parameter on the OSPF_INTERFACE statement to designate whether each OSPF interface is primary or backup. If the IP_address parameter on an OSPF_INTERFACE statement is using wildcards (*), also include the Name parameter for the interface to distinguish the primary from the backups. For additional information on the OSPF_INTERFACE statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

Point-to-point (For example CTC and CLAW)

For point-to-point interfaces, the destination IP address must be known to OMPROUTE. If OSPF or RIP is run on the interface, the destination IP address is learned when the router at the other end comes up and shares information with OMPROUTE. Additionally, defining a destination address on an interface that is running OSPF or RIP allows OMPROUTE to learn and advertise a route to that destination address before a neighboring router has become fully adjacent. This can be beneficial if the neighboring router takes a long time to come up, or is otherwise not expected to be promptly and reliably available.

Tip: For a point-to-point interface running OSPF, OMPROUTE does not advertise a host route to its own home address on the point-to-point interface. By default, OMPROUTE advertises a host route to the link destination, and relies on the router at the other end to advertise a host route to OMPROUTE's home address. This behavior is described by the OSPF architecture, RFC 1583 (OSPF version 2), section 12.4.1. This means that OMPROUTE's home address on the point-to-point link will not be advertised as reachable unless there is a neighboring router available to advertise it. OMPROUTE implements an extension described in RFC 2328 to overcome this limitation. If a neighboring router will not be reliably available over the point-to-point link, you might want to code the parameter SUBNET=YES on the OSPF_INTERFACE statement for the point-to-point interface. This causes OMPROUTE to implement option 2 described in RFC 2328, section 12.4.1.1, and advertise a route to the point-to-point link's subnet address. This makes both endpoints reachable regardless of the status of a neighboring router.

If the interface is simply an INTERFACE (not running OSPF or RIP), specify the DESTINATION_ADDR parameter to allow for the creation of a host route to the address at the remote end of the interface.

Sample OSPF_INTERFACE

```
OSPF_INTERFACE
 IP_Address=9.67.106.7
 Name=CTC7TO4
 Subnet_mask=255.255.255.0
 Attaches_to_Area=1.1.1.1
 Destination_Addr=9.67.106.4;
```

Sample RIP_INTERFACE

```
RIP_INTERFACE
 IP_Address=9.67.103.7
 Name= CTC7TO6
 Subnet_mask=255.255.255.0
 Destination_Addr=9.67.103.6
 RIPV2=Yes;
```

Sample INTERFACE

```
INTERFACE
 IP_Address=9.67.111.1
 Name=CTCX
 Subnet_mask=255.255.255.0
 Destination_addr=9.67.111.2;
```

Note: If another router is directly attached through a CLAW device, and the OSPF protocol is being communicated with that router, the other router must also be configured to view the CLAW device as a point-to-point interface. Failure to do this results in a failure to add any routes through that router.

Point-to-multipoint

For point-to-multipoint capable interfaces (for example MPCPTP interfaces including XCF and IUTSAMEH connections), OMPROUTE must know the IP addresses of the other routers (neighbors) with which it needs to communicate the OSPF or RIP packets. However, due to underlying signaling that takes place when a host connects to these network types, the stack is able to learn the required addresses. In turn, OMPROUTE learns those IP addresses from the stack. As a result, it is not necessary to configure the IP addresses of the other routers on the interface statements.

Sample OSPF_INTERFACE

```
OSPF_INTERFACE
 IP_Address=9.27.13.81
 Name=XCFD00
   Attaches_to_Area=1.1.1.1
 Subnet_mask=255.255.255.0;
```

Sample RIP_INTERFACE

```
RIP_INTERFACE
 IP_Address=9.27.23.81
 Name=MPCA01
 Subnet_mask=255.255.255.0
 RIPV2=Yes;
```

Sample INTERFACE

```
INTERFACE
 IP_Address=9.27.33.81
 Name=XCFB00
 Subnet_mask=255.255.255.0;
```

Non-broadcast network interfaces (For example, Hyperchannel and ATM)

If the OSPF or RIP protocol communicates with one or more routers over a non-broadcast network interface, OMPROUTE must know the IP addresses of the other routers (neighbors) with which it needs to communicate. For non-broadcast network interfaces, there is no underlying signaling that allows the stack to learn the required IP addresses. As a result, the neighbor addresses must be configured to OMPROUTE with the parameters configured as follows:

– DR_NEIGHBOR and/or the NO_DR_NEIGHBOR parameters on the OSPF_INTERFACE statement

– NEIGHBOR parameter on the RIP_INTERFACE statement
– NON_BROADCAST=YES and ROUTER_PRIORITY parameters on the OSPF_INTERFACE statement

In the OSPF case, DR_NEIGHBOR defines which routers within the non-broadcast network can become the designated router. NO_DR_NEIGHBOR defines which routers cannot become the designated router. ROUTER_PRIORITY defines the priority of this router on the non-broadcast network so that the designated router can be elected for the network. Note that multiple DR_NEIGHBOR and NO_DR_NEIGHBOR parameters can be coded on one statement.

Sample OSPF_INTERFACE

```
OSPF_INTERFACE
 IP_Address=9.37.84.49
 Name=HCHE00
 Subnet_mask=255.255.255.0
   Attaches_to_Area=1.1.1.1
 Non_Broadcast=Yes
 DR_Neighbor=9.37.84.53
 No_DR_Neighbor=9.37.84.63
 Cost0=3
 Router_Priority=2;
```

Sample RIP_INTERFACE

```
RIP_INTERFACE
 IP_Address=9.37.104.79
 Name=ATME00
 Subnet_mask=255.255.255.0
 RIPV2=Yes
 Neighbor=9.37.104.85
 Neighbor=9.37.104.53;
```

Sample INTERFACE

```
INTERFACE
 IP_Address=9.77.13.49
 Name=ATMB00
 Subnet_mask=255.255.255.0;
```

Broadcast network interfaces (For example, Ethernet)

When the OSPF or RIP protocol is communicated over a broadcast medium such as Ethernet, these networks allow for broadcasting and multicasting. Therefore, it is not necessary for OMPROUTE to know the IP addresses of the other routers on the network for OSPF or RIP packets to be communicated with those routers. OMPROUTE sends packets to the other routers on the network by using appropriate broadcast or multicast addresses. The IP addresses of the other routers are learned as OSPF/RIP packets are received from them. The OSPF_INTERFACE must include the ROUTER_PRIORITY parameter to assist in electing a designated router for the network.

Sample OSPF_INTERFACE

```
OSPF_INTERFACE
 IP_Address=9.59.101.5
 Name=TR1
   Subnet_mask=255.255.255.0
 Attaches_to_Area=1.1.1.1
 Cost0=2
 Router_Priority=1;
```

Sample RIP_INTERFACE

```
RIP_INTERFACE
 IP_Address=9.29.107.3
 Name=TR2
 Subnet_mask=255.255.255.0
 RIPV2=Yes;
```

Sample INTERFACE

```
INTERFACE
 IP_Address=9.77.14.49
 Name=ETHB00
 Subnet_mask=255.255.255.0;
```

If OMPROUTE will be communicating with the OSPF or RIP Version 2 protocol over a token ring media where an attached router does not listen for multicast MAC address 0xC000.0004.0000, see "Token-ring multicast" on page 275.

For interfaces into broadcast media which contain routers that do not support multicast, it is possible to configure the interfaces as non-broadcast network interfaces. This would cause OMPROUTE to unicast to the neighbor addresses rather than using a multicast address. However, it would also be necessary to configure all the routers on the network to unicast. Otherwise, their multicast packets would never be received.

Note that it is possible to define neighbors using DR_NEIGHBOR and/or NO_DR_NEIGHBOR parameters for OSPF_INTERFACEs and using NEIGHBOR parameters for RIP_INTERFACEs that are broadcast capable, but it is not required or recommended. If you define neighbors on these interfaces, you must define all of them, as OMPROUTE will not communicate RIP or OSPF to undefined neighbors if any are defined on an interface.

VIPA interfaces (Static VIPA and Dynamic VIPA)

If only the RIP protocol is used by OMPROUTE, VIPA interfaces should be defined with the INTERFACE statement. If only OSPF or if both OSPF and RIP are used by OMPROUTE, VIPA interfaces should be defined with the OSPF_INTERFACE statement.

Sample OSPF_INTERFACE

```
OSPF example:
 OSPF_INTERFACE
 IP_Address=4.4.4.4
 Name=VIPA1
   Subnet_mask=255.255.255.252;
```

Sample INTERFACE

```
non-OSPF example:
 INTERFACE
 IP_Address=6.6.6.6
 Name=VIPA1
 Subnet_mask=255.255.255.252;
```

Rule: The most specific subnet mask you can specify is 255.255.255.252.

If the name in an OSPF_INTERFACE or INTERFACE statement refers to a link of type VIRTUAL, then OMPROUTE generates and advertises the following routes whenever applicable:

- A network route to the network specified in that statement
- A subnet route to the subnet specified in that statement
- A host route to the IP_address specified in that statement

Following are the conditions for advertising these routes on a physical network interface to a network:

– Network route - if VIPA is not in the same network as the physical network interface and is allowed by filters or RANGE.
– Subnet route - VIPA subnet routes are advertised in OMPROUTE in all conditions, except for RIP when filters prevent it.
– Host route - as allowed by filters or RANGE. Advertisement of the host route for a VIPA defined on an OSPF_INTERFACE statement can be controlled by the SUBNET parameter on the OSPF_INTERFACE statement that defines that VIPA. If SUBNET=YES, then the host route is not advertised. If SUBNET=NO (the default), the host route is advertised. Take care in using this parameter. VIPA host routes should not be suppressed for dynamic VIPAs or for VIPAs whose subnet might exist on multiple hosts. It is up to the user to ensure these restrictions are enforced, as they are not and cannot be enforced by OMPROUTE.

On the RIP_INTERFACE statement for a physical network interface, the VIPA routes are allowed to be advertised by the following filter parameters:

– Send_Net_Routes
– Send_Subnet_Routes
– Send_Host_Routes, and Send_Only

In addition, the global FILTER and Send_Only statements for RIP can be used to specify which routes are advertised or not.

For OSPF, the RANGE statement can be used to advertise or not to advertise the VIPA routes external to an area in terms of address range based on a subnet mask.

Note: For RIP, the Send_Only = (VIRTUAL) filter in conjunction with the Send_Net_Routes, Send_Subnet_Routes, and Send_Host_Routes filters, or the FILTER statement with VIPA routes, indicates whether or not VIPA routes can be advertised over a RIP interface. Unlike RIP, there are no routing filters for OSPF. For OSPF, the RANGE statement can be used to control which address range of routes can be advertised or not advertised external to an area; however, it is not granular enough for use as a routing filter. In area-border router configurations, if there are multiple VIPA addresses that are uniquely subnetted, the RANGE statement can be used to specify which VIPA subnet address range of routes can be advertised or not advertised external to an area.

For Dynamic VIPA (DVIPA), link names are assigned programmatically by the stack when the DVIPA is created. Therefore, the name field set on the INTERFACE or OSPF_INTERFACE statement is ignored by OMPROUTE for DVIPAs.

Because a stack could have a large number of DVIPAs defined, as well as DVIPA ranges, additional wildcard capabilities exist on the OSPF_INTERFACE and INTERFACE statements for use only with DVIPAs.

Ranges of DVIPA interfaces can be defined using the Subnet_Mask parameter on the OSPF_INTERFACE or INTERFACE statement. The range defined in this way will be all the IP addresses that fall within the subnet defined by the mask and the IP address. The IP address parameter must be the subnet number of the range being defined, not a host address within that range. Further information on the Subnet_Mask parameter is available earlier in this step.

In the following example, DVIPA interfaces in the range of 10.138.65.81 through 10.138.65.94 are defined:

Sample OSPF_INTERFACE

```
OSPF example:
 OSPF_INTERFACE
 IP_Address=10.138.65.80
 Name=DVIPAs
   Subnet_mask=255.255.255.240;
```

Sample INTERFACE

```
non-OSPF example:
 INTERFACE
 IP_Address=10.138.65.80
 Name=DVIPAs
 Subnet_mask=255.255.255.240;
```

In the following example, only an interface with home address 10.138.65.98 is being defined, because the subnet number (obtained by performing a binary AND operation of the IP_Address parameter and the Subnet_mask parameter) for this definition is 10.138.65.96. Since the IP_Address parameter does not equal that subnet number, this definition will not be treated as a DVIPA wildcard.

```
OSPF_INTERFACE
IP_Address=10.138.65.98
Name=DVIPA
Subnet_mask = 255.255.255.240;
```

You must consider an additional issue when VIPAs are being moved between TCP/IP stacks and dynamic routing is provided for those stacks by OMPROUTE. This movement of VIPAs can be done manually or automatically using Dynamic VIPAs. For the VIPAs to be correctly processed and advertised by the routing protocols, they (like all other interfaces) must be configured to OMPROUTE at the time that they become active on the TCP/IP stack. This configuration of VIPAs to OMPROUTE can be accomplished by:

- Explicitly configuring each VIPA with its own OSPF_INTERFACE or INTERFACE statement
- Configuring a range of DVIPAs with a single OSPF_INTERFACE or INTERFACE statement
- Configuring a group of VIPAs with a single OSPF_INTERFACE or INTERFACE statement, using the wildcarding feature available on the interface statements

The recommended approach for configuring OMPROUTE for VIPAs that might move is to preconfigure the OMPROUTE on each TCP/IP stack with all VIPAs that could potentially exist on that stack at some time. Preconfiguring in this way prepares each OMPROUTE for the possible addition of the VIPAs to its stack. During times when the VIPAs do not exist on a particular OMPROUTE's stack, the configuration information will not be used. However, during periods when the VIPAs do exist on that OMPROUTE's stack, the configuration information will be available for use by OMPROUTE. This method is recommended because of its ability to respond to movement of the VIPAs between TCP/IP stacks without modification of the OMPROUTE configuration with each move.

If the pre-configuration of VIPAs described in this topic has not been done, it is still possible to define a VIPA to OMPROUTE such that it is properly processed and advertised when it becomes active on the corresponding TCP/IP stack. To do this, add the appropriate OSPF_INTERFACE or INTERFACE statement to the OMPROUTE

configuration file and then cause OMPROUTE to reread the configuration file by issuing the MODIFY *procname*,RECONFIG command.

Rule: If you have not coded GLOBAL_OPTIONS IGNORE_UNDEFINED_INTERFACES=YES in your OMPROUTE configuration file, you must modify the OMPROUTE configuration file and issue the RECONFIG command prior to the first time that the VIPA moves to the corresponding TCP/IP stack.

Guideline: If you have coded GLOBAL_OPTIONS IGNORE_UNDEFINED_INTERFACES=YES in your OMPROUTE configuration file, you can use OMPROUTE reconfiguration to add a definition for a VIPA interface that is or has been active in the stack but ignored by OMPROUTE. However, OMPROUTE does not associate the VIPA with the new definition until the interface has been deleted from the stack and re-added, either by DVIPA movement or by some other method.

Method of assigning interface definitions to stack interfaces (wildcard and explicit):

Wildcard interface definitions can be a convenient way of making your interface definitions easier. However, to avoid unintended results, be sure to understand how they are parsed, and how different types of interface definitions interact with each other. Following is the outline of the algorithm OMPROUTE uses to find the matching definitions in the OMPROUTE configuration file for an IPv4 stack interface.

a. Search for a RIP_Interface definition for the interface as follows:
   1) Search for an explicit matching RIP_Interface definition (IP address matches exactly if a dynamic VIPA, otherwise name and IP address match exactly). If found, use that definition and go to step b.
   2) If the interface is a dynamic VIPA, search for a RIP_Interface definition that matches as a dynamic VIPA wildcard. A matching dynamic VIPA wildcard definition is one where the definition IP address matches the value obtained by ANDing the definition subnet mask with the interface home address. The definition name parameter is ignored when searching for a dynamic VIPA wildcard definition. If a matching dynamic VIPA wildcard definition is found, use that definition and go to step b.
   3) Search for a one-octet wildcard RIP_Interface definition (n.n.n.*), where the first three octets match the first three octets of the interface's home address and the name matches the interface's link name. If found, use that definition and go to step b.
   4) Search for a two-octet wildcard RIP_Interface definition (n.n.*.*), where the first two octets match the first two octets of the interface's home address and the name matches the interface's link name. If found, use that definition and go to step b.
   5) Search for a three-octet wildcard RIP_Interface definition (n.*.*.*), where the first octet matches the first octet of the interface's home address and the name matches the interface's link name. If found, use that definition and go to step b.
   6) Search for a one-octet wildcard RIP_Interface definition (n.n.n.*), where the first three octets match the first three octets of the interface's home address, ignoring the name parameter if coded. If found, use that definition and go to step b.

7) Search for a two-octet wildcard RIP_Interface definition (n.n.*.*), where the first two octets match the first two octets of the interface's home address, ignoring the name parameter if coded. If found, use that definition and go to step b.

8) Search for a three-octet wildcard RIP_Interface definition (n.*.*.*), where the first octet matches the first octet of the interface's home address, ignoring the name parameter if coded. If found, use that definition and go to step b.

9) If there is a four-octet wildcard RIP_Interface definition (*.*.*.* or ALL), use that definition and go to step b.

Restriction: Only one four-octet wildcard of each type (OSPF_INTERFACE or RIP_INTERFACE) is allowed.

b. Search for an OSPF_Interface definition for the interface. Note that this step is done regardless of the outcome of step a. The steps for searching OSPF_Interface definitions are the same as the steps for searching RIP_Interface definitions, except that OSPF_Interface definitions are searched.

c. If either a RIP_Interface or an OSPF_Interface definition, or both, are found, the algorithm is complete. In this case, Interface definitions are not searched. If neither a RIP_Interface nor an OSPF_Interface definition was found, go to step d.

d. Search for an Interface definition for the interface. The steps for searching Interface definitions are the same as the steps for searching RIP_Interface statements, except that Interface definitions are searched.

e. If no definitions are found, check the value of Global_Options Ignore_Undefined_Interfaces. If this option is turned on, the interface is ignored. If it is not turned on, the interface is treated as if it were defined with an Interface statement, with an MTU value of 576 and a subnet mask of the class mask.

The algorithm is complete. Key conclusions of this algorithm are as follows:

- A wildcard interface definition with a matching name is preferred over a wildcard interface definition of the same type without a matching name, regardless of which definition is a more specific wildcard.
- If the interface is not a dynamic VIPA, the subnet mask coded on the definition statement has no influence on which definition, wildcard or otherwise, is selected for an interface. The subnet mask is a characteristic of the definition, not a selection criterion.
- If a RIP_Interface or an OSPF_Interface definition, or both, are found, Interface definitions are not considered. This means that any matching RIP_Interface or OSPF_Interface definition supersedes all Interface definitions, even if the Interface definitions are explicit or are more specific wildcard matches. For example, a three-octet wildcard OSPF_Interface definition supersedes an explicit Interface definition.
- An interface can be both a RIP_Interface and an OSPF_Interface. OMPROUTE supports running both protocols over the same interface. However, an interface cannot be both an interface that runs no routing protocol (that is, defined with the Interface statement) and one that runs RIP, OSPF, or both.

---

5. Define IPv6 interfaces, if the IPv6 OSPF or IPv6 RIP protocol is used.

   Each IPv6 interface in use by the stack can be defined to OMPROUTE using an IPV6_OSPF_INTERFACE, IPV6_RIP_INTERFACE, or IPV6_INTERFACE

statement. Defining IPv6 interfaces to OMPROUTE is much simpler than defining IPv4 interfaces, because you do not specify IP addresses or MTU sizes to OMPROUTE. Instead, you simply define interfaces by their names and OMPROUTE learns IP addresses and MTU sizes from the TCP/IP stack. Also, because multicast support is a basic requirement of IPv6, there are no non-broadcast multiaccess considerations or other considerations that might require definitions of neighbors or destination addresses.

Use the following guidelines when configuring IPv6 interfaces to OMPROUTE:

- An interface over which the IPv6 OSPF protocol is communicated with other routers must be configured with the IPV6_OSPF_INTERFACE statement.
- An interface over which the IPv6 RIP protocol is communicated with other routers must be configured with the IPV6_RIP_INTERFACE statement.
- All other interfaces can be configured with the IPV6_INTERFACE statement, if OMPROUTE default values are not acceptable or you wish to define additional prefixes on the interface.
- The interface name must be coded on the IPV6_INTERFACE, IPV6_OSPF_INTERFACE, and IPV6_RIP_INTERFACE statements. The value of the NAME parameter must match the interface name coded on the INTERFACE statement in the TCP/IP profile. Wildcard names ending with an asterisk (*) can be coded. For example, OSAQDIO* would match stack interfaces named OSAQDIO1, OSAQDIO2, OSAQDIOABC, and so on.

  If the interface is dynamically generated by the TCP/IP stack, its name parameter must match what is generated by the TCP/IP stack. Interfaces that are dynamically generated by the TCP/IP stack are named as follows:

  – An IPv6 dynamic XCF interface that is generated to attach to other TCP/IP stacks within the same z/OS host is always named EZ6SAMEMVS.
  – An IPv6 dynamic XCF interface that is generated to attach to TCP/IP stacks in another z/OS image is always named EZ6XCF*xx*, where *xx* is the SYSCLONE value of the other z/OS host.

  If the routing parameters for your dynamic XCF interfaces will all be the same, you can use wildcard definitions to avoid having to know and build definitions for every possible dynamic XCF interface on your system. For example, a wildcard definition for name EZ6* would match all dynamic XCF interfaces that could be generated on a TCP/IP stack. A wildcard definition for EZ6XCF* would match all dynamic XCF interfaces that could be generated to attach to other z/OS images.

  The following definition would define all IPv6 dynamic XCF interfaces to OMPROUTE, with the hello and dead router intervals changed from the default values:

```
IPV6_OSPF_INTERFACE
 NAME=EZ6*
 HELLO_INTERVAL = 30
 DEAD_ROUTER_INTERVAL = 120;
```

  If the default values of 10 and 40 for the hello and dead router intervals are acceptable, this definition can be simplified even more:

```
IPV6_OSPF_INTERFACE
 NAME=EZ6*;
```

- To define one or more prefixes on an interface, use the PREFIX parameter on the IPV6_OSPF_INTERFACE, IPV6_RIP_INTERFACE, and

IPV6_INTERFACE statements. You should only need to do this for prefixes that you need to define to an interface, which will not be learned using IPv6 router discovery. Also note that prefixes defined to OMPROUTE in this manner are not used by TCP/IP to autoconfigure home addresses on the interface.

The following sample shows an IPv6 OSPF interface with prefixes defined:

```
IPV6_OSPF_INTERFACE
 NAME=OSAQDIO4L6
 PREFIX=2001:0DB8:1::/48
 PREFIX=2001:0DB8:2::/48;
```

The prefixes defined in this manner on an IPv6 OSPF interface are advertised as reachable, and are also included in the link LSA generated by OMPROUTE, so all IPv6 OSPF routers on the link will know they are local prefixes. If OMPROUTE is also running IPv6 RIP, they are also advertised into the IPv6 RIP autonomous system as reachable, if IPv6 RIP filters permit it.

The following sample shows an IPv6 RIP interface with prefixes defined:

```
IPV6_RIP_INTERFACE
 NAME=OSAQDIO3L6
 PREFIX=2001:0DB8:3::/48
 PREFIX=2001:0DB8:4::/48;
```

The prefixes defined in this manner on an IPv6 RIP interface are advertised into the IPv6 RIP autonomous system as reachable if IPv6 RIP filters permit it. They are also advertised into the IPv6 OSPF autonomous system as reachable, if OMPROUTE is running IPv6 OSPF and is configured as an IPv6 AS boundary router importing RIP routes.

The following sample shows an IPv6 generic interface with prefixes defined:

```
IPV6_INTERFACE
 NAME=OSAQDIO2L6
 PREFIX=2001:0DB8:5::/48
 PREFIX=2001:0DB8:6::/48;
```

The prefixes defined in this manner on an IPv6 generic interface are advertised into the RIP autonomous system as reachable, if OMPROUTE is running IPv6 RIP and IPv6 RIP filters permit it. They are also advertised into the IPv6 OSPF autonomous system as reachable, if OMPROUTE is running IPv6 OSPF and is configured as an IPv6 AS boundary router importing direct routes.

Method of assigning interface definitions to stack interfaces (wildcard and explicit):

For IPv6 interfaces, interface-name wildcards can be used to simplify definitions. However, be sure to understand how they are parsed, and how different types of interface definitions interact with each other, to avoid unintended results. Following is the outline of the algorithm OMPROUTE uses to find the matching definitions in the OMPROUTE configuration file for an IPv6 stack interface.

a. Search for an IPv6_RIP_Interface definition for the interface as follows:
   1) Search for an explicit matching IPv6_RIP_Interface statement for the interface. This is one where the name parameter exactly matches the interface's name. If one is found, use that definition and go to step b.
   2) Search for the best IPv6_RIP_Interface wildcard match for the name. The IPv6_RIP_Interface wildcard definitions are searched, starting with the most specific (longest wildcard name string) and checking

each in order of declining specificity until a match is found. As soon as a match is found, use that definition and go to step b.

b. Search for an IPv6_OSPF_Interface definition for the interface. Note that this step is done regardless of the outcome of step a. The steps for searching IPv6_OSPF_Interface definitions are the same as the steps for searching IPv6_RIP_Interface definitions, except that IPv6_OSPF_Interface definitions are searched.

c. If either an IPv6_RIP_Interface or an IPv6_OSPF_Interface definition, or both, are found, the algorithm is complete. In this case, IPv6_Interface definitions are not searched. If neither an IPv6_RIP_Interface nor an IPv6_OSPF_Interface definition was found, go to step d.

d. Search for an IPv6_Interface definition for the interface. The steps for searching IPv6_Interface definitions are the same as the steps for searching IPv6_RIP_Interface statements, except that IPv6_Interface definitions are searched.

e. If no definitions are found, check the value of Global_Options Ignore_Undefined_Interfaces. If this option is turned on, the interface is ignored. If it is not turned on, the interface is treated as if it were defined with an IPv6_Interface statement. Default values will be used for all parameters.

The algorithm is complete. Key conclusions of this algorithm are as follows:

- If an IPv6_RIP_Interface definition, an IPv6_OSPF_Interface definition, or both, are found, IPv6_Interface definitions are not considered. This means that any matching IPv6_RIP_Interface or IPv6_OSPF_Interface definition supersedes all IPv6_Interface definitions, even if the IPv6_Interface definitions are explicit or more specific wildcard matches. For example, an IPv6_OSPF_Interface definition with a name parameter of V* supersedes any IPv6_Interface, explicit or wildcard, with a name parameter that begins with V. In this case, the IPv6_Interface definition is redundant and will never be used. If OMPROUTE detects this case, it issues message EZZ8068I and deletes the redundant IPv6_Interface definition.

  Note: If an IPv6_Interface definition has already been selected for an interface that is installed in the stack, and then an IPv6_OSPF_Interface or IPv6_RIP_Interface definition that would make that IPv6_Interface definition redundant is added using RECONFIG, OMPROUTE issues message EZZ8069I and retains the IPv6_Interface definition.

- An interface can be both an IPv6_RIP_Interface and an IPv6_OSPF_Interface. OMPROUTE supports running both protocols over the same interface. However, an interface cannot be both an interface that runs no routing protocol (that is, defined with the IPv6_Interface statement) and one that runs IPv6 RIP, IPv6 OSPF, or both.

---

6. Define interface costs (OSPF_INTERFACE, RIP_INTERFACE, IPV6_OSPF_INTERFACE, and IPV6_RIP_INTERFACE).

   Both the OSPF and RIP protocols have a cost value associated with interfaces. With both protocols, the cost of a route to reach a destination is the sum of the costs of each link that will be traversed on the way to the destination. In the sample network shown in Figure 37 on page 259, the cost of a route to get from TCPCS7 to router 3.3.3.3 through TCPCS4 is the cost of the link from TCPCS7 to TCPCS4 plus the cost of the link from TCPCS4 to router 3.3.3.3.

The method for configuring cost values differs between the OSPF and RIP protocols. The cost values of OSPF links should be configured to ensure that preferred routes to destinations will have a lower cost than less preferable routes. The less preferable routes, with the higher cost, will not be used except upon failure of the preferred routes.

For the purpose of the following examples, the sample network shown in Figure 37 on page 259 is used and the convention stack (interface) is used to refer to the cost configured for a particular interface on a stack. For instance TCPCS7(9.67.106.7) refers to the cost configured for interface 9.67.106.7 on TCPCS7. While these examples use the IPv4 portion of the sample network, the same methods for computing route costs would also be used by the IPv6 portion.

There are three possible routes from TCPCS7 to router 3.3.3.3. They are:

- Direct (TCPCS7 —> 3.3.3.3),
- Through TCPCS4 (TCPCS7 —> TCPCS4 —> 3.3.3.3)
- Through router 8.8.8.8 and TCPCS4 (TCPCS7 —> 8.8.8.8 —> TCPCS4 —> TCPCS3)

If the preferred route from TCPCS7 to router 3.3.3.3 is through TCPCS4, then interface costs must be configured such that the following are true:

```
TCPCS7(9.67.106.7) + TCPCS4(9.67.101.4) < TCPCS7(9.67.102.7)
TCPCS7(9.67.106.7) + TCPCS4(9.67.101.4) < TCPCS7(9.67.100.7) +
8.8.8.8(9.67.105.8) + TCPCS4(9.67.101.4)
```

The reasons for preferring one route over another are numerous. One approach for assigning OSPF link costs would be to set the costs to values inversely proportional to the bandwidth of the physical media. This would result in higher bandwidth routes having lower costs, thus becoming the preferred routes.

The cost values of RIP links are generally set to a value of 1. This results in the cost of a route to a destination being the number of hops to reach the destination. In the sample network, this would result in the three possible RIP routes from TCPCS7 to router 3.3.3.3 having the following costs:

- Direct (TCPCS7 -> 3.3.3.3), cost = 1
- Through TCPCS4 (TCPCS7 -> TCPCS4 -> 3.3.3.3), cost = 2
- Through router 8.8.8.8 and TCPCS4 (TCPCS7 -> 8.8.8.8 -> TCPCS4 -> TCPCS3), cost = 3

If it were desired that the route through TCPCS4 be the preferred route, this could be accomplished by increasing the cost of getting directly from TCPCS7 to router 3.3.3.3. This could be done by increasing either the out metric for 9.67.102.3 on router 3.3.3.3 or the in metric for 9.67.102.7 on TCPCS7. Take care when increasing in metric and out metric values to be sure that the cost to reach any destination does not exceed the RIP maximum of 15.

IPv4 OSPF and RIP

The cost value of an OSPF interface is set using the COST0 parameter of the OSPF_INTERFACE statement. The in metric and out metric of a RIP interface are set using the IN_METRIC and OUT_METRIC parameters of the RIP_INTERFACE statement.

IPv6 OSPF and RIP

The cost value of an IPv6 OSPF interface is set using the COST parameter of the IPV6_OSPF_INTERFACE statement. The in metric and out metric of an IPv6 RIP interface are set using the IN_METRIC and OUT_METRIC parameters of the IPV6_RIP_INTERFACE statement.

7. Configure virtual links, if the OSPF protocol is used.

   The OSPF protocol is dependent upon complete connectivity of the backbone area. To maintain backbone connectivity, each backbone router must be interconnected. If the configuration of an OSPF autonomous system is such that the backbone area will become separated into two or more disconnected sections, connectivity must be restored for the protocol to work correctly. This can be done using a virtual link. An OSPF virtual link should not be confused with a VIPA link. Virtual links can be configured between any two backbone routers that have an interface to a common non-backbone area.

   IPv4 OSPF

   The VIRTUAL_LINK statements specify the router ID of the link endpoint and must be configured at both endpoints. In the sample network shown in Figure 37 on page 259, a virtual link is configured between TCPCS4 and TCPCS7 to restore backbone connectivity through area 1.1.1.1.

   ```
   TCPCS4:
   VIRTUAL_LINK
      Virtual_Endpoint_RouterID=7.7.7.7
      Links_Transit_Area=1.1.1.1;
   TCPCS7:
   VIRTUAL_LINK
      Virtual_Endpoint_RouterID=4.4.4.4
      Links_Transit_Area=1.1.1.1;
   ```

   IPv6 OSPF

   The IPV6_VIRTUAL_LINK statements specify the router ID of the link endpoint and must be configured at both endpoints. In the sample network, a virtual link is configured between TCPCS64 and TCPCS67 to restore backbone connectivity through area 6.6.6.6.

   ```
   TCPCS64:
   IPV6_VIRTUAL_LINK
      Virtual_Endpoint_RouterID=67.67.67.67
      Links_Transit_Area=6.6.6.6;
   TCPCS67:
   IPV6_VIRTUAL_LINK
      Virtual_Endpoint_RouterID=64.64.64.64
      Links_Transit_Area=6.6.6.6;
   ```

8. Manage high-cost links, if the OSPF protocol is used.

   The periodic nature of OSPF routing traffic requires a link's underlying data-link connection to be constantly open. This can result in unwanted usage charges on network segments whose costs are very high. There are two configuration steps that can be taken to inhibit the periodic nature of the protocol.

   The first step that can be taken is to define the link as a demand circuit. When this is done, link state advertisements (LSAs) sent over the interface will not be periodically refreshed. Only LSAs with real changes will be readvertised. In addition, aging of these LSAs will be disabled such that they will not age out of the link state database.

   Another step that can be taken is to define hello suppression for the link. Hello suppression is only meaningful if the link is a demand circuit and is either point-to-point or point-to-multipoint. Hello suppression will inhibit the periodic transmission of OSPF hello packets.

   IPv4 OSPF

To define OSPF interfaces as demand circuits, the Demand_Circuit=YES parameter must first be specified on the global OSPF configuration statement. Then, the OSPF_INTERFACE statement for each interface to be configured as a demand circuit must be specified with the Demand_Circuit=YES parameter. Use the Hello_Suppression parameter of the OSPF_INTERFACE statement to configure hello suppression. For more information on configuring the Hello_Suppression parameter on the OSPF_INTERFACE statement, see *z/OS Communications Server: IP Configuration Reference*. If hello suppression is implemented, the PP_Poll_Interval parameter of the OSPF_INTERFACE statement can be used to specify the interval at which OMPROUTE should attempt to contact a neighbor to reestablish a neighbor relationship when the relationship has failed, but the interface is still available.

IPv6 OSPF

To define IPv6 OSPF interfaces as demand circuits, the Demand_Circuit=YES parameter must first be specified on the global IPV6_OSPF configuration statement. Then, the IPV6_OSPF_INTERFACE statement for each interface to be configured as a demand circuit must be specified with the Demand_Circuit=YES parameter. Use the Hello_Suppression parameter of the IPV6_OSPF_INTERFACE statement to configure hello suppression. For more information on configuring the Hello_Suppression parameter on the IPV6_OSPF_INTERFACE statement, see *z/OS Communications Server: IP Configuration Reference*. If hello suppression is implemented, the PP_Poll_Interval parameter of the IPV6_OSPF_INTERFACE statement can be used to specify the interval at which OMPROUTE should attempt to contact a neighbor to reestablish a neighbor relationship when the relationship has failed, but the interface is still available.

---

9. Define RIP filters, if the RIP protocol is used.

   RIP Filters can be configured to OMPROUTE such that certain RIP routing information will not be broadcast out to other routers and/or accepted from other routers. The filters can be applied to individual RIP interfaces or to all RIP interfaces. When defining a filter, a filter type (sending or receiving) is specified along with values identifying the route information to be filtered. By using filters, an installation can limit the amount of RIP routing information broadcast into the network and/or the amount of RIP routing information maintained by OMPROUTE. In addition, filters can be used to hide destination addresses from portions of the network.

   IPv4 RIP

   To configure a filter for an individual RIP interface, use the FILTER parameter of the RIP_INTERFACE statement. To configure a filter that applies to all IPv4 RIP interfaces, use the global FILTER statement. In the sample network shown in Figure 37 on page 259, if you wanted to hide the 10.1.1.0 subnet from TCPCS6 (as well as all routers and hosts on the remote side of TCPCS6), you could define the following filter on TCPCS7:

   ```
   Filter=(nosend,10.1.1.0,255.255.255.0);
   ```

   IPv6 RIP

   To configure a filter for an individual IPv6 RIP interface, use the FILTER parameter of the IPV6_RIP_INTERFACE statement. To configure a filter that applies to all IPv6 RIP interfaces, use the global IPV6_RIP_FILTER statement. In the sample network shown in Figure 37 on page 259, for

example, if you wanted to hide the 2001:0DB8:0:A1B/64 prefix from TCPCS4, you could define the following filter on TCPCS4:

```
IPv6_RIP_Filter=(noreceive,2001:0DB8:0:A1B/64);
```

---

10. Define route precedence in a multiprotocol environment, if the OSPF protocol is used.

    Note that this discussion of route precedence is quite complicated. If only the OSPF or IPv6 OSPF routing protocol, or both, are used in your network, route precedence is less of a concern. If, in addition, none of your OSPF or IPv6 OSPF routers are configured as AS boundary routers, the route precedence concern is entirely eliminated. For environments with multiple protocols or AS boundary routers, the following information is provided. Note that in this discussion, RIP is meant to apply to both RIP and IPv6 RIP, OSPF is meant to apply to both OSPF and IPv6 OSPF, and the OSPF configuration statement is meant to apply to both the OSPF statement and the IPV6_OSPF statement.

    OMPROUTE applies an order of precedence in choosing between two routes to the same destination that were learned through different routing protocols or using information provided by an OSPF AS boundary router. To describe this order of precedence applied by OMPROUTE, a few terms must first be defined.

    RIP route
    : A route learned through the RIP protocol. A RIP route is generated using information provided in a RIP packet from a neighboring router. For example, in the sample network shown in Figure 37 on page 259, the route from TCPCS7 to destination subnet 30.1.1.0 is a RIP route.

    OSPF internal route
    : A route learned through the OSPF protocol where the entire path traversed to reach the destination lies within the OSPF autonomous system. For example, in the sample network shown in Figure 37 on page 259, the route from TCPCS7 to destination 9.67.108.2 on Router 2.2.2.2 is an OSPF internal route.

    OSPF external route
    : A route learned through the OSPF protocol where part of the path traversed to reach the destination does not lie within the OSPF autonomous system. The path will leave the autonomous system if it uses information brought into the OSPF autonomous system by an AS boundary router. This information brought into the OSPF AS may be information imported from a different autonomous system (for example, RIP) or information about destinations statically configured on or directly connected to the AS boundary router. For example, in the sample network shown in Figure 37 on page 259, the route from TCPCS4 to destination 9.67.103.6 on TCPCS6 is an OSPF external route. TCPCS7, configured as an AS boundary router, has imported information about that destination into the OSPF AS from the RIP AS.

      OSPF external routes fall into two categories based upon the setting of the multiprotocol comparison value. If the comparison value is set to Type1 on the AS boundary router that imports the external information into the OSPF AS, then OSPF external routes generated using this information will be OSPF type 1 external routes. If the

comparison value is set to Type2 on the AS boundary router, then the generated routes will be OSPF type 2 external routes. For example, in the sample network shown in Figure 37 on page 259, if the comparison value on TCPCS7 (an AS boundary router) is set to Type1, the route from TCPCS4 to destination 9.67.103.6 on TCPCS6 is an OSPF type 1 external route. If the comparison value on TCPCS7 is set to Type2, the route is an OSPF type 2 external route.

Multiprotocol comparison

You can configure this comparison value to allow for the specification of how route costs from different autonomous systems should be treated when they coexist. In OMPROUTE, you can configure this value using the COMPARISON parameter on the OSPF or IPV6_OSPF configuration statements. When COMPARISON=Type1 is configured, the route cost values used within different autonomous systems (for example, the OSPF AS and the RIP AS) are considered comparable. With COMPARISON=Type2 configured, the route cost values used with the different autonomous systems are considered non-comparable.

The comparison value can be used in several different ways, depending on the function being performed by a router:

- As an AS boundary router, OMPROUTE uses the comparison value to determine the type of external routes (type 1 or type 2) generated by routers in the OSPF AS using routing information that the AS boundary router imports into the OSPF AS.
- As an AS boundary router, OMPROUTE also uses the comparison value in determining how route cost values will be assigned when importing routes from the OSPF AS into the RIP AS.
  - When COMPARISON=Type1 is configured (indicating that cost values are comparable), an OSPF route imported into the RIP AS will be advertised with the actual cost of the OSPF route. For example, in the sample network, if TCPCS7 is configured with COMPARISON=Type1 and the OSPF route from TCPCS7 to destination 9.67.108.2 on TCPCS2 has a cost of 7, then TCPCS7 will advertise into the RIP AS a RIP route to that destination with a cost of 7.

    Notes:

    a. An exception to this rule (defining how OSPF routes are advertised into the RIP AS when COMPARISON=Type1) occurs when the OSPF route to be imported is an OSPF type 2 external route. When this is the case, the route is not advertised into the RIP AS at all.

    b. It is important to remember the requirement that all destinations in the RIP AS must be reachable with a cost no greater than 15. Using COMPARISON=Type1 requires that the cost values of OSPF routes be low. Any destinations in the OSPF AS that can only be reached from the RIP AS with a cost greater than 15 will become unreachable.
  - When COMPARISON=Type2 is configured (indicating that cost values are non-comparable), an OSPF route imported into the RIP AS is advertised with a cost of 1. If a router in the RIP AS has two possible routes to a destination, one internal to the RIP AS and another that was imported from OSPF, this approach results in the route imported from OSPF being favored. For example, in the sample network shown in Figure 37 on page 259, if TCPCS7 is configured with COMPARISON=Type2 and TCPCS7 can somehow reach a destination in

the 30.1.1.0 subnet without passing through TCPCS6 (using links not shown in the sample), then TCPCS7 advertises into the RIP AS a RIP route to the destination with a cost of 1. As a result, TCPCS6 determines that the destination can be reached through TCPCS7 with a cost of 2. If the cost of the route for TCPCS6 to reach the destination internal to the RIP AS is greater than 2, then the route through TCPCS7 is chosen.

Note: An exception to this rule (defining how OSPF routes are advertised into the RIP AS when COMPARISON=Type2) occurs when the OSPF route to be imported is an OSPF type 2 external route. When this is the case, the route is advertised into the RIP AS with the actual cost of the OSPF type 2 external route.

- As any router that has routing information from different autonomous systems, OMPROUTE uses the comparison value while choosing between the routes generated using the information from the different autonomous systems. How the comparison value is used in this case is shown in Table 17.

Given these definitions, the order of precedence used in choosing between multiple routes to the same destination, which were learned through the different protocols or by using information provided by an OSPF AS boundary router, can be shown in Table 17. In Table 17, *Source comparison* refers to the setting of the comparison value (using the COMPARISON parameter on the OSPF configuration statement) on the router that is using the order of precedence to choose between the multiple routes. *Route 1* and *Route 2* are the two possible routes being chosen between.

Table 17. Route precedence

Source comparison	Route 1 type	Route 2 type	Route chosen
Type 1	OSPF internal	RIP	OSPF internal
Type 1	OSPF internal	OSPF type 1 external	OSPF internal
Type 1	OSPF internal	OSPF type 2 external	OSPF internal
Type 1	RIP	OSPF type 1 external	Lowest cost route
Type 1	RIP	OSPF type 2 external	RIP route
Type 1	OSPF type 1 external	OSPF type 2 external	OSPF type 1 external
Type 2	OSPF internal	RIP	OSPF internal
Type 2	OSPF internal	OSPF type 1 external	OSPF internal
Type 2	OSPF internal	OSPF type 2 external	OSPF internal
Type 2	RIP	OSPF type 1 external	OSPF type 1 external
Type 2	RIP	OSPF type 2 external	Lowest cost route
Type 2	OSPF type 1 external	OSPF type 2 external	OSPF type 1 external

Minimizing the routing responsibility of z/OS Communications Server

OMPROUTE may be run on z/OS Communications Server for a variety of reasons. If the z/OS Communications Server host is being used as an application or server host and the routing daemon is being run primarily to provide access to network resources, or to provide network resources access to the z/OS Communications Server host, then care must be taken to ensure that the z/OS Communications Server host is not overly burdened with routing work. Unlike routers or other network boxes whose sole purpose is routing, an application host z/OS

Communications Server will be doing many things other than routing, and it is not desirable for a large percentage of machine resources (memory and CPU) to be used for routing tasks, as can happen in very complex or unstable networks. In this case the z/OS Communications Server should not be configured as a backbone router, either intentionally or inadvertently. Careful network design can minimize the routing burdens on the z/OS Communications Server application host without compromising the accessibility of z/OS Communications Server resources to the network and vice versa. If care is not taken to minimize the routing work required by the z/OS Communications Server host, OMPROUTE may consume excessive cycles or memory processing huge numbers of routing updates from the network. Or the burden of routing updates may become so large that the z/OS Communications Server cannot keep up because of other workloads on the machine. Since OSPF is heavily timer-driven, this could cause loss of adjacencies and routing problems.

The primary way to reduce the routing burdens on the z/OS Communications Server host is by use of OSPF areas. See step 2 on page 289 for more information. A z/OS Communications Server application host or sysplex can be placed into a non-backbone area with dedicated routers acting as area-border routers. The area-border routers would advertise the z/OS Communications Server resources to other attached areas (for example the backbone) and would summarize the network outside the local area to the z/OS Communications Server hosts. If possible, this can be further refined to reduce routing protocol traffic by use of interarea route summarization, accomplished in OMPROUTE area-border routers by the RANGE and IPV6_RANGE statements, and in Cisco routers with the area range command. For more information, see *z/OS Communications Server: IP Configuration Reference* and step 3 on page 290.

An even further, and ideal, optimization would be to make the area containing the z/OS Communications Server application host or sysplex a stub area. A stub area can be configured such that route summaries (IPv4) or prefixes (IPv6) from other areas are not flooded into the stub area by the area border routers. When this is done, only routes to destinations within the stub area are shared among the hosts. Default routes are used to represent all destinations outside the stub area. The stub area's resources are still advertised to the network at large by the area-border routers. You can use this optimization, sometimes referred to as a totally stubby area, if the following apply to your network:

- It is acceptable to use default routes to reach destinations outside the stub area. This means that either there is only one area-border router connecting the stub area to the rest of the network, or if there are multiple such connections they are redundant, so that it does not matter which one is used to get outside the stub area.
- You have no non-OSPF destinations to advertise to the network at large. Stub areas do not permit importation of OSPF external routes. This means for example that you do not have a RIP network attached to the stub area, or if you do, you do not want its destinations reachable from the stub area. Other types of routes that cannot be imported into stub areas include direct routes (for example, for networks attached to interfaces that are not running the OSPF protocol) and static routes. RIP or static routes can be used by the z/OS Communications Server that learns them, they just cannot be advertised.

  Tip: If you define your VIPAs as OSPF interfaces in your OMPROUTE configuration file, routes to their addresses will be considered OSPF routes, and therefore importable into the stub area and able to be advertised by the area-border routers to the network at large.

It is highly recommended to put z/OS Communications Server application hosts or sysplexes into stub areas if at all possible.

A further optimization is to prevent z/OS Communications Server from becoming the designated router on multiaccess media, when pure routers that can perform this function are present. On a multiaccess medium, the designated router and the backup designated router will carry the majority of the routing protocol load for all hosts on the medium. While z/OS Communications Server is capable of performing this role, it does impose additional routing overhead on the system. It would be preferable to allow pure routers to perform this role, if they are available. This is accomplished by ensuring that the pure routers' interfaces onto the medium have higher ROUTER_PRIORITY values than the z/OS Communications Server interfaces on the same medium. However, if the only hosts on a medium are z/OS Communications Server, such as in HiperSockets communications, then one or two of them will have to be designated router or backup designated router.

Tip: You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

Preventing futile neighbor state loops during adjacency formation

In OSPF environments in which there might be a problem with some remote hardware (for example, router, switch, or network cable) that is beyond detection by z/OS hardware or software, OMPROUTE can get into an infinite (or futile) neighbor state loop over one of its interfaces with a neighbor. This loop might contribute to increased workload. In LAN configurations in which there are parallel OSPF interfaces that can reach the same neighbor for adjacency formation, unless you are using OMPROUTE futile neighbor state loop detection or unless you manually fix the problem, the backup interfaces are not used until after an outage occurs for the OSPF interface that was initially involved in an adjacency formation attempt with a designated router. For information about parallel OSPF interfaces, see step 4 on page 292.

Futile neighbor state loops can occur during adjacency formation with a neighboring designated router before full adjacency has been reached. According to OSPF protocol, all routers on a multiaccess network attempt to establish adjacency with the designated router (DR) and backup designated router (BDR) after two-way communication has been established. When a problem occurs during the adjacency formation process, the adjacency formation attempt is restarted. Repeated adjacency attempts can continue until full adjacency has been established or an interruption occurs. Interruption occurs from an interface outage to the neighbor or from a neighbor outage. Whether or not parallel interfaces are used, OMPROUTE repeatedly attempts to establish full adjacency with the neighbor, and if the problem is due to a cabling error or failure or some other non-transient condition, it is highly unlikely that the problem will be resolved and the loop will become futile.

To stop a futile neighbor state loop, you can either manually deactivate the interface or suspend the OSPF interface within OMPROUTE so that OMPROUTE will stop attempting to form the adjacency over the interface. If the OSPF interface is suspended, any active sessions using static routes over the interface will not be

disrupted. If the interface is deactivated, all active sessions over the interface will be disrupted. If a parallel OSPF interface is available, OMPROUTE will then attempt to form adjacency with the neighbor over the parallel interface.

OMPROUTE futile neighbor state loop detection removes the need for manual detection of futile neighbor state loops, manual intervention to resolve the loops, and the disruption of existing sessions due to deactivating the interface. Code the DR_MAX_ADJ_ATTEMPT parameter on the OSPF or IPV6_OSPF statement, or both, in your OMPROUTE configuration file to enable this function. OMPROUTE will then report and control futile neighbor state loops during the adjacency formation process. For a list of interfaces that support the futile neighbor state loop detection function, see *z/OS Communications Server: IP Configuration Reference*

If you use the DR_MAX_ADJ_ATTEMPT parameter, futile neighbor state loops are automatically detected and reported using message EZZ8157I. If a parallel OSPF interface is not available, adjacency formation attempts continue to be retried over the same interface. If parallel OSPF interfaces are available, an interface change is reported using message EZZ8158I and adjacency formation attempts are retried over a parallel OSPF interface. The problematic interface is suspended within OMPROUTE, but the interface is not deactivated and active sessions over the interface are not disrupted.

After a problematic OSPF interface is suspended in OMPROUTE and adjacencies are formed on a parallel OSPF interface, you might want to switch back to the original interface once you have fixed the problem that caused the futile neighbor state loop. To accomplish this, activate the repaired interface and then suspend the parallel interface. Once OSPF adjacencies are established over the repaired interface, the parallel interface can be reactivated so it is once again available as a backup for the repaired interface. Use the ACTIVATE function of the OMPROUTE MODIFY command to activate a suspended OSPF interface. Use the SUSPEND function of the OMPROUTE MODIFY command to manually suspend an OSPF interface. For more information about these functions of the MODIFY command for OMPROUTE, see *z/OS Communications Server: IP System Administrator's Commands*.

Verification of OMPROUTE IPv4 configuration and state

The following topics show sample output from each of the commands that can be used to display OMPROUTE IPv4 information. The syntax of these DISPLAY commands, as well as detailed information about the data displayed, can be found in *z/OS Communications Server: IP System Administrator's Commands*.

Note: All commands that include the LIST subparameter indicate that the information being displayed is configured information only and does not necessarily mean that the information is currently being used by OMPROUTE. To display information in current use, use related commands to display current, run-time statistics, and parameters. There are cases when the configured information will not match the in-use information due to some undefined or unresolved information in the OMPROUTE configuration. For example, undefined interfaces or parameters in the OMPROUTE configuration or an incorrect sequence of dynamic reconfiguration with the MODIFY OMPROUTE,RECONFIG command can result in no update of the in-use information at all. Information defined on wildcard interfaces is not displayed in the LIST commands; it is only displayed in the corresponding non-LIST commands when wildcard information is resolved to actual physical interfaces.

Displaying all OSPF configuration information

To display all of the OSPF configuration information, enter the following command:

```
D TCPIP,TCPCS7,OMP,OSPF,LIST,ALL

```

Displaying information about configured RIP interfaces

To display information about configured RIP interfaces, enter the following command:

```
D TCPIP,TCPCS7,OMP,RIP,LIST,IFS
EZZ7843I RIP CONFIGURATION 806
TRACE: 0, DEBUG: 0, SADEBUG LEVEL: 0
STACK AFFINITY: TCPCS7
RIP: ENABLED
RIP DEFAULT ORIGINATION: ALWAYS, COST = 1
PER-INTERFACE ADDRESS FLAGS:
CTC7TO6          9.67.103.7      RIP-2 MULTICAST.
                                 SEND NET AND SUBNET ROUTES
                                 RECEIVE NO DYNAMIC HOST ROUTES
                                 RIP INTERFACE INPUT METRIC: 1
                                 RIP INTERFACE OUTPUT METRIC: 0
                                 RIP RECEIVE CONTROL: ANY
```

Displaying the routes to be unconditionally accepted

To display the routes to be unconditionally accepted, as configured with the Accept_RIP_Route statement, enter the following command:

```
D TCPIP,TCPCS7,OMP,RIP,LIST,ACCEPTED
EZZ7844I RIP ROUTE ACCEPTANCE 808
ACCEPT RIP UPDATES ALWAYS FOR:
  30.1.1.8          30.1.1.4
```

Displaying current run-time information about RIP interfaces

To display current, run-time information about RIP interfaces, enter the following command:

```
D TCPIP,TCPCS7,OMP,RIP,IF
EZZ7859I RIP INTERFACES 810
IFC ADDRESS      IFC NAME         SUBNET MASK     MTU   DESTINATION
9.67.103.7       CTC7TO6          255.255.255.0   1024  0.0.0.0
```

Displaying current run-time information about a specific RIP interface

To display current, run-time information about a specific RIP interface, enter the following command:

```
D TCPIP,TCPCS7,OMP,RIP,IF,NAME=CTC7TO6
EZZ7860I RIP INTERFACE DETAILS 812
INTERFACE ADDRESS:      9.67.103.7
INTERFACE NAME:         CTC7TO6
SUBNET MASK:            255.255.255.0
MTU                     1024
```

```
DESTINATION ADDRESS:    0.0.0.0

RIP VERSION:            2     SEND POIS. REV. ROUTES: YES

DYNAMIC ROUTING PARAMETERS
  INTERFACE:  CTC7TO8          NEXT HOP: ANY
```

Result: If the policy-based route table is configured with no dynamic routing parameters, OMPROUTE has no knowledge of the route table. If there are no policy-based route tables configured with dynamic routing parameters, message EZZ8150I is issued.

Displaying the routes to a specific destination in a policy-based routing table

To display information about the routes to a specific destination that are in a policy-based routing table, enter the following command:

```
D TCPIP,TCPCS7,OMP,RTTABLE,PR=SECHIGH,DEST=130.201.0.0
EZZ7874I ROUTE EXPANSION 165
TABLE NAME: SECHIGH
DESTINATION:    130.201.0.0
MASK:           255.255.0.0
ROUTE TYPE:     SPE2
```

```
DISTANCE:       0
AGE:            548
NEXT HOP(S):    9.67.100.8        (CTC7TO8)
```

Result: If the policy-based route table is configured with no dynamic routing parameters, OMPROUTE has no knowledge of the route table. If there are no policy-based route tables configured with dynamic routing parameters, message EZZ8150I is issued.

Displaying all of the generic configuration information

To display all of the IPv4 configuration information that is not related to any routing protocol, enter the following command:

```
D TCPIP,TCPCS3,OMP,GENERIC,LIST,ALL
EZZ8053I IPV4 GENERIC CONFIGURATION
TRACE: 2, DEBUG: 3, SADEBUG LEVEL: 0
IPV4 TRACE DESTINATION: /TMP/AMPROUT3.DBG
STACK AFFINITY: TCPCS3

EZZ8056I IPV4 GEN INT CONFIGURATION
IFC NAME         IFC ADDRESS     SUBNET MASK       MTU DESTADDR
NSQDIO3L         9.67.120.3      255.255.255.0     576  N/A
CTC3TO4          9.67.101.3      255.255.255.0   10000  9.67.101.4
```

Displaying information about configured generic interfaces

To display information about configured generic interfaces (that is, interfaces defined to OMPROUTE with the INTERFACE statement, or not defined to OMPROUTE but learned from the stack), enter the following command:

```
D TCPIP,TCPCS3,OMP,GENERIC,LIST,IFS
EZZ8056I IPV4 GEN INT CONFIGURATION
IFC NAME         IFC ADDRESS     SUBNET MASK       MTU DESTADDR
NSQDIO3L         9.67.120.3      255.255.255.0     576  N/A

63.63.63.63         8     0     0     0  OFF       1 NSQDIO1L6
64.64.64.64       128     0     0     0  OFF       1 NSQDIO1L6
68.68.68.68       128     0     0     0  OFF       1 NSQDIO1L6
64.64.64.64       128     0     0     0  OFF       1 *
```

Tip: On multiaccess media (LANs), attached routers become adjacent only with the designated router and the backup designated router. Routers that are not performing a designated router role do not become adjacent to each other on LAN networks. Therefore, in this example, the state of 8 for 63.63.63.63 does not necessarily represent a problem or an incomplete adjacency. You can conclude that 64.64.64.64 and 68.68.68.68 are the designated routers, and 63.63.63.63 is simply another router on the network. State 8 is the final state in this case.

Displaying statistics and parameters for a specific IPv6 OSPF neighbor

To display current, run-time statistics and parameters for a specific IPv6 OSPF neighbor, enter the following command:

```
D TCPIP,TCPCS67,OMP,IPV6OSPF,NBR,ID=64.64.64.64,IFNAME=NSQDIO1L6
EZZ8130I IPV6 OSPF NEIGHBOR DETAILS 737

```

Displaying information about a specific IPv6 RIP interface

To display information about a specific IPv6 RIP interface, enter the following command:

```
D TCPIP,TCPCS4,OMP,IPV6RIP,IF,NAME=OSAQDIO46
EZZ8028I IPV6 RIP INTERFACE DETAILS
INTERFACE NAME:     OSAQDIO46
INTERFACE ADDRESS:  FE80::1:2:3:1
INTERFACE PREFIX:   RADV 2001:0DB8:1::/48
MTU:                    9000     STATE:                  UP
IN METRIC:              1        OUT METRIC:             0
SEND PREFIX ROUTES:     YES      SEND HOST ROUTES:       NO
SEND STATIC ROUTES:     NO       SEND DEFAULT ROUTES:    NO
SEND RTR. ADV. ROUTES:  YES      SEND POIS. REV. ROUTES: YES
RECEIVE PREFIX ROUTES:  YES      RECEIVE HOST ROUTES:    NO
```

```
SEND ONLY:  ALL

FILTERS: NONE
```

Displaying the routes to be unconditionally accepted by IPv6 RIP

To display the routes to be unconditionally accepted by IPv6 RIP, as configured with the IPv6_Accept_RIP_Route statement, enter the following command:

```
D TCPIP,TCPCS4,OMP,IPV6RIP,ACCEPTED
EZZ8031I IPV6 RIP ROUTE ACCEPTANCE
ACCEPT IPV6 RIP UPDATES ALWAYS FOR:
  2001:0DB8:0:A1C::2
  2001:0DB8:0:A1C::1
```

Displaying the global IPv6 RIP filters

To display the global IPv6 RIP filters, enter the following command:

```
D TCPIP,TCPCS4,OMP,IPV6RIP,FILTERS
EZZ8029I GLOBAL IPV6 RIP FILTERS

SEND ONLY: ALL

IGNORE IPV6 RIP UPDATES FROM:
  FE80::1:2:3:8

FILTERS: NORECEIVE       2001:0DB8:0:A1C::/64
```

Displaying the routes in the OMPROUTE IPv6 routing table

To display all of the routes in the OMPROUTE IPv6 routing table, enter the following command:

```

```

Displaying the routes to a specific IPv6 destination

To display information about the routes to a specific IPv6 destination, enter the following command:

```
D TCPIP,TCPCS4,OMP,RT6TABLE,DEST=2001:0DB8:0:A10::
EZZ7980I IPV6 ROUTE EXPANSION
DESTINATION: 2001:0DB8:0:A10::/60
ROUTE TYPE:  RIP
COST:        2
AGE:         352
NEXT HOP(S): FE80::1:2:3:3                          (OSAQDIO46)
             FE80::1:2:3:4                          (OSAQDIO46)
```

Displaying all of the IPv6 generic information

To display all of the IPv6 generic information, enter the following command:

```
D TCPIP,TCPCS4,GENERIC6,ALL
EZZ8053I IPV6 GENERIC CONFIGURATION
TRACE6: 2, DEBUG6: 3
IPV6 TRACE DESTINATION: /TMP/OMPROUT6.DBG
STACK AFFINITY: TCPCS4

EZZ8060I IPV6 GENERIC INTERFACES
NAME               MTU STATE CONFIGURED
VIPA16           65535    UP     YES
```

Displaying information about IPv6 generic interfaces

To display information about IPv6 generic interfaces (that is, interfaces defined in the OMPROUTE configuration file using IPv6_INTERFACE statements, or IPv6 interfaces not defined to OMPROUTE but learned from the stack), enter the following command:

```
D TCPIP,TCPCS4,OMP,GENERIC6,IFS
EZZ8060I IPV6 GENERIC INTERFACES
NAME               MTU STATE CONFIGURED
VIPA16           65535    UP     YES
```

Displaying information about a specific IPv6 generic interface

To display information about a specific IPv6 generic interface, enter the following command:

```
D TCPIP,TCPCS4,OMP,GENERIC6,IF,NAME=VIPA16
EZZ8065I IPV6 GEN INTERFACE DETAILS
INTERFACE NAME:     VIPA16
INTERFACE ADDRESS:  2001:0DB8:6:6:6:6:6:6
INTERFACE PREFIX:   STAT 2001:0DB8:6::/48
MTU:               65535
STATE:              UP
CONFIGURED:         YES
```

Policy-based routing

Policy-based routing enables the TCP/IP stack to make routing decisions that take into account criteria other than just the destination IP address. The additional criteria can include job name, source port, destination port, protocol type (TCP or UDP), source IP address, NetAccess security zone, and multilevel secure environment security label. Policy-based routing might be useful in the following sample scenarios:

- You might want to favor high bandwidth links for batch traffic, but for interactive traffic you prefer low-latency links. If so, you could define policies such that Telnet traffic is routed over the low-latency links, and FTP traffic is routed over the high bandwidth links.
- You could define a policy to ensure that traffic that is tagged with a security label and zone is routed to a secured network over an appropriate outbound interface.
- You might want to control the links used by Enterprise Extender traffic to keep that traffic from being impacted by other IP traffic loads.

Restrictions:

- Policy-based routing applies to only IPv4 TCP and UDP traffic that originates at the TCP/IP stack. Traffic using protocols other than TCP and UDP, all traffic being forwarded by the TCP/IP stack, and all IPv6 traffic is always routed using the main route table, even when policy-based routing is in use.
- If Common INET (CINET) is used to run multiple z/OS Communications Server TCP/IP stacks concurrently, CINET has no knowledge of the policy-based route tables used by those TCP/IP stacks. CINET has knowledge only of the routes in each TCP/IP stack's main route table. Avoid using policy-based routing in a CINET environment, unless at least one of the following is true:
  - All applications establish affinity with a particular TCP/IP stack.
  - The route destinations in each TCP/IP stack route table are mutually exclusive with the route destinations on the other TCP/IP stacks, including the default route.

Options for configuring policy-based routing

Policy-based routing is configured using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the policy-based routing for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF)

  z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you

can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.

- As a standalone application that you can run on your workstation

  You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

Through a series of wizards and online help panels, you can use the Configuration Assistant to create policy-based routing configuration files for any number of z/OS images with any number of TCP/IP stacks per image.

With the Configuration Assistant you use traffic descriptors, reusable objects that define traffic by its ports, protocol, security zone, security label, or sending application job name. The Configuration Assistant comes with a number of IBM-supplied traffic descriptors that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects. For each TCP/IP stack, you then create a set of policy-based route tables and routing rules, which map traffic descriptors and IP addresses to the policy-based route tables to be used when making routing decisions for that traffic.

The Configuration Assistant can dramatically reduce the amount of time that is required to create policy-based routing files, contributing to ease of configuration and maintenance. Using the GUI ensures that you have a consistent and easily manageable interface for implementing policy-based routing.

This information primarily describes option 2, manual configuration. However, if you are using the Configuration Assistant, reading this information will help you understand policy-based routing concepts and the relationship between Policy Agent and policy-based routing.

Option 2: Manual configuration

You can manually create the policy-based routing configuration files by coding all the required statements in a z/OS UNIX file or MVS data set. This information describes the procedure for creating a routing policy by manually creating and editing the configuration files. For details about the routing policy statements, see *z/OS Communications Server: IP Configuration Reference*.

Specifying the routing configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information about these different roles, see "Policy types and infrastructure overview" on page 829. Regardless of which option you use to configure Routing policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves Routing policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve Routing policies from the policy server, specify the configuration files using the RoutingConfig statement on the policy client.

- If you are not using a policy client and policy server environment, specify the configuration files using the RoutingConfig statement on the single Policy Agent.

When specifying configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

Routing policy configuration

Routing policy is provided to the stack by the Policy Agent. The Policy Agent main configuration file contains a TcpImage statement for each stack that is to receive policy, and can optionally contain a CommonRoutingConfig statement that identifies a local shared routing policy file. The TcpImage statement identifies the z/OS UNIX file or MVS data set that contains policy for that stack. This policy file can contain a RoutingConfig statement to identify the z/OS UNIX file or MVS data set that contains the local routing policy. The RoutingConfig statement is required for each stack that is to receive routing policy. If both a RoutingConfig statement and a CommonRoutingConfig statement are defined, the specified CommonRoutingConfig file is processed before the RoutingConfig policy file specified for that stack.

On the policy server, use the DynamicConfigPolicyLoad statement to specify the remote routing policies. On the policy client, use the PolicyServer statement to retrieve the remote routing policies from the policy server.

In the routing policy file, routing rules define sets of conditions that are compared when a route is being selected to send IPv4 TCP or UDP traffic that originates in the TCP/IP stack. If a rule match is found, an appropriate route for the traffic is selected based on the route tables that are specified in the action associated with the rule.

Routing rules

A RoutingRule statement consists of a set of conditions that are compared against the traffic that is being sent. When a match is found, policy lookup stops and the traffic is assigned the actions associated with the rule. The rule conditions are as follows:

IPSourceAddr

Source IP address or addresses. The source IP address for a TCP outbound connection, or for a UDP outbound packet, can be influenced by a number of configuration and application options. For the hierarchy of ways that the source IP address of an outbound packet is determined, see "Source IP address selection" on page 218. For the following source IP address selection methods, a route lookup is needed to determine the source IP address.

- SOURCEVIPA: Static VIPA address from the HOME list (IPv4 interface defined with the LINK statement) or from the SOURCEVIPAINTERFACE parameter (IPv4 interface defined with the INTERFACE statement)
- HOME IP address of the interface over which the packet is sent

The IpSourceAddr condition should not be used as a selector for traffic that relies on these methods to select its source IP address. At the time that the route lookup is performed, the source IP address has not yet been selected.

IPDestAddr

Destination IP address or addresses.

SourcePortRange
Source port or ports.

DestinationPortRange
Destination port or ports.

Protocol
TCP or UDP.

Jobname
Job name of the sending application or wildcard job name.

SecurityZone
NetAccess security zone that outbound traffic must match. The outbound traffic's destination IP address is used to determine the NetAccess security zone in the NetAccess table defined in the TCP/IP profile. For more information about network access control and the NETACCESS TCP/IP profile statement, see *z/OS Communications Server: IP Configuration Reference*.

SecurityLabel
Multilevel secure networking security label of the NetAccess security zone that outbound traffic must match. The outbound traffic's destination IP address is used to determine the packet's NetAccess security zone in the NetAccess table defined in the TCP/IP profile. The security label is the label associated with the NetAccess zone. For more information, see Chapter 4, "Preparing for TCP/IP networking in a multilevel secure environment," on page 153.

If a condition is not specified, that condition is not considered when comparing the rule and the traffic for a match. You can specify multiple values for the conditions, either directly in the condition or as a referenced group.

Each RoutingRule statement can also have a priority. Priority values can be integers in the range 1 – 2 000 000 000; 2 000 000 000 is the highest priority. When assigning priorities, you should skip some values to accommodate future rule insertion between existing rules.

If traffic does not map to any of the active routing rules, the IP layer routes traffic by searching the main route table.

Tip: If traffic can map to more than one rule, always use priority and leave priority space between rules.

A RoutingRule statement must reference an action using the RoutingActionRef parameter. The RoutingActionRef parameter includes the name of a globally defined RoutingAction statement.

Routing actions

The RoutingAction statement must specify a minimum of one policy-based route table using the RouteTableRef parameter, or it must specify UseMainRouteTable YES. Specify UseMainRouteTable YES and no RouteTableRef parameters if you want traffic that matches the corresponding RoutingRule statement to be routed using only the main route table.

A maximum of eight RouteTableRef parameters can be specified on a RoutingAction statement. Each RouteTableRef parameter includes the name of a globally defined RouteTable statement. The order in which the RouteTableRef parameters are specified on the RoutingAction statement determines the order in which the TCP/IP stack uses the route tables when making routing decisions. The

stack searches the first table for a route that can be used to reach the destination of the traffic. If no usable route (host, subnet, network, or default) exists in that route table, the next table is searched. This continues until a usable route to the destination is found, or all specified tables are exhausted. Specify the UseMainRouteTable parameter to indicate whether the main route table should also be searched when no usable route is located in any of the specified policy-based route tables. For a description of the algorithm used by the IP layer to search a route table for a usable route to a destination, see "Route selection algorithm" on page 258.

Performance guideline: There is a performance cost for each policy-based route table that is searched on a route lookup. Minimize the number of RouteTableRef parameters that you specify on a RoutingAction statement.

Routing tables

The RouteTable statement can include the following:

- A set of static routes (both replaceable and non-replaceable static routes are supported)
- A set of dynamic routing parameters, used to control the scope of dynamic routes computed by OMPROUTE
- A dynamic XCF routes indicator

A static route is included using the Route parameter of the RouteTable statement. A dynamic routing parameter is included using the DynamicRoutingParms parameter of the RouteTable statement. A dynamic routing parameter consists of an interface, and optionally a next-hop router. OMPROUTE adds dynamic routes to a policy-based route table only if that interface is included in the dynamic routing parameters for that table. If a next-hop router is specified with an interface, dynamic indirect routes that use the specified interface are added only if they also use the specified next-hop router.

If only static routes are included in a RouteTable statement, the static routes are added to the policy-based route table, but no dynamic routes are added to the table by OMPROUTE. If only dynamic routing parameters are included, dynamic routes are added to the policy-based route table by OMPROUTE, but no static routes are added to the table. If both static routes and dynamic routing parameters are included, the static routes are added to the policy-based route table and OMPROUTE updates the table with the appropriate dynamic routes.

A dynamic route that is added to a policy-based route table is the best route known by OMPROUTE to that destination. The calculation of the best route is based on the current network topology. The best route might be a route that was learned from the OSPF protocol or from the RIP protocol, depending on the OMPROUTE configuration. For a description of these protocols, see "IPv4 dynamic routing using OMPROUTE" on page 267. When computing the best routes for a policy-based route table, OMPROUTE considers only routes that adhere to the dynamic routing parameters configured on the RouteTable statement as described.

Performance guideline: Each policy-based route table that is configured for dynamic routing adds additional processing cost to OMPROUTE. Do not configure duplicate route tables, and do not configure a large number of policy-based route tables that use dynamic routing.

If DynamicXCFRoutes Yes is specified on the RouteTable statement and IPCONFIG DYNAMICXCF is specified in the TCP/IP profile, direct host routes to dynamic

XCF addresses on other TCP/IP stacks are added to the route table when the dynamic XCF links to those stacks are active. These are the same routes that are automatically generated in the main route table when dynamic XCF links are active. For information about the dynamic XCF function and the definitions that are automatically generated when IPCONFIG DYNAMICXCF is specified in the TCP/IP profile, see "Dynamic XCF" on page 434.

After a new routing policy is installed in the TCP/IP stack, traffic is mapped using the new policy, even for existing connections.

Getting started with policy-based routing

Assume you have a TCP application that has the name SECBATCH running on a z/OS TCP/IP stack. Because this application handles sensitive data sent as batch traffic, you want the traffic to be sent only over secure networks and you want to prefer high bandwidth links over lower bandwidth links. The application creates a TCP socket bound to IP address INADDR_ANY and port 7000.

For the tasks that must be completed to configure the local routing policy to control routing decisions made for traffic sent by the application, see Table 18. Assuming that the link names specified on the routing policy statements are already defined to TCP/IP and OMPROUTE, you do not need to perform additional configuration in the TCP/IP profile or in the OMPROUTE configuration file to enable policy-based routing.

Table 18. Configuring policy-based routing

Task	Specification
Determine routing requirements	Determine your requirements for the TCP/IP stack to make routing decisions based on more than just destination IP address. The additional criteria can include job name, source port, destination port, protocol type (TCP or UDP), source IP address, NetAccess security zone, and security label.
Create Policy Agent files	1. Create a Policy Agent main configuration file containing a TcpImage statement for the stack. 2. Create a Policy Agent image configuration file for the stack. 3. If routing policies are to be retrieved from the policy server, create image-specific routing configuration files, and optionally, common routing configuration files, on the policy server.

Table 18. Configuring policy-based routing (continued)

Task	Specification

Add routing configuration	1. For local Routing policies, add a RoutingConfig statement to the Policy Agent image configuration file, identifying the RoutingConfig policy file location:
	`RoutingConfig` *`configFilepath`*
	2. For remote Routing policies, add a PolicyServer statement to the policy client image configuration file:
	`PolicyServer`
	`{`
	`ClientName` *`name`*
	`PolicyType Routing`
	`{`
	`...`
	`}`
	`...`
	`}`
	Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:
	`DynamicConfigPolicyLoad` *`clientname`*
	`{`
	`PolicyType Routing`
	`{`
	`PolicyLoad` *`configFilepath`*
	`}`
	`...`
	`}`

Add statements to the Routing policy file to configure the policy-based route tables to be used by the TCP/IP stack for routing the application traffic.
 	
Table SecFast contains a replaceable static default route. The dynamic routing parameters for SecFast direct OMPROUTE to compute routes that use only link SECHIGH2, with any first hop, and link SECHIGH1, with a first hop of 9.67.101.3.
 	
Table SecSlow contains a replaceable static default route. The dynamic routing parameters for SecSlow direct OMPROUTE to only compute routes that use link SECLOW2, with a first hop of 9.67.104.3, and link SECLOW1, with a first hop of either 9.67.106.7 or 9.67.106.15.
	Add the following Routing policy statements to the *configFilepath* file:
	`RouteTable SecFast # Secure link, high bandwidth`
	`{`
	`# Static Routes:`
	`# Destination Subnet Mask First Hop Link Name Packet Size Options`
	`Route DEFAULT 9.67.101.3 SECHIGH1 MTU 2000 Replaceable`
	`#`
	`# Dynamic Routing Parameters:`
	`# Link Name First Hop`
	`DynamicRoutingParms SECHIGH2`

Table 18. Configuring policy-based routing (continued)

Task	Specification

Add statements to the Routing policy file to ensure that the application traffic is sent over only secure links, favoring high bandwidth links over lower bandwidth links.	Add the following Routing policy statements to the *configFilepath* file:
	`RoutingRule SecBatchRule`
	`{`
	`  TrafficDescriptor`
	`  {`
	`  Protocol TCP`
	`  SourcePortRange 7000`
	`  Jobname SECBATCH`
	`  }`
	`  RoutingActionRef SecBatchAction`
	`}`
	`RoutingAction SecBatchAction`
	`{`
	`  UseMainRouteTable No`
	`  RouteTableRef SecFast`
	`  RouteTableRef SecSlow`
	`}`

Start Policy Agent	You know you are done when the Routing policies are installed to the TCP/IP stack and the following console message is displayed: `EZZ8771I PAGENT CONFIG POLICY PROCESSING COMPLETE FOR` *image* `: ROUTING`

Considerations for using policy-based routing with IP security

Policy-based routing allows traffic described in a routing rule to be routed using one or more route tables. When IP security is active on a TCP/IP stack that is using policy-based routing, it is important to understand how the two functions interact. On a stack with IP security active, traffic can be encapsulated in an AH, ESP, or UDP-encapsulated ESP header. An additional IP header can be added if the encapsulated traffic is being sent to a security gateway (that is, the remote tunnel endpoint is not the same as the remote data endpoint). A matching routing rule is selected based on the characteristics of the original non-encapsulated traffic. The route tables associated with the matching routing rule and action are used to route the encapsulated traffic.

For example, assume the following configuration:

- An IPSec filter rule, FilterRule1, is configured for traffic with source address 9.1.1.1 and destination address 167.0.0.0/8 to have IPSec protection. Traffic is encapsulated and sent to router 9.2.2.2, the security gateway.
- A routing rule, FTPRULE, is configured for FTP traffic with source address 9.1.1.1. The associated action specifies that route table FTPRTES should be used to route traffic and that the main route table should not be searched.

Given this configuration, the following processing is performed for FTP traffic sent from IP address 9.1.1.1 to IP address 167.1.1.1:

1. The FTP traffic matches routing rule FTPRULE, and a route is found in route table FTPRTES that is used to route to destination 167.1.1.1.
2. The FTP traffic matches IPSec filter rule FilterRule1.
3. The FTP traffic is encapsulated and a new IP header is added with destination address 9.2.2.2.
4. The encapsulated packet is routed based on the routes defined in route table FTPRTES. To successfully send the traffic, route table FTPRTES must also contain a route that is used to route to destination 9.2.2.2. Otherwise, the traffic

would be sent using the route that was found to destination 167.1.1.1. The success of the traffic depends on network connectivity.

Requirement: When a routing rule applies to traffic that will be IPSec encapsulated and sent to a security gateway, the route tables associated with the routing rule and action must contain a route that can be used to reach the security gateway, as well as a route that can be used to reach the original destination.

For more information about IP security, see Chapter 19, "IP security," on page 923.

Considerations for mixed routing environments

Read this topic if you will be using any combination of static, dynamic, and policy-based routing on a single TCP/IP stack. These considerations will help you understand how these different types of routing interact, and how to configure them to get the results that you want.

Using static routing with OMPROUTE

You should not use non-replaceable static routes with OMPROUTE because this prevents those routes from being dynamically updated in response to network topology changes. An exception is when routes need to be defined to destinations that, for some reason, will not be learned dynamically through the routing protocol. If IPv4 static routes are required, use the BEGINROUTES or GATEWAY statement in PROFILE.TCPIP to define them. If IPv6 static routes are required, use the BEGINROUTES statement in PROFILE.TCPIP to define them.

TCP/IP treats static routes that are defined as replaceable on the BEGINROUTES statement as last-resort routes. If a dynamic route is learned for the destination that was specified in a replaceable static route, the dynamic route replaces the static route in the route table. Additionally, if a replaceable static route is replaced with a dynamic route, TCP/IP always retains knowledge of the replaceable static route and re-installs it if the destination becomes unreachable using dynamic routes. TCP/IP does not need to relearn replaceable static routes that have been replaced. For this reason, replaceable static routes can be used with OMPROUTE as backup routes to use if nothing is found dynamically.

Another situation in which static routes might be required is when multiple, equal-cost routes to a destination are needed and the RIP or IPv6 RIP routing protocol is used. Static routes might be required in this case because, with the exception of directly attached resources, the RIP and IPv6 RIP protocols do not create multiple, equal-cost routes to a destination. In other words, if multiple adjacent routers are advertising through RIP or IPv6 RIP that they can reach the same destination, OMPROUTE adds a route to the TCP/IP route table through only one of those adjacent routers. If more than one of these routes must exist, they need to be statically configured in PROFILE.TCPIP (using the BEGINROUTES or GATEWAY statement for IPv4 routes and the BEGINROUTES statement for IPv6 routes). For example, using Figure 37 on page 259, this would be necessary if you wanted host TCPCS4 to have two routes to the IPv6 prefix 2001:DB8:0:A10::/60 (one through router A and one through router B).

If a TCP/IP stack has multiple interfaces to a directly attached network and you want to use one interface for input packets and one for output packets (traffic splitting), you can use static routes. To use traffic splitting, you can define a static route for one and only one interface, forcing all output packets to use that interface. The other routers on the directly attached network have to be defined

with a similar static route, but for the other interface. Although this is the easiest way to implement traffic splitting, if one of the interfaces fails, a host might become unreachable even though the other interface remains active.

Tip: A more robust way of accomplishing traffic splitting is to use dynamic routes and make one route preferred over the other through the configured interface costs. For more information, see step 6 on page 303.

The BSDROUTINGPARMS statement in PROFILE.TCPIP is not used when the OMPROUTE routing daemon is used. Instead, the IPv4 interface characteristics, including subnet mask, are defined in the OMPROUTE configuration file.

Requirement: If you are using NCPROUTE with OMPROUTE, the BSDROUTINGPARMS statement is required to route Transport PDUs prior to OMPROUTE activation. Because the BSDROUTINGPARMS parameters are overridden by the IPv4 interface parameters defined in the OMPROUTE configuration, ensure that the interface parameters for the SNALINK or IP/CDLC channel connections are identical in the BSDROUTINGPARMS statement and the OMPROUTE configuration file.

Using IPv6 static routing with router advertisements

You should not use non-replaceable static routes with IPv6 router discovery, when those routes are to destinations that will be learned through received router advertisements. Defining these non-replaceable static routes prevents them from being dynamically updated in response to network topology changes. Examples of routes that are not learned through router advertisements are routes for which the destination address is a specific host address.

TCP/IP treats replaceable static routes as last-resort routes. These routes can be replaced by dynamic (router discovery) routes. In addition, if a replaceable static route is replaced with a dynamic route, TCP/IP always retains knowledge of the replaceable static route and can re-install it if the destination becomes unreachable using dynamic routes. TCP/IP does not need to relearn replaceable static routes that have been replaced. For this reason, replaceable static routes can be used with IPv6 router discovery as backup routes, to be used if nothing is learned dynamically.

Using policy-based routing with static or dynamic routing

If a policy-based route table is configured with both static routes and dynamic routing parameters, review the considerations in "Using static routing with OMPROUTE" on page 345. The same considerations apply with the following exceptions:

- References made to IPv6 in that topic do not apply, because policy-based routing is supported for IPv4 only.
- References made to static routes in that topic refer to static routes configured using the Route parameter on the RouteTable policy statement.

When policy-based routing is used, policies are defined that instruct the TCP/IP stack to use specific policy-based route tables when making routing decisions, based on the traffic being routed. The main route table is used only when one of the following are true:

- The traffic for which a route is being selected does not match any active policy-based routing rule.

- The traffic for which a route is being selected matches an active policy-based routing rule. However, no usable route exists in the route tables specified by policy to be used for the traffic, and the policy indicates that the main route table is to be used when this occurs.

Verifying static, dynamic, and policy-based routing

- If OMPROUTE is used for the OSPF protocol only and AUTOLOG is not configured correctly (see step 2 on page 278), OMPROUTE will be periodically restarted and the following messages are displayed:

```
$HASP100 OMPROUTE ON STCINRDR
$HASP373 OMPROUTE STARTED
IEF403I OMPROUT1 - STARTED
      OMPROUT1    OMPROUTE    BPXBATCH    0000
EZZ7800I OMPROUTE STARTING
EZZ7872I OMPROUTE FOUND ANOTHER ROUTING APPLICATION ALREADY ACTIVE
EZZ8074I OMPROUTE PROCESSING ERROR
EZZ7805I OMPROUTE EXITING ABNORMALLY - RC(11)
OMPROUT1    *OMVSEX     BPXPRECP    0011
IEF404I OMPROUT1 - ENDED
$HASP395 OMPROUT1 ENDED
```

- If a configuration statement in the OMPROUTE configuration file has a missing semicolon, the syntax checker might issue the following message:

```
EZZ7830I SYNTAX ERROR AT LINE 22 OF OMPROUTE CONFIGURATION FILE
PROCESSING END OF FILE
```

- If policy-based routing is in use, see the Netstat ALL/-A command report to determine the policy-based routing information in use by a TCP connection or UDP socket. If the value Yes is displayed for RoutingPolicy, RoutingTableName and RoutingRuleName reflect the last traffic attempted to be sent by the displayed TCP connection or UDP socket. RoutingRuleName displays the name of the routing policy rule that was last mapped to the traffic sent by the displayed TCP connection or UDP socket. RoutingTableName displays the name of the route table that was used to select the route for the last traffic sent by the displayed TCP connection or UDP socket. This can be the name of a policy-based route table associated with the displayed RoutingPolicyRule, EZBMAIN if the main route table was used, or *NONE* if a route was not found.

  If no traffic has been sent or the last traffic sent did not map to a configured routing rule, the value No is displayed for RoutingPolicy. RoutingTableName and RoutingRuleName are not included in the display when RoutingPolicy has the value No.

Verifying connections with Netstat, Ping, and Traceroute

The interfaces were verified with the instructions in Chapter 2, “IP configuration overview,” on page 11. The first thing to verify is that the devices and interfaces are started. In the case of point-to-point links like the CTCs in TCPCS4, the following message is written to the z/OS console when the device starts:

```
EZZ4313I INITIALIZATION COMPLETE FOR DEVICE CTCE02
```

In the case of IPv6 interfaces like OSAQDIO46 in TCPCS4, the following message is written to the z/OS console when the interface starts:

```
EZZ4340I INITIALIZATION COMPLETE FOR INTERFACE OSAQDIO46
```

The same information can be determined using the Netstat DEvlinks/-d command. Following is a portion of the output of the Netstat DEvlinks/-d command with the

CTCE02 device shown as ready. The Netstat DEvlinks/-d command can be issued on TCPCS4 and TCPCS7 to verify that the devices on both systems are ready.

```
DevName: CTCE02            DevType: CTC       DevNum: 0E00
  DevStatus: Ready
  LnkName: CTC4TO7           LnkType: CTC         LnkStatus: Ready
    NetNum: 0    QueSize: n/a
    ActMtu: 32760
  Routing Parameters:
    MTU Size: 01500             Metric: 01
    DestAddr: 0.0.0.0           SubnetMask: 255.255.255.0
  Multicast Specific:
    Multicast Capability: Yes
  GROUP             REFCNT
  -----             ------
  224.0.0.5         0000000001
  224.0.0.1         0000000001
  Link Statistics:
    BytesIn                          = 488
    Inbound Packets                  = 0
    Inbound Packets In Error         = 0
    Inbound Packets Discarded        = 0
    Inbound Packets With No Protocol  = 0
    BytesOut                         = 1092
    Outbound Packets                 = 0
    Outbound Packets In Error        = 0
    Outbound Packets Discarded       = 0
```

Following is a portion of the output of the Netstat DEvlinks/-d command with an IPv6 interface (OSAQDIO46) shown as ready.

```
IntfName: OSAQDIO46        IntfType: IPAQENET6 IntfStatus: Ready
    NetNum: n/a  QueSize: 0   Speed: 0000001000
   MacAddress: 0002559A3F65
    DupAddrDet: 1
    CfgRouter: Non                   ActRouter: Non
    CfgMtu: None                     ActMtu: 8992
  Multicast Specific:
    Multicast Capability: Yes
    RefCnt      Group
    ------      -----
    0000000001  ff02::1:ff03:1
    0000000002  ff02::1
  Interface Statistics:
    BytesIn                           = 592
    Inbound Packets                   = 0
    Inbound Packets In Error          = 0
    Inbound Packets Discarded         = 0
    Inbound Packets With No Protocol  = 0
    BytesOut                          = 1008
    Outbound Packets                  = 0
    Outbound Packets In Error         = 0
    Outbound Packets Discarded        = 0
```

If the devices do not have a LnkStatus or IntfStatus of Ready, this must be resolved before continuing. There are several things that might cause the LnkStatus or IntfStatus to not be ready. For example, the device might not be defined to z/OS correctly, the device might not be defined in PROFILE.TCPIP correctly, and so on.

You can use the PING command to verify indirect routes exist to others hosts within the network .

```
ping 9.67.107.7
 CS V1R6: Pinging host 9.67.107.7
 Ping #1 response took 0.048 seconds.
 READY
```

```
ping 2001:0db8:0:a1b:2:559a:3f65:3
 CS V1R6: Pinging host 2001:0db8:0:a1b:2:559a:3f65:3
 Ping #1 response took 0.051 seconds.
 READY
```

Use the Traceroute command to verify that the correct route is being taken for each indirectly attached host:

```
tracerte 9.67.107.5
 CS V1R6: Traceroute to 9.67.107.5 (9.67.107.5)
 1 9.67.106.7 (9.67.106.7)  40 ms  7 ms  6 ms
 2 9.67.107.5 (9.67.107.5)  9 ms  8 ms  9 ms
 READY
```

Following is an IPv6 example for indirectly attached hosts:

```
tracerte 2001:0db8:0:a1c:2:36a4:b39a:7
 CS V1R6: Traceroute to 2001:0db8:0:a1c:2:36a4:b39a:7
 at IPv6 address: 2001:0db8:0:a1c:2:36a4:b39a:7
 1 fe80::1:2:3:4
 (fe80::1:2:3:4) 13 ms 25 ms 40 ms
 2 2001:0db8:0:a1c:2:36a4:b39a:7
 (2001:0db8:0:a1c:2:36a4:b39a:7) 29 ms 263 ms 196 ms
```

Chapter 7. Virtual IP Addressing

This topic contains information about the following subtopics:

- Terminology
- Introduction to VIPA
- Moving VIPA (Upon outage of TCP/IP)
- Static VIPAs, dynamic VIPAs (DVIPAs), and distributed dynamic VIPAs
- Using static VIPAs
- Using dynamic VIPAs (DVIPAs)
- Choosing which form of dynamic VIPA to use
- Configuring distributed DVIPAs — sysplex distributor
- Resolution of DVIPA conflicts
- IPv6 considerations
- Other considerations
- Example of configuring dynamic and distributed VIPAs
- Verifying the DVIPAs in a sysplex
- Verifying sysplex distributor workload
- DVIPAs and routing protocols

Note: This information applies to both IPv4 and IPv6, unless otherwise noted.

Terminology

Virtual IP Address (VIPA)
A VIPA is a generic term that refers to an internet address on a z/OS host that is not associated with a physical adapter. There are two types of VIPAs:

- A *Static VIPA* cannot be changed except through a VARY TCPIP,,OBEYFILE operator command.
- A *dynamic VIPA (DVIPA)* can move to other TCP/IP stack members in a sysplex or it can be activated by an application program or by a supplied utility. Dynamic VIPAs are used to implement sysplex distributor as described in "Considerations for VIPA" on page 61.

Distributed DVIPA
A distributed DVIPA, which is a special type of DVIPA, can distribute connections within a sysplex.

Dynamic routing
VIPAs are designed to interoperate with a dynamic routing daemon. Therefore, it is highly recommended that a routing daemon be used on a z/OS host that uses VIPAs.

Introduction to VIPA

Traditionally, an IP address is associated with each end of a physical link (or each point of access to a shared-medium LAN), and the IP addresses are unique across the entire visible network, which can be the Internet or a closed intranet. The majority of IP hosts have a single point of attachment to the network, but some

hosts (particularly large server hosts) have more than one link into the network. A TCP/IP host with multiple points of attachment also has multiple IP addresses, one for each link.

Within the IP routing network, failure of any intermediate link or adapter disrupts end user service only if there is not an alternate path through the routing network. Routers can route IP traffic around failures of intermediate links in such a way that the failures are not visible to the end applications or IP hosts. However, because an IP packet is routed based on ultimate destination IP address, if the adapter or link associated with the destination IP address fails, there is no way for the IP routing network to provide an alternate path to the stack and application. Endpoint (source or destination) IP adapters and links thus constitute single points of failure. While this might be acceptable for a client host, where only a single user will be cut off from service, a server IP link might serve hundreds or thousands of clients, all of whose services would be disrupted by a failure of the server link.

The virtual IP address (VIPA) removes the adapter as a single point of failure by providing an IP address that is associated with a stack without associating it with a specific physical network attachment. Because the virtual device exists only in software, it is always active and never experiences a physical failure. A VIPA has no single physical network attachment associated with it. Also, the TCP/IP stack does not maintain interface counters for VIPA interfaces (VIRTUAL links).

To the routing network, a VIPA appears to be a host address indirectly attached to the z/OS. When a packet with a VIPA destination reaches the stack, the IP layer recognizes the address and passes it to the protocol layer in the stack.

The failure of the physical interface can be extended to the failure of the TCP/IP address space, the entire z/OS, or for planned outages. A VIPA just needs to move to a backup stack, and the routes to the VIPA need to be updated. Then clients can transparently connect to the backup stack. This process is known as VIPA takeover.

VIPA takeover improved with the introduction of dynamic virtual IP address (DVIPA) and distributed dynamic virtual IP address (distributed DVIPA). The DVIPA function improves VIPA takeover by allowing a system programmer to plan for system outages and provide for backup systems to take over without operator intervention or external automation. The distributed DVIPA function allows the connections for a single DVIPA to be serviced by applications on several stacks listed in the configuration statement (the distribution list). This adds the benefit of limiting the scope of an application or stack failure, while also providing enhanced work load balancing.

In general, z/OS configured with VIPA provides the following advantages:

- Automatic and transparent recovery from device and adapter failure.

  When a device (for example, a channel-attached router) or adapter (for example, an OSA-Express adapter) fails, if there is another device or link that provides the alternate paths to the destination:

  – IP will detect the failure, find an alternate path for each network, and route outbound traffic to hosts and routers on those networks via alternate paths.
  – Inbound and outbound traffic will not need to reestablish the active TCP connections that were using the failed device.
  – For connection requests originating at a z/OS TCP/IP stack, tolerance of device and adapter failures can be achieved by using source VIPA addressing.

- Recovery from z/OS TCP/IP stack failure (where an alternate z/OS TCP/IP stack has the necessary redundancy).

  Assuming that an alternate stack is installed to serve as a backup, the use of VIPAs enables the backup stack to activate the VIPA address of the failed stack.

  Connections on the failed primary stack will be disrupted but they can be reestablished on the backup using the same IP address as the destination. In addition, the temporarily reassigned VIPA address can be restored to the primary stack after the cause of failure has been removed.
- Limited scope of a stack or application failure.

  If a DVIPA is distributed among several stacks, the failure of only one stack affects only the subset of clients connected to that stack. If the distributing stack experiences the failure, a backup assumes control of the distribution and maintains all existing connections.
- Enhanced workload management through distribution of connection requests.

  With a single DVIPA being serviced by multiple stacks, connection requests and associated workloads can be spread across multiple z/OS images, according to Workload Manager (WLM) and Service Level Agreement policies (for example, QOS) or according to configured active connection distribution goals.
- Allows the non-disruptive movement of an application server to another stack so that workload can be drained from a system in preparation for a planned outage.

Moving a VIPA (for TCP/IP outage)

While a VIPA provides non-disruptive rerouting of IP data during failure of a physical interface, termination of the stack or the associated z/OS (including planned outages) will disrupt connections or UDP sessions to applications on the terminated stack. While failure of the TCP connection or UDP session will be visible to the clients, the duration of the outage is determined by how long the client application is unable to reconnect to an appropriate server application. Because it is common in large enterprises to have multiple instances of an application residing on different z/OS images, if the VIPA address can be moved to another stack that supports the application, the clients can reconnect and the perceived outage will be over.

An IP address associated with a particular physical device is unavailable until the owning stack is restarted; however, a VIPA is not associated with any particular physical interface. If termination of a stack is detected and a suitable application already is active on another stack, the VIPA can be moved. Connections on the terminated stack will be disrupted, but they can be reestablished on the backup stack using the original VIPA.

Movement of a static VIPA to a backup stack can be accomplished by using VARY TCPIP,,OBEYFILE commands on the backup. The data set specified on the command must contain an appropriate set of DEVICE, LINK, HOME, and optionally, BSDROUTINGPARMS statements for IPv4 static VIPAs or INTERFACE statements for IPv6 static VIPAs. If OMPROUTE is used as the routing daemon, an appropriate interface statement is needed in the OMPROUTE configuration file. If the TCP/IP configuration file with the statements defining the VIPA is created in advance, the transfer can be accomplished via automation. This procedure is documented in *z/OS Communications Server: IP Configuration Reference*. Movement of a DVIPA, on the other hand, can be accomplished by configuring a stack to backup a specific DVIPA that is defined on another stack. In this case, failure of the defining stack causes the DVIPA to move without operator intervention or extra

automation. See “Planning for dynamic VIPA takeover” on page 360 for more information. Regardless of the type of VIPA to be moved, it is up to the system programmer or operator to ensure that the VIPA is moved to a backup stack that has the appropriate server applications.

In the absence of a failure, a VIPA is just like any other IP address, and routing for a VIPA is the same as for an IP address associated with a physical link.

Static VIPAs, dynamic VIPAs, distributed DVIPAs

z/OS TCP/IP stack supports two types of VIPAs: static and dynamic. Dynamic VIPAs (DVIPAs) can be used to distribute connections in a sysplex. This is referred to as a distributed DVIPA.

All three VIPAs can coexist on a given stack, but there are differences in how these VIPAs are configured and used.

Static VIPAs have the following characteristics:

- They can be activated during TCP/IP initialization or VARY TCPIP,,OBEYFILE command processing, and are configured using an appropriate set of DEVICE, LINK, HOME, and optionally, OMPROUTE configuration statements or BSDROUTINGPARMS statements for IPv4 Static VIPAs or INTERFACE statements for IPv6 Static VIPAs.
- Using the SOURCEVIPA configuration option, static VIPAs can be used as the source IP address for outbound datagrams for TCP, RAW, UDP (except routing protocols), and ICMP requests. For IPv6 static VIPAs to be used as source addresses, the SOURCEVIPA configuration option must be enabled and the VIPA interface must appear on the SOURCEVIPAINT keyword on some other INTERFACE statement. This provides tolerance of device and adapter failures for connection requests originating at a z/OS TCP/IP stack.
- They can be specified as the source IP address for outbound TCP connection requests for all applications using this stack with TCPSTACKSOURCEVIPA.
- They can be specified as the source IP address for outbound TCP connection requests for specific jobs or specific destinations through the use of the SRCIP profile statement block.
- The number of static VIPAs on a stack is limited only by the range of host IP addresses that are available for that host.
- They can be moved to a backup stack after the original owning stack has failed, by using VARY TCPIP,,OBEYFILE command processing to configure the VIPA on the backup stack and updating the routers.

Dynamic VIPAs have the following characteristics:

- They can be configured to be moved dynamically from a failing stack to a backup stack within the same sysplex without operator intervention or external automation.
- They can be moved manually by deactivating or reactivating them with the VARY TCPIP,,SYSPLEX operator command.
- They can be dynamically activated by an application program.
- They can distribute connections within a sysplex.
- They can be specified on a TCPSTACKSOURCEVIPA statement. This allows a user to specify one VIPA to be used as the source IP address for outbound datagrams for TCP-only requests.

- They can be specified as the source IP address for outbound TCP connection requests for specific jobs or specific destinations by using the SRCIP profile statement block.
- Unlike static VIPAs, dynamic VIPAs:
  - Are limited to 1024 per stack.
  - Cannot be specified as the VIPA used by Enterprise Extender for connectivity purposes. (See "Configuring static VIPAs for Enterprise Extender" on page 358 for details.)

Distributed DVIPAs have the following characteristics:

- They have all the characteristics of DVIPAs, except that they cannot be dynamically activated by an application program.
- One stack defines a DVIPA and advertises its existence to the network. Stacks in the target distribution list activate the DVIPA and accept connection requests.
- Connection workload can be spread across several stacks.

See "Configuring distributed DVIPAs — sysplex distributor" on page 371 for more detailed descriptions.

Recommendation: OSA-Express devices have a limit on the number of IP addresses (both IPv4 and IPv6 addresses) that can be registered to the device. The limit is dependent on the microcode level of the OSA-Express device. This limit applies across all TCP/IP stacks that share the OSA-Express device. When defining a large number of VIPAs, take care not to exceed this limit. If the limit is exceeded, IP addresses beyond the limit will not be registered with the OSA-Express devices, and incoming packets with those IP addresses will not be routed to the correct stack unless that stack is designated as the primary router.

Using static VIPAs

The following topics describe how to configure static VIPAs, the special case of static VIPAs and Enterprise Extender, and how to implement static VIPA takeover.

Because a VIPA is associated with a z/OS TCP/IP stack and it is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex or *even* to any z/OS TCP/IP stack if the address fits into the network configuration.

Steps for configuring static VIPAs for a z/OS TCP/IP stack

Perform the following steps to configure a static VIPA address in one stack:

1. When configuring static VIPAs for the IPv4 network, add DEVICE, LINK, HOME, and optionally BSDROUTINGPARMS statements for each static VIPA to be defined. When configuring static VIPAs for the IPv6 network, add INTERFACE statements of type VIRTUAL6 for each static VIPA to be defined.

   Notes:

   a. A VIPA link or VIPA interface cannot be coded on a static route in the GATEWAY or BEGINROUTES statements.

   b. If you want to add a static VIPA in an IPv4 network with an address that already exists in the HOME list, you must first delete the existing address using the VARY TCPIP,,OBEYFILE command with the existing address omitted from the HOME list. Then use the VARY TCPIP,,OBEYFILE command with a new and complete HOME list.

2. For IPv4 networks, if tolerance of device and adapter failures is desired for connection requests originating at a z/OS TCP/IP stack, specify the SOURCEVIPA option on the IPCONFIG statement.

   Tips:

   - For the SOURCEVIPA option to work properly, the receiving nodes in the network must be configured to recognize the SOURCEVIPA addresses using the static or dynamic routing protocols. Otherwise, timeouts for the connection or request responses will occur as a result of the VIPA addresses being network unreachable.
   - If TCPSTACKSOURCEVIPA is specified on the IPCONFIG statement, it overrides SOURCEVIPA for outbound IPv4 TCP connections. If the SRCIP profile statement block is defined to establish one or more job-specific or destination-specific source IPv4 addresses, these IP addresses override TCPSTACKSOURCEVIPA or the VIPAs in the HOME list for IPCONFIG SOURCEVIPA, or both, for the specified job names and destinations. For information about the hierarchy of various ways that the source IP address of an outbound connection is determined, see "Source IP address selection" on page 218.

   For more information on configuring IPv4 SOURCEVIPA or TCPSTACKSOURCEVIPA addresses on the IPCONFIG statement, or SRCIP addresses in the SRCIP statement block, see *z/OS Communications Server: IP Configuration Reference*.

3. For IPv6 networks, if tolerance of device and adapter failures is desired for connection requests originating at a z/OS TCP/IP stack, specify the following:

   - The SOURCEVIPA option on the IPCONFIG6 statement.
   - The SOURCEVIPAINT keyword with a VIPA interface name on the INTERFACE statements of the real (physical) interfaces, or on the DYNAMICXCF specification on the IPCONFIG6 statement.

   Tips:

   - For the SOURCEVIPA option to work properly, the receiving nodes in the network must be configured to recognize the SOURCEVIPAINT addresses using the static or dynamic routing protocols. Otherwise, timeouts for the connection or request responses will occur as a result of the VIPA addresses being network unreachable.
   - If the TCPSTACKSOURCEVIPA parameter is specified on the IPCONFIG6 statement, it overrides the SOURCEVIPA value for outbound IPv6 TCP connections. If the SRCIP profile statement block is defined to establish one or more job-specific or destination-specific source IPv6 addresses, these IP addresses override the TCPSTACKSOURCEVIPA value, the SOURCEVIPAINT value, or both, for the specified job names and destinations. For information about the hierarchy of various ways that the source IP address of an outbound connection is determined, see "Source IP address selection" on page 218.

   For more information on configuring IPv6 SOURCEVIPA or TCPSTACKSOURCEVIPA addresses on the IPCONFIG6 statement, or SRCIP addresses in the SRCIP statement block, see *z/OS Communications Server: IP Configuration Reference*.

4. For host name resolution of a VIPA address, configure the domain name servers to associate the host name with the VIPA.

---

5. Configure the routing daemon to advertise the presence of the VIPA.

   As described in prior steps, remember that the VIPA to be advertised can be determined by the SOURCEVIPA or TCPSTACKSOURCEVIPA parameters on the IPCONFIG and IPCONFIG6 statements, or by the SRCIP statement. For more information, see *z/OS Communications Server: IP Configuration Reference*.

Figure 39 illustrates a simple configuration showing multiple network attachments using a single static VIPA address. Since any other network interface can be used with static VIPA's, see "Setting up physical characteristics in PROFILE.TCPIP" on page 221 for descriptions of other network interfaces. The simple configuration will be used as the TCPCS6 system throughout this information.

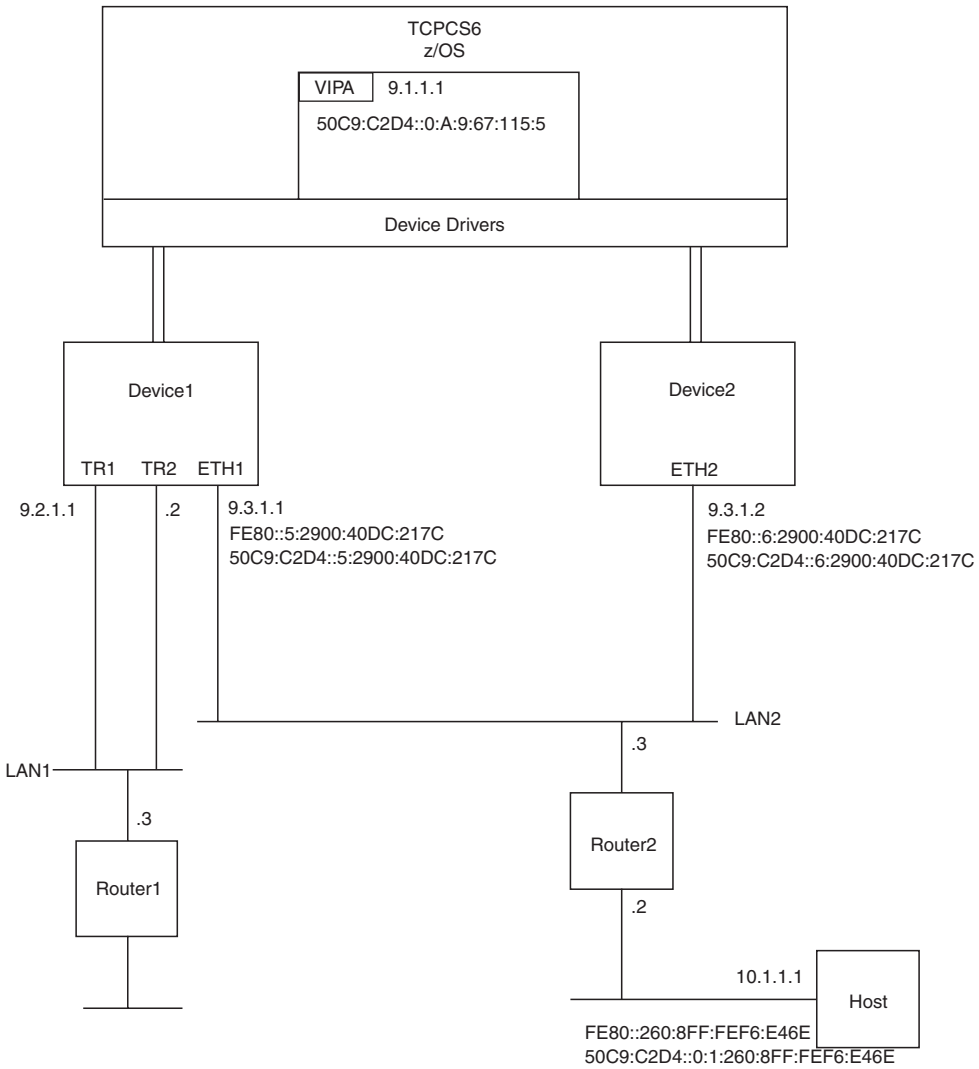

Figure 39. Static VIPA configuration

Configuring static VIPAs for Enterprise Extender

Defining at least one static VIPA is required by VTAM to access the IP network. Since VTAM does not move within a sysplex, a dynamic VIPA cannot be used. Enterprise Extender supports the use of multiple static VIPA addresses, and a VIPA address is chosen as follows:

1. VTAM uses the IPADDR value specified on the Enterprise Extender XCA major node GROUP definition statement, or the VIPA address obtained when name-to-address resolution is performed on the HOSTNAME value specified on the Enterprise Extender XCA major node GROUP definition statement.
2. If the GROUP definition statement specifies neither IPADDR nor HOSTNAME, VTAM uses the static VIPA address specified on the VTAM IPADDR start option, or the static VIPA address returned by the resolver when name-to-address resolution is performed on the value of the VTAM HOSTNAME start option.
3. If neither the IPADDR nor the HOSTNAME start option is specified, VTAM uses the first IPv4 static VIPA in the HOME list.

If remote APPN nodes use a host name and not a host address to define the destination of an Enterprise Extender connection, the domain name server must return the VIPA address used by VTAM for the host name. Alternatively, if the Enterprise Extender endpoints reside across a firewall or for another reason require network address translation, the domain name server should return a network address translation (NAT) address. This NAT address should in turn map, on the destination side, to the static VIPA address of the intended target VTAM host.

Rule: If you plan on using IPv4 protocols for your Enterprise Extender communication, you must define DEVICE, LINK, and optionally HOME statements for IUTSAMEH, or specify IPCONFIG DYNAMICXCF in the appropriate TCPIP profile data set. If you plan on using IPv6 protocols for your Enterprise Extender communication, you must define an INTERFACE statement for IUTSAMEH or specify IPCONFIG6 DYNAMICXCF in the appropriate TCPIP profile data set.

For more information about using Enterprise Extender, see *z/OS Communications Server: SNA Network Implementation Guide*.

Considerations when using static VIPAs with IPv6

When static VIPAs are configured for use with IPv6, it is recommended that the prefixes of the IPv6 VIPA addresses be different than the prefixes used for addresses assigned to real interfaces. This reduces the likelihood of address collisions between the manually configured VIPA addresses and the autoconfigured addresses of the real interfaces.

To allow other hosts that share links with the z/OS TCP/IP stack to access the IPv6 VIPA addresses, without the need for manual route configuration, a router on each of the links should include the VIPA prefix in its router advertisements. The router advertisements should define the prefix as being on-link and should indicate that the prefix should not be used for autoconfiguration.

Planning for static VIPA takeover and takeback

Because a VIPA is associated with a z/OS TCP/IP stack and is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex or even to any z/OS TCP/IP stack as long as the address fits into the network configuration. Moving a static VIPA can be done manually by an operator or by customer-programmed automation. Movement of the static VIPA allows

other hosts that were connected to the primary stack to reestablish connections with a backup TCP/IP stack using the same VIPA. After the primary TCP/IP stack has been restored, the reassigned VIPA address can be moved back.

Consider the following when backing up and restoring a z/OS TCP/IP stack:

- All connections on the failing host will be disrupted.
- The client can use any ephemeral port number when reestablishing the connection to the backup server.
- Having a different port number for the backup and primary server is not recommended. For example, if the primary FTP used port 21 and the backup FTP used port 1021, when backing up and restoring a z/OS TCP/IP stack, the client would have to know whether to use port 21 or 1021.

If you are deploying both static VIPA and OSA-Express QDIO, see "VIPAs, OSA-Express QDIO, and Spanning Tree Protocol" on page 406 to determine whether or not network bridge or switch configuration settings might potentially impact the environment for VIPA takeover and takeback.

Using dynamic VIPAs

Dynamic VIPA (DVIPA) support allows:

- Dynamic movement of a VIPA from a failing TCP/IP stack to a backup stack
- Dynamic allocation of a VIPA by an application program
- Manual movement of a VIPA by deactivating or reactivating it with the VARY TCPIP,,SYSPLEX command

Dynamic VIPAs (DVIPAs) are IP addresses like all other IP addresses associated with a TCP/IP, and they appear as though they had been defined at the end of the HOME list.

Dynamic VIPAs can be either IPv4 or IPv6, and both can be configured within the same VIPADYNAMIC block. A single statement (for example, VIPADEFINE or VIPABACKUP) must contain either IPv4 addresses or IPv6 addresses, but not both. However, statements containing IPv4 addresses can be intermixed with statements containing IPv6 addresses within the same VIPADYNAMIC block in any manner desired.

Configuring DVIPA support

Unlike static VIPAs, DVIPAs are not configured using DEVICE, LINK, and HOME statements (for IPv4) or using INTERFACE statements (for IPv6). The configuration statements for the DVIPA support are contained within the VIPADYNAMIC block and consist of the following:

- VIPADEFINE and VIPABACKUP statements used to configure DVIPAs to be dynamically moved from a failing TCP/IP to a backup TCP/IP
- VIPARANGE used to specify a range of IP addresses which may be dynamically activated as a VIPA by an application program
- VIPADELETE used to delete existing DVIPAs
- VIPADISTRIBUTE used to configure a DVIPA as a distributed DVIPA and designate the target stacks

The following topics discuss how these statements are used to provide the DVIPA support. For syntax details, see *z/OS Communications Server: IP Configuration*

Reference. For more information, see *Communications Server for z/OS V1R10 TCP/IP Implementation Volume 3: High Availability, Scalability, and Performance*, SG24–7698.

When dynamically created DVIPAs are deleted, any applications bound to those DVIPAs (VIPARANGE or MODDVIPA) will receive an asynchronous error, EUNATCH (3448) - the protocol required to support the address family is unavailable.

Planning for dynamic VIPA takeover

Movement by network management automation or operator intervention is not always desirable. Operator intervention takes time and is subject to errors. Automation requires proper detection of the failure and is also prone to error if the failure does not produce the exact console messages anticipated.

The dynamic VIPA takeover function addresses this problem. It is important to understand that dynamic VIPA takeover does not introduce functions that could not be accomplished by operator action or automation. It just removes the dependency on human detection of the error or customer programming for automation. Dynamic VIPA takeover is completely accomplished by the TCP/IP stacks.

DVIPA takeover is possible when a DVIPA is configured as active (using VIPADEFINE) on one stack and as backup (using VIPABACKUP) on another stack within the sysplex. When the stack on which the DVIPA is active terminates or leaves the sysplex group, the backup stack automatically activates the DVIPA and notifies the routing daemon. For information on what causes a stack to leave the sysplex group, see "Sysplex problem detection and recovery" on page 449.

For DVIPA takeover to be useful, the applications that service the DVIPA addresses must be available on the backup stacks. In the absence of the application, the DVIPA will be active, but client connections to the application will still fail. If OMPROUTE is used, it is recommended that GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN be configured. This causes DVIPA takeover to be delayed until OMPROUTE is active and able to advertise DVIPAs on the takeover stack. For more information on how DELAYJOIN works, see "Sysplex problem detection and recovery" on page 449.

To preserve connections during DVIPA takeover, the TCP/IP stacks require XCF links. The DYNAMICXCF option must be coded in the TCP/IP profile of both stacks.

A determination of how the workload will be distributed among the backup stacks when the primary stack fails should be made. It is possible to designate a single stack as a backup and move all the workload to it, or the workload can be spread among several stacks. In the first case, you need to configure only one DVIPA with a VIPADEFINE statement on the primary stack, and only one VIPABACKUP statement is required on the backup stack. For the second option, you must configure multiple DVIPAs with a VIPADEFINE statement on the primary stack.

After determining the workload distribution, each of the secondary stacks will require a VIPABACKUP statement for the DVIPA it will be supporting.

The following example shows how to implement a single stack backup for multiple applications.

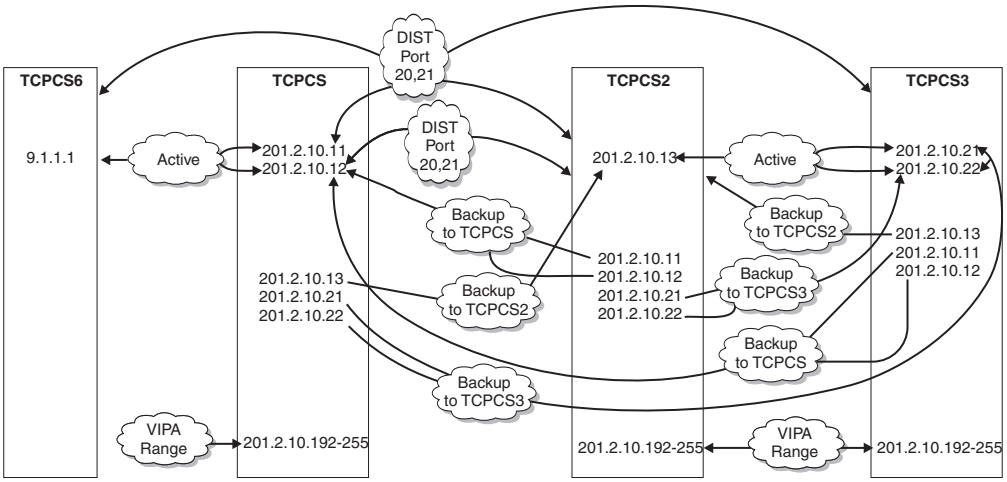

Figure 40. Sample DVIPA addressing in a sysplex environment

Stack TCPCS:

```
Uses VIPADEFINE to define 201.2.10.11
Has a Web server running that binds to INADDR_ANY.
  Web client programs use 201.2.10.11 as their destination address.
Has an FTP server running that binds to INADDR_ANY.
  FTP client programs use 201.2.10.11 as their destination address.
```

Stack TCPCS3:

```
Uses VIPABACKUP to define 201.2.10.11 as backup for stack TCPCS.
Has a Web server running that binds to INADDR_ANY.
Has an FTP server running that binds to INADDR_ANY.
```

In the preceding scenario, when stack TCPCS goes down, stack TCPCS3 receives all new connection requests for both the Web and FTP servers. FTP and Web client programs continue to use 201.2.10.11 as their destination address, but they now connect to stack TCPCS3.

The following example shows how to implement a multiple stack backup for multiple applications.

Stack TCPCS:

```
Uses VIPADEFINE to define 201.2.10.11 and 201.2.10.12
Has a Web server running that binds to INADDR_ANY.
  Web client programs use 201.2.10.11 as their destination address.
Has an FTP server running that binds to INADDR_ANY.
  FTP client programs use 201.2.10.12 as their destination address.
```

Stack TCPCS2:

```
Uses VIPABACKUP to define 201.2.10.11 as backup for stack TCPCS.
Has a Web server running that binds to INADDR_ANY.
```

Stack TCPCS3:

```
Uses VIPABACKUP to define 201.2.10.12 as backup for stack TCPCS.
Has an FTP server running that binds to INADDR_ANY.
```

In the preceding scenario, when stack TCPCS goes down, new connections for the Web server at 201.2.10.11 will connect with stack TCPCS2, and new connections for the FTP server at 201.2.10.12 will connect with stack TCPCS3.

Manually initiating takeover for an individual dynamic VIPA

There might be times when you want a takeover to occur for an individual DVIPA for temporary, operational purposes, such as dealing with temporary shifts in available capacity. An operator command, VARY TCPIP,,SYSPLEX,DEACTIVATE, is provided to deactivate an active VIPADEFINE DVIPA so that it appears to have been deleted from the stack. This enables an already-configured backup stack to takeover the DVIPA. This command also saves the original configuration definition.

When you want to move the DVIPA back to the original stack, you can issue another operator command, VARY TCPIP,,SYSPLEX,REACTIVATE, on the original stack to cause the DVIPA to be redefined with its saved configuration. This causes a VIPADEFINE DVIPA to be activated again on the original stack, and causes the backup stack to relinquish ownership of the DVIPA and return to being a backup stack.

The following example shows how to deactivate a DVIPA:

```
VARY TCPIP,,SYSPLEX,DEACTIVATE,DVIPA=203.1.1.99
```

The following example shows how to reactivate a DVIPA that has been deactivated:

```
VARY TCPIP,,SYSPLEX,REACTIVATE,DVIPA=203.1.1.99
```

Deactivating a DVIPA can be done only for DVIPAs that have been configured on the stack with VIPADEFINE or VIPABACKUP. You cannot deactivate a VIPARANGE DVIPA created by BIND, the SIOCSVIPA or SIOCSVIPA6 ioctl command, or the MODDVIPA utility. When you deactivate a DVIPA, if there are any existing connections to the DVIPA on this stack and there is another stack able to maintain the connections, the DVIPA is kept in QUIESCING status until the last connection terminates, and then the DVIPA is deactivated.

You can also use these operator commands to deactivate and reactivate a backup DVIPA. If you deactivate a DVIPA that is in backup status, it makes that stack ineligible to takeover the DVIPA. Reactivating a VIPABACKUP DVIPA makes the stack eligible again to takeover the DVIPA.

While a DVIPA is deactivated it still appears in the Netstat VIPADCFG/-F report, where it is identified as deactivated, but it does not appear in any other Netstat reports unless the DVIPA is in QUIESCING status or this stack is a target for that DVIPA from some other distributing stack.

Different application uses of IP addresses and DVIPAs

Not all IP-based server applications relate to IP addresses in the same way. Automated movement of DVIPAs, and the planning for dynamic VIPA takeover, must take this difference into account.

Some IPv4 or IPv6 applications, such as FTP or the TN3270E Telnet server (Telnet) will accept client requests on any IP address by binding to INADDR_ANY or the IPv6 unspecified address (in6addr_any). The distinguishing feature of such an application is the function it provides, such as the particular set of SNA applications for Telnet. If the function is replicated across multiple z/OS images in the sysplex, as is often the case for distributed workload, the DVIPA must merely be moved to a stack supporting the application. This scenario is called the multiple

application-instance scenario. For the multiple application-instance scenario, the stacks in the sysplex do all the work of activating a DVIPA in the event of a failure.

For other types of applications, each application instance must have a unique IP address. This scenario is called the unique application-instance scenario and uses DVIPAs that are activated with an ioctl or a bind().

To maintain the relationship between an application instance and its DVIPA, the application must indicate to the stack that the DVIPA needs to be activated. This occurs in the following cases:

- When the application instance issues a bind() function call and specifies an IP address that is not active on the stack. The stack will activate the address as a DVIPA, provided it meets certain criteria. When the application instance closes the socket, the DVIPA is deleted.
- Some applications cannot be configured to issue bind() for a specific IP address, but are unique application-instance scenario applications. For such applications, a utility is provided (MODDVIPA), which issues SIOCSVIPA or SIOCSVIPA6 ioctl() to activate or deactivate the DVIPA. This utility can be included in a JCL procedure or OMVS script to activate the DVIPA before initiating the application. As long as the same JCL package or script is used to restart the application instance on another node in the event of a failure, the same DVIPA will be activated on the new stack. For information about the authorization required to execute the MODDVIPA utility, see "Using the MODDVIPA utility" on page 368.
- An alternative for unique application-instance scenario server applications that cannot themselves bind to a unique IP address is to use the BIND parameter on the PORT reservation statement. It is always a good practice to reserve a port for the listening socket of a server application. If the BIND parameter and an IP address are specified on the PORT reservation statement for a server application, and the application binds a socket to that port and either the IPv4 INADDR_ANY address or the IPv6 unspecified address (in6addr_any), z/OS TCP/IP will convert the bind to be specific to the IP address specified on the PORT reservation statement. From that point on, it will appear as though the application itself had issued the bind() specifying the designated IP address, including having the IP address deleted when the server application closes the socket.

Configuring dynamic VIPAs

To allow continued and unchanged operation of static VIPAs in z/OS TCP/IP, DVIPAs are defined with configuration statements in the PROFILE.TCPIP data set. An overview of the relevant configuration statements is provided in the following topics, and also see "Verifying the DVIPAs in a sysplex" on page 412 for a description of the configuration statements. For an example of the VIPADYNAMIC configuration statement and display commands for dynamic VIPAs, see *z/OS Communications Server: IP Configuration Reference*.

Configuring the multiple application-instance scenario

For the multiple application-instance scenario, each instance is assigned a unique DVIPA. The VIPADEFINE keyword of the VIPADYNAMIC configuration statement is used to create the DVIPA on the stack where the DVIPA is normally expected to be active. When the VIPADEFINE statement is processed in a TCP/IP profile, corresponding DEVICE, LINK, HOME, and BSDROUTINGPARMS statements are

generated automatically for IPv4 addresses. For IPv6 addresses, an INTERFACE statement is automatically generated. Routing daemons are automatically informed.

Additional configuration is required on other stacks in the sysplex to indicate which stack should take over the DVIPA in the event of a failure. The VIPADYNAMIC statement has a VIPABACKUP keyword for this purpose. A VIPABACKUP configures the DVIPA but does not activate it until it is necessary. Because more than one TCP/IP can backup a single DVIPA, a rank parameter on the VIPABACKUP statement determines the order in which several stacks will assume responsibility for a DVIPA.

The stacks in the sysplex exchange information on all VIPADEFINEs and VIPABACKUPs defined in the sysplex, so that all are aware of which stack should take over a particular DVIPA. The list of backup stacks for a specific DVIPA can be different from the list of backup stacks for all other DVIPAs.

In the multiple application-instance scenario, instances of the application in question are activated among sysplex nodes according to some plan, presumably related to balancing workload across available capacity. This activation is done independently of VIPA takeover. Configure the associated DVIPAs as follows:

1. For each instance of a particular application to be supported via DVIPA, add a VIPADEFINE statement to the TCP/IP profile for the TCP/IP associated with the application instance.
2. For each of the dynamic VIPAs in step 1, determine which application instance or instances should take over the workload (considering probable capacity and any other application-related considerations). If more than one TCP/IP is to provide backup for a DVIPA, determine the order in which the selected TCP/IPs should be designated as backup. Add a VIPABACKUP statement to each TCP/IP that is to provide backup for the DVIPA, with appropriate rank values to determine the order. Do this for each of the DVIPAs in step 1.
3. Perform steps 1 and 2 for each other application to be supported by DVIPAs.

   Note: It is possible to share a dynamic VIPA among several different applications, but in doing so, ensure that instances of all such applications will exist together on any TCP/IP to which the DVIPA may be moved in case of a failure.

After these steps are complete, start the affected TCP/IPs (or modify their configuration using the VARY TCPIP,,OBEYFILE command), if applicable, configure DNS for the application names, and start the application instances. From that point on, the TCP/IPs in the sysplex will collaborate to ensure that each dynamic VIPA is kept active somewhere within the sysplex as long as there is at least one functioning TCP/IP which has been designated as backup for the dynamic VIPA.

Configuring the unique application-instance scenario

The unique application-instance scenario ties a DVIPA to a specific instance of an application. To isolate errors in configuring applications, TCP/IP needs a mechanism to identify permissible DVIPAs. This is provided with one or more VIPARANGE statements. The VIPARANGE statement identifies a range of IP addresses which can be activated as DVIPAs by an application instance. Each TCP/IP stack can have up to 256 VIPARANGE definition statements for IPv4 and up to 256 for IPv6. The VIPARANGE statement consists of an IPv4 address and subnet mask, or an interface name and an IPv6 address and prefix length, and defines a subnet for DVIPAs. More than one VIPARANGE statement with different

ranges can be defined on a TCP/IP. VIPARANGE does not itself cause any DVIPAs to be activated. Rather, DVIPAs are activated either by an application issuing a bind() for a specific IP address, by use of the SIOCSVIPA or SIOCSVIPA6 ioctl() command issued by an authorized application, or by the MODDVIPA utility.

When an application issues bind() for a specific IP address or an address was selected using the BIND keyword on the PORT statement, the receiving stack checks it against addresses in the HOME list. If the IP address has already been activated on this stack (whether for a physical device, a static VIPA, or a dynamic VIPA), the bind() execution is successful. If the IP address is not active on this TCP/IP, the current VIPARANGEs are checked to see if the IP address falls within one of them. If an appropriate VIPARANGE is found, the IP address is activated as a DVIPA and the operation succeeds. If no appropriate VIPARANGE is found, or if the IP address is active elsewhere in the sysplex other than by a NONDISRUPTIVE bind(), the request fails and bind() returns EADDRNOTAVAIL.

When an authorized application issues the SIOCSVIPA or SIOCSVIPA6 ioctl() command to create a DVIPA, or when the MODDVIPA utility is executed in JCL or an OMVS script to activate a DVIPA on behalf of an application instance, the current VIPARANGES are checked to see whether the IP address falls within one of them. If an appropriate VIPARANGE is found, and the IP address is not currently active on this TCP/IP or elsewhere in the sysplex as an IP address or a VIPADEFINE/VIPABACKUP dynamic VIPA, then the IP address is activated as a DVIPA. However if no appropriate VIPARANGE is found on this TCP/IP, or if the IP address is currently defined on this TCP/IP or configured elsewhere in the sysplex as an IP address or a VIPADEFINE/VIPABACKUP dynamic VIPA, then the request fails with errno and errnojr set to indicate the reason for the failure and the utility ends with a nonzero condition code. See “Dynamic VIPA creation results” on page 396 for more information.

Tip: If the requested IP address has been activated as a dynamic VIPA by a bind(), SIOCSVIPA ioctl, or SIOCSVIPA6 ioctl elsewhere in the sysplex, the result depends on how the stacks were configured. See “Dynamic VIPA creation results” on page 396 for more information.

Application-instance DVIPAs provide high availability features for applications and workloads that exploit them. The creation and movement of these DVIPAs is quite flexible, as it can be triggered without modification to the TCP/IP profile and without issuing TCP/IP operator commands. While this flexibility is useful, it can also present problems for the network administrator in determining when and how a DVIPA is activated on a TCP/IP stack.

To help alleviate these problems, TCP/IP provides auditing facilities to track the state changes of application-instance DVIPAs. When an application-instance DVIPA is created or deleted dynamically through an explicit bind, by executing the MODDVIPA utility or by invoking the SIOCSVIPA or SIOCSVIPA6 ioctl command, messages are issued (EZD1204I, EZD1205I, EZD1206I, or EZD1207I) to the job log of the TCP/IP started procedure and to the system log. These messages include the method (bind, ioctl, or MODDVIPA utility) used to create or delete the DVIPAs, and the job name at the time the bind, ioctl, or MODDVIPA utility was invoked. For more information about EZD1204I, EZD1205I, EZD1206I, and EZD1207I, see *z/OS Communications Server: IP Messages Volume 2 (EZB, EZD)*.

The Netstat VIPADyn/-v report is enhanced for application-instance DVIPAs to include the job name and the time stamp that this DVIPA was activated on the local TCP/IP stack (either because it is the owner of the DVIPA or is a target for

this DVIPA). For more details about Netstat VIPADyn/-v, see *z/OS Communications Server: IP System Administrator's Commands*.

In the unique application-instance scenario, each application instance is assigned a unique IP address as its DVIPA. Before defining individual DVIPAs, one or more blocks of IP addresses must be defined for these DVIPAs, and the individual DVIPAs must be defined from within the blocks. Each block should be represented as a subnet, so that a VIPARANGE statement can be defined for it.

Follow these steps when setting up any unique application instances:

1. For each application instance, assign a DVIPA from one of the blocks of IP addresses for this purpose. Do not assign an IP address which is also assigned to another application instance, or which is defined by VIPADEFINE for the multiple application-instance scenario. Configure the application to use this DVIPA [if it issues bind() for a particular IP address], or add a BIND parameter to the PORT reservation statement for the port of the application's listening socket to cause the listening socket to be bound to this DVIPA. Alternatively, add the MODDVIPA utility to the JCL or OMVS script and configure the MODDVIPA utility to activate the DVIPA before starting the application. When the application ends, use the MODDVIPA utility to delete the DVIPA.
2. For each application instance, determine on which stack the application instance will normally be executed and to which stacks the application instance could be moved in case of failure of the normal stack or the application itself. For each such stack, add a valid VIPARANGE statement to the profile.

   Note: The dynamic VIPA must be within the VIPARANGE subnet. The broadcast address and the net prefix cannot be used.
3. Perform steps 1 and 2 until all application instances have been allocated a unique DVIPA.

The application restart strategy should ensure that the worst-case failure scenario does not attempt to activate more than 1024 DVIPAs on a single stack. If such an attempt is made, activation of the 1025th DVIPA will fail, with possible resulting loss of connectivity from clients to the server application.

Note: The limit of 1024 DVIPAs on a single TCP/IP applies to all DVIPAs, whether defined by VIPADEFINE/ VIPABACKUP configuration statements, through a VIPADISTRIBUTE statement on another stack, by a bind() call, or by executing the MODDVIPA utility.

Defining a single block makes the definition process easier, but also provides less individual control. Alternatively, since the smallest subnet consists of four IP addresses, defining a unique subnet for each DVIPA in this scenario *wastes* three other IP addresses that could have been used for DVIPAs.

Using the SIOCSVIPA or SIOCSVIPA6 ioctl command

An ioctl command, SIOCSVIPA or SIOCSVIPA6, allows an application to create or delete a dynamic VIPA on the stack where the application is running. The application issuing the SIOCSVIPA or SIOCSVIPA6 ioctl command must be APF authorized. If there is no security product, or if the security product indicates that no profile for MODDVIPA has been defined, the application must be running under a user ID with superuser authority. If the profile for the MODDVIPA program has been defined, the user ID must be permitted READ access to the profile even if the ID has superuser authority. Some security products indicate that there is no access available when no profile is defined. If you are not using RACF,

you might need to define the profile to use these ioctl commands. For more information, see "Defining a security profile for MODDVIPA" on page 369.

To create a new dynamic VIPA, the requested IP address must be within a subnet that has been previously specified by a VIPARANGE configuration statement in the PROFILE.TCPIP data set for this stack. The SIOCSVIPA or SIOCSVIPA6 ioctl command can be used to delete any existing dynamic VIPA on the stack, except for distributed DVIPAs.

The following example shows how to set up the SIOCSVIPA ioctl command for applications that will use IPv4 addresses.

```
#include "ezbzdvpc.h"               /* header that contains
                                      the structure for
                                      SIOCSVIPA ioctl
                                       and needed constants*/
struct dvreq dv;                    /* the structure passed
                                         on the ioctl command*/
dv.dvr_version = DVR_VER1;           /*version               */
dv.dvr_length = sizeof(struct dvreq);  /* structure length     */
dv.dvr_option = DVR_DEFINE;           /* to define a new
                                         dynamic VIPA.  Use
                                         DVR_DELETE to delete
                                         a dynamic VIPA        */
dv.dvr_addr.s_addr = inet_addr(my_ipaddr);  /* where my_ipaddr is
                                               a character string
                                               in standard
                                               dotted-decimal
                                               notation */
```

The ioctl command is then invoked as follows:

```
rc = ioctl(s, SIOCSVIPA, &dv);
```

The following example shows how to set up the SIOCSVIPA6 ioctl command using the input parameter list that supports IPv6 addresses.

```
#include "ezbzdvpc.h"           /* header that contains
                                    the structure for
                                    SIOCSVIPA6 ioctl
                                    and needed constants */
 struct dvreq6 dv6;              /* the structure passed on
                                    the ioctl command */
 dv6.dvr6_version = DVR_VER2;   /* version */
 dv6.dvr6_length = sizeof(struct dvreq6); /* structure length */
 dv6.dvr6_option = DVR_DEFINE;  /* to define a new dynamic
                                    VIPA.  Use DVR_DELETE to
                                    delete a dynamic VIPA. */
inet_pton(AF_INET6, my_ipv6addr, dv6.dvr6_addr6.s6_addr);
                                 /* where my_ipv6addr
                                    is a character string in
                                    standard IPv6 address
                                    notation, representing a
                                    fully qualified IPv6
                                    address */
```

The ioctl command is then invoked as follows:

```
rc = ioctl(s, SIOCSVIPA6, &dv6);
```

The SIOCSVIPA or SIOCSVIPA6 ioctl command sets nonzero errno and errnojr values to indicate error conditions. See *z/OS Communications Server: IP and SNA Codes* for a description of the errnojr values returned.

Using the MODDVIPA utility

You can use the MODDVIPA utility to activate or delete a dynamic VIPA. The utility can be initiated from JCL or an OMVS script. MODDVIPA must be loaded from an APF-authorized library and be run under a user ID that has an OMVS segment defined (or by default). If there is no security product, or if the profile for MODDVIPA has not been defined, the application must be running under a user ID with superuser authority. If the profile for the MODDVIPA program has been defined, the user ID must be permitted READ access to the profile even if the ID has superuser authority. For more information, see "Defining a security profile for MODDVIPA" on page 369.

Input parameters: The input parameters for the utility are:

-p <tcpipname>
Specifies the TCP/IP which is to create or delete a DVIPA.

-c <IPaddress> or -d <IPaddress>
Specifies to create (**-c**) or delete (**-d**) the address (IP address) specified.

Notes:

1. The input parameters **-p**, **-c**, and **-d** must be entered in lowercase.
2. <*tcpipname*> must be entered in upper case.
3. For IPv4 addresses, <*IPaddress*> is dotted-decimal notation. For IPv6 addresses, <*IPaddress*> is standard colon-hexadecimal notation for specifying IPv6 addresses.
4. To create a DVIPA, the specified IP address must be within a subnet that has been previously specified by a VIPARANGE configuration statement in the PROFILE.TCPIP data set for the specified TCP/IP.

Output: The MODDVIPA utility sets the following exit (completion) codes for create (**-c**):

0 Success: The DVIPA was activated.

4 Warning: The requested DVIPA was not activated because the specified IP address is already active on this stack.

8 Error: The IP address was not defined as a DVIPA on this TCP/IP.

12 An error was found in the input parameters

The MODDVIPA utility sets the following exit (completion) codes for delete (**-d**):

0 Success: The dynamic VIPA was deleted.

8 Error: The requested DVIPA was not deleted.

12 An error was found in the input parameters

Notes:

1. When an error is detected, the ernno text and errnojr value are printed to stderr.
2. If the IP address requested for the DVIPA is not within a VIPARANGE configured on this stack, completion code 8 is returned even if the IP address is currently active on this stack

Examples

Within JCL:

```
//TCPDVP EXEC  PGM=MODDVIPA,REGION=0K,TIME=1440,                      X
//             PARM='POSIX(ON) ALL31(ON)/-p TCPCS3 -c 1.2.3.4'
```

From OMVS shell:

```
moddvipa -p TCPCS3 -c 1.2.3.4
```

From the TSO command prompt:

```
moddvipa -p TCPCS3 -c 1.2.3.4
```

Restriction: MODDVIPA must be listed in the AUTHCMD NAMES section of the IKJTSO*xx* member of SYS1.PARMLIB.

Defining a security profile for MODDVIPA

Note: Wherever SIOCSVIPA is used in this topic, SIOCSVIPA6 can be used as well.

You can restrict access to the MODDVIPA (EZBXFDVP) program by defining a security profile under the SERVAUTH class and specifying the user IDs that are authorized to execute the SIOCSVIPA ioctl or the MODDVIPA utility program. You can decide on the level of control that is appropriate for your installation.

To restrict access to the SIOCSVIPA ioctl (and thus the MODDVIPA utility), you can define a security profile using the following RACF example:

```
RDEFINE SERVAUTH (EZB.MODDVIPA.sysname.tcpname)
        UACC(NONE)

PERMIT EZB.MODDVIPA.sysname.tcpname
       ACCESS(READ) CLASS(SERVAUTH) ID(USER1)
```

If you are using another security product, see the documentation for that product for the equivalent commands.

In this example, *sysname* is the name of the MVS system where the ID will execute the MODDVIPA utility or issue the SIOCSVIPA ioctl, and *tcpname* is the job name of the TCP/IP started task. The job name for started tasks, such as TCP/IP, is derived depending on how it is started:

- If the START command is issued with the name of a member in a cataloged procedure library (for example, S TCPIPX), the job name will be the member name (for example, TCPIPX).
- If the member name on the START command is qualified by a started task identifier (for example, S TCPIPX.ABC), the job name will be the started task identifier (for example, ABC). The started task identifier is not visible to all MVS components, but TCP/IP uses it to build the RACF resource name.
- The JOBNAME parameter can also be used on the START command to identify the job name (for example, S TCPIPX,JOBNAME=XYZ).
- The JOBNAME can also be included on the JOB card.

In this example, user ID *USER1* is being permitted to invoke the MODDVIPA utility (and thus the SIOCSVIPA ioctl).

If this security profile is created, the user ID must be permitted to access this profile or else the SIOCSVIPA ioctl (and thus the MODDVIPA utility) will fail with a 'permission denied' error, regardless of SuperUser authority.

Also note that when using RACF, a refresh of these profiles might be required before they take effect. This can be accomplished by the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

For more information, see *z/OS Security Server RACF Security Administrator's Guide*.

Choosing which form of dynamic VIPA support to use

The following topics explain which of the features should be used for the type of application being used.

When should VIPADEFINE and VIPABACKUP be used to define a dynamic VIPA?

- One or more applications bind to the IPv4 INADDR_ANY address or to the IPv6 unspecified address (in6addr_any), and the applications exist on multiple TCP/IPs.
- Dynamic VIPA takeover is desired.
- The DVIPA does not need to be deleted when the application is stopped.

When should VIPARANGE and bind() be used to define a dynamic VIPA?

- The application cannot bind to INADDR_ANY or in6addr_any, or dynamic VIPA takeover is not desired.
- The IP address to which the application binds can be controlled by the user. The application's first explicit bind (the listening socket) will remain for the life of the application. Otherwise, the DVIPA will be removed everytime the application's DVIPA owning socket is closed, and re-added everytime there is a new DVIPA owning socket (another explicit bind has been done and the DVIPA does not exist).
- Automatic deletion of the dynamic VIPA when the application is stopped is acceptable.
- A specific dynamic VIPA address must be associated with a specific application.
- The application is not APF authorized, or not run under a user ID with superuser authority.

When should VIPARANGE and the MODDVIPA utility (or ioctl command SIOCSVIPA or SIOCSVIPA6) be used to define a dynamic VIPA?

- The application cannot bind to INADDR_ANY or in6addr_any, or dynamic VIPA takeover is not desired.
- The IP address to which the application binds is known but cannot be controlled by the user.
- Automatic deletion of the dynamic VIPA when the application is stopped is not acceptable.
- The MODDVIPA utility (or application issuing the ioctl command) will be run from an APF-authorized library and under a user ID with appropriate authority. See "Using the SIOCSVIPA or SIOCSVIPA6 ioctl command" on page 366 or "Using the MODDVIPA utility" on page 368.

Configuring distributed DVIPAs — sysplex distributor

A distributed DVIPA exists on several stacks, but is advertised outside the sysplex by only one stack. This stack receives all incoming connection requests and routes them to all the stacks in the distribution list for processing. This provides the benefit of distributing the workload of incoming requests and providing additional fail-safe precautions in the event of a server failure.

You can distribute connections destined for a dynamic VIPA (DVIPA) by adding a VIPADISTRIBUTE configuration statement for a previously defined dynamic VIPA. The order of the statements is important. The VIPA is first defined with the VIPADEFINE statement and then included on a VIPADISTRIBUTE statement. Another TCP/IP can act as a backup for the distributed DVIPA by properly coding a VIPABACKUP statement; the backup will perform the routing function in the event of a failure. The options specified on a VIPADISTRIBUTE statement are inherited by a backup stack unless the second stack has its own VIPADISTRIBUTE statement for that DVIPA, in which case it will use its own VIPADISTRIBUTE statement for distributing. You can also code a VIPADISTRIBUTE statement with just the VIPABACKUP statement and not for the VIPADEFINE statement. This would allow workload distribution only during a primary outage.

You can change the distribution of a DVIPA after a backup stack has activated it. However, if the backup stack did not not have its own distribution defined by a VIPADISTRIBUTE statement before it activated the DVIPA, any distribution changes made while the DVIPA is active on the backup stack are temporary. Those changes will be in effect while the DVIPA remains active on the backup stack, but will not be remembered if this stack takes over the DVIPA again in the future.

Following is an example of a properly coded distributed DVIPA:

```
IPCONFIG SYSPLEXROUTING DYNAMICXCF 193.9.200.4 255.255.255.240 1
IPCONFIG6 DYNAMICXCF 2000::93:9:200:4
VIPADYNAMIC
  VIPADEFINE  255.255.255.192 9.67.240.02
  VIPADISTRIBUTE DEFINE  9.67.240.02 PORT 20 21 8000 9000 DESTIP
          193.9.200.2
          193.9.200.4
          193.9.200.6
  VIPADEFINE V6DVIPA1 2000::9:67:240:2
  VIPADISTRIBUTE DEFINE V6DVIPA1 PORT 20 21 8000 9000 DESTIP
          2000::93:9:200:2
          2000::93:9:200:4
          2000::93:9:200:6
ENDVIPADYNAMIC
```

Prior to z/OS V1R6 Communications Server, the TCP/IP stack that was configured as a distributor of dynamic VIPAs was required to enable IP forwarding using the IPCONFIG (or IPCONFIG6) DATAGRAMFWD TCP/IP profile statement. For installations that do not wish to configure their TCP/IP stack as a forwarding node, it is no longer a requirement for distributing dynamic VIPAs. However, if your installation is configured such that target TCP/IP stacks only have XCF connectivity, datagram forwarding still needs to be configured on the distributor, as all packets originating from the target will be forwarded by the distributor.

There are several configuration changes that can be made to affect the method the distributing stack will use to forward connections to the target stacks. In each of the following items, *all participating stacks* is used to refer to the distributing stack and all target stacks.

WLM-based forwarding based on target system workload

If the DISTMethod BASEWLM parameter is specified on the respective VIPADISTRIBUTE statement, or if the DISTMethod parameter is not specified, this distribution method is enabled. This is the default distribution method. To enable the distributing stack to forward connections based upon the workload of each of the target stacks, specify SYSPLEXROUTING on the IPCONFIG statement in all participating stacks. This registers all participating stacks with WLM and enables the distributing stack to request workload information from WLM.

The WLM workload information is based on a comparison of available general CPU capacity for each target system. If the application uses System z Application Assist Processor (zAAP) capacity or System z Integrated Information Processor (zIIP) capacity, you can configure the VIPADISTRIBUTE statement so that available zAAP CPU capacity and zIIP CPU capacity are also considered. For these additional processor types to be considered, no distributor and target systems used by this application can be earlier than z/OS V1R9 Communications Server. If you need to consider zAAP and zIIP CPU capacity, evaluate whether you can use SERVERWLM distribution as an alternative to BASEWLM distribution for this application. SERVERWLM distribution has the advantage that processor proportions are automatically determined and dynamically updated by WLM based on the actual CPU usage of the application. If you need BASEWLM distribution, to determine the processor proportions to configure, study the workload usage of assist processors by analyzing SMF records, using performance monitors reports such as RMF, and so on.

WLM-based forwarding based on server-specific workload

If the DISTMethod SERVERWLM parameter is specified on the respective VIPADISTRIBUTE statement, the distributing stack selects from the available servers for a DVIPA/port and forwards connections based on a WLM recommendation indicating how well each server is executing on its system. To enable the distributing stack to forward connections based on server-specific workload, specify SYSPLEXROUTING on the IPCONFIG statement in all participating stacks.

If the server uses System z Application Assist Processor (zAAP) capacity or System z Integrated Information Processor (zIIP) capacity, processor proportions are automatically determined and dynamically updated by WLM, based on the actual CPU usage of the application; however, you can influence the WLM server-specific recommendation with configuration options on the VIPADISTRIBUTE statement. You can use the PROCXCOST parameter on the VIPADISTRIBUTE statement so that the WLM recommendation favors servers with available zAAP or zIIP capacity over servers on which work targeted for the specialty processors might instead run on the conventional processor. You can also use the ILWEIGHTING parameter on the VIPADISTRIBUTE statement to influence how aggressively the WLM recommendation favors servers on systems with displaceable capacity at lower importance levels over servers on systems with displaceable capacity at higher importance levels. For these additional factors to be considered by WLM, no systems can run a release prior to z/OS V1R11 Communications Server.

WLM/QoS-based forwarding

Regardless of whether BASEWLM or SERVERWLM weights are being used, to enable the distributing stack to forward connections based upon a combination of workload information and network performance information (TCP retransmissions and time-outs), specify

SYSPLEXROUTING on the IPCONFIG statement in all participating stacks, and also define a sysplex distributor performance policy on the target stacks. For information on configuring these policies, see "Sysplex distributor policy example" on page 884.

Round-robin forwarding
If the DISTMethod ROUNDROBIN parameter is specified on the respective VIPADISTRIBUTE statement, the distributing stack uses a round-robin mechanism to select one of the DVIPA/port targets for each connection.

Weighted active forwarding
If the DISTMethod WEIGHTEDActive parameter is specified on the respective VIPADISTRIBUTE statement, the distribution of incoming TCP connection requests is balanced across the targets, such that the number of active connections on each target is proportionally equivalent to a configured active connection weight for each target. However, server-specific abnormal completion information, server-specific health information, and the TSR value are used to reduce the active connection weight when these indicators are not optimal. To enable the distributing stack to use server-specific abnormal completion and health information to affect the active connection weight, specify SYSPLEXROUTING on the IPCONFIG statement for all participating stacks.

Hot-standby forwarding
If the DISTMethod HOTSTANDBY parameter is specified on the respective VIPADISTRIBUTE statement, one preferred target server and one or more backup (hot-standby) target servers are configured. The distributing stack does not perform load balancing of new connection requests across multiple targets; Instead, the preferred target server with an active listener receives all new incoming connection requests, and the hot-standby target servers, which typically also have a ready listener application, do not receive any new connection requests. If the preferred target server becomes unavailable, then the highest ranked backup server becomes the active target server and receives all new connection requests. To enable the distributing stack to use server-specific abnormal completion and health information to affect the availability of the preferred target, specify SYSPLEXROUTING on the IPCONFIG statement for all participating stacks.

Target-controlled forwarding
If the DISTMethod TARGCONTROLLED parameter is specified on the respective VIPADISTRIBUTE statement, distribution is controlled using weights that are received from the targets. This distribution method can be used with only non-z/OS tier 1 targets, such as DataPower appliances. For more information, see "Sysplex distribution with DataPower" on page 491.

Result: If you have not made the changes needed to enable WLM-based forwarding (SYSPLEXROUTING has not been specified for all participating stacks), and BASEWLM or SERVERWLM is specified, the distributing stack will use round-robin forwarding to distribute connections.

Tip: The weights received from WLM are returned based on the first 24 characters of the HOSTNAME value. The HOSTNAME value is determined by the search path at initialization time. To ensure correct distribution, verify that the first 24 characters of each HOSTNAME value are unique for every system.

Regardless of the distribution method used, sysplex distributor routing policies can further affect the distribution of connections. Sysplex distributor routing policies,

configured on the distributing stack, are used to specify a set of target stacks for a given set of traffic. For example, all traffic destined to a given port/DVIPA from a specified subnet can be assigned one group of target stacks, while traffic for the same port/DVIPA from another subnet can be assigned to a different group of target stacks. For more information on configuring these types of policies, see "Sysplex distributor policy example" on page 884.

Distribution of connections to target servers can also be affected by the responsiveness of the target stacks or target servers. The sysplex distributor stack monitors how well target servers respond to connection setup requests, calculating a target server responsiveness (TSR) value for each server.

For WLM-based forwarding based on target system workload, WLM/QoS-based forwarding, WLM-based forwarding based on server-specific workload, or weighted active forwarding, new connection setup requests are diverted away from target servers that are handling connection setup requests relatively poorly. For round-robin forwarding, if the sysplex distributor determines that a target server is not successfully accepting connection setup requests at all, that target server is bypassed. Periodically, the distributor sends a new connection request to a target with a TSR of 0, to check whether the responsiveness of that target has improved.

By default, the sysplex distributor updates the status of each target server at 1-minute intervals as follows:

- When BASEWLM distribution is being used, the distributor polls WLM for new system weights.
- When SERVERWLM distribution is being used, each target stack polls WLM for server-specific weights and sends these weights to the distributor.
- The TSR value for each server is updated.

The default 1-minute interval is sufficient for most workloads. However, in some environments, particularly when the load on each target system will be close to 100% capacity and when the workload consists of a high volume of short-lived connections, you might want to use a shorter interval so that the distributor reacts faster to changes in a target server's status. You can change the interval by using the SYSPLEXWLMPOLL parameter on the GLOBALCONFIG statement.

Each distributing stack and each target stack must have an IPv4 or IPv6 DYNAMICXCF address, or both. This address is used by other distributing stacks as a destination point. When using sysplex distributor, do not define an IUTSAMEH link. These links will be created automatically from the DYNAMICXCF statement. See *z/OS Communications Server: IP Configuration Reference* for directions for coding DYNAMICXCF on the IPCONFIG or IPCONFIG6 statements. For more information on additional configuration parameters required, also see the usage notes related to the DYNAMICXCF parameter under the IPCONFIG or IPCONFIG6 statements in *z/OS Communications Server: IP Configuration Reference*.

The VIPADISTRIBUTE statement specifies how new connection requests are routed to a set of candidate target stacks. The VIPADISTRIBUTEd DVIPA can be followed by up to 64 ports. The preceding example shows the well-known ports for FTP and the ports for a custom application.

Up to 32 target TCP/IPs follow the DESTIP keyword and are identified by their respective dynamic XCF IP addresses. Alternatively, the VIPADISTRIBUTE

statement can specify DESTIP ALL, in which case all current and future stacks with activated dynamic XCF can participate in the distribution as candidate target stacks. As an application listens to one of the specified ports on each listed TCP/IP, the routing TCP/IP begins to forward connections to that stack.

Guideline: If you are using OMPROUTE for connectivity to a dynamic VIPA, the LPAR with the distributing stack that owns that dynamic VIPA is the only target stack (that is, no remote target stacks are available), and a HiperSockets (iQDIO) interface is not configured, code a static route representing the shared IP address in the attached network router to maintain connectivity; otherwise, because a HiperSockets interface is not configured, OMPROUTE does not advertise the routing information representing the shared IP address for the dynamic XCF interfaces in that LPAR, and the address might become unreachable because the interfaces to the remote target stacks are deleted or marked inactive. Unlike IUTSAMEH and DXCF interfaces, a HiperSockets interface that shares an IP address can remain active when there are no more remote target stacks available, and OMPROUTE advertises the routing information to the neighboring network routers (for example, Cisco) for connectivity to the shared IP address.

For more information about sysplex distributor, see *Communications Server for z/OS V1R10 TCP/IP Implementation Volume 3: High Availability, Scalability, and Performance*, SG24–7698.

Manually quiescing DVIPA sysplex distributor server applications

You can stop a particular server application, or all server applications, on a target stack from receiving new DVIPA sysplex distributor workload using the VARY TCPIP,,SYSPLEX command with the QUIESCE parameter and either the PORT=*portnum*, JOBNAME=*jobname*, or TARGET parameter.

This command, entered on the target stack where the application exists, prevents the application from receiving any new DVIPA sysplex distributor connections but does not affect existing connections. This command can be issued to gracefully quiesce a target application or target system, before the application or system is brought down for planned maintenance. It can also be used to temporarily divert new workload requests from a particular application or a target stack.

The VARY TCPIP,,SYSPLEX command with the RESUME parameter and either the PORT=*portnum*, JOBNAME=*jobname*, or TARGET parameter can then be used to resume using the application as a target for new DVIPA sysplex distributor connections.

For more details on the VARY TCPIP,,SYSPLEX command and its parameters, see *z/OS Communications Server: IP System Administrator's Commands*.

Route selection for distributing packets

Sysplex distributor uses the dynamic XCF interfaces (DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statements) to distribute all incoming packets to target stacks. For information about how to determine route selection to tier 1 non-z/OS targets, see "Sysplex distribution with DataPower" on page 491.

Using dynamic XCF interfaces has several advantages, such as simplified configuration, because you can leverage the existing XCF communication links in your sysplex environment and do not have to define separate communication

paths to all target systems. This is especially useful in scenarios where target systems do not have direct network connectivity, but rather rely on the network connectivity of the routing stacks.

Sysplex distributor also includes some optimization logic that enables it to select alternative network paths for forwarding DVIPA packets. This optimization logic is automatically performed by the sysplex distributor in the following configurations:

- When the routing stack and the target stacks reside in the same MVS image, the routing stack uses internal communication links (IUTSAMEH) to forward DVIPA packets to the target, avoiding an external network altogether.
- When the routing stack and a target stack are running in different LPARs but on the same zSeries central processor complex (CPC), and HiperSockets connectivity is available, the HiperSockets connectivity is automatically used for forwarding DVIPA packets instead of the dynamic XCF interfaces.

These optimizations provide the best performance characteristics for forwarding DVIPA packets within the same CPC.

For configurations where the routing and target stacks reside in different CPCs, there are some scenarios where it might be desirable to use interfaces other than the dynamic XCF interfaces for forwarding distributed DVIPA packets:

- When sysplex XCF communication interface links, whether configured through CTCs or through the coupling facility, are constrained or are heavily used by other, non-DVIPA communications.
- When the routing and target stacks have direct network connectivity over high speed, low latency, and wide bandwidth networks, such as access to the same Gigabit Ethernet segments using the OSA-Express feature.

In these configurations, forwarding DVIPA packets over these alternative network connections can actually improve performance (that is, reduce latency and CPU cost) while reducing the utilization of sysplex XCF interfaces.

You can use the VIPAROUTE statement in the VIPADYNAMIC block in the TCP/IP profile to influence the sysplex distributor's logic in selecting a route and interface to forward DVIPA packets to a target stack. Using the VIPAROUTE statement, you can indicate which IP address on the target stack is to be used as the destination or target IP address during the route lookup selection. When sysplex distributor processes the incoming packet, it determines whether a matching VIPAROUTE statement has been defined, and if it has, the TCP/IP stack returns the best available route to reach the target IP address. The incoming packet is then encapsulated using a destination of the VIPAROUTE target IP address in the outer header, and forwarded to the target stack. Generic routing encapsulation (GRE) is used to encapsulate IPv4 packets, while an outer IPv6 header is used to encapsulate IPv6 packets. This enables you to select the optimal interface for forwarding DVIPA packets across different CPCs, while retaining the optimized communication paths when the routing and target stacks reside on the same MVS image, the same CPC, or both.

If you do not want to use the dynamic XCF interfaces at all, you must define the dynamic routes so that the cost to reach the IP address on the target stack using the dynamic XCF interfaces is higher than the cost to reach that IP address using other interfaces. For more information, see “Steps for configuring OSPF and RIP (IPv4 and IPv6)” on page 288. If this is not done, it is possible that dynamic XCF interfaces will be used if the normal routing tables select those interfaces. By ensuring that the route using the dynamic XCF interfaces has a higher cost, you

can exploit the other interfaces for forwarding most DVIPA traffic, yet maintain the dynamic XCF interface as a backup should the preferred network interfaces fail.

In the following cases, even though VIPAROUTE was specified, the dynamic XCF interface is used for distribution:

- A target IP address is specified that is not owned by the target stack.
- The defined dynamic XCF address is for a pre-V1R7 target stack.

When these conditions are detected, messages are issued at the distributing stack, as well as when the distributing stack first attempts to route a connection request to the target stack.

The dynamic XCF address must still be configured even if VIPAROUTE definitions are used, as sysplex distributor continues to use a dynamic XCF address to identify every target TCP/IP stack in the sysplex. In addition, there are several functions that continue to depend on dynamic XCF connectivity for intra-sysplex communications:

- Sysplex-wide security associations (SWSA)
- Multilevel security packets
- QoS performance data collection of Policy Agent

Generic routing encapsulation

Generic routing encapsulation (GRE) is a standard protocol described by RFC 1701, and is used for several TCP/IP functions. GRE is implemented for only IPv4 packets. GRE enables a wrapper to be placed around a packet during transmission of the data. A receiving stack that supports GRE removes the GRE wrapper, enabling the original packet to be processed by the receiving stack. GRE is often used to deliver a packet to a stack using an alternate destination IP address.

Fragmentation considerations

For IPv4, when incoming packets destined for a DVIPA address need to be forwarded to a target TCP/IP stack using a route that was determined by a VIPAROUTE statement, the packet is encapsulated using GRE prior to being forwarded. This enables the packet to be forwarded through the network to the target stack while preserving the original packet's destination IP address (that is, the DVIPA address). The GRE encapsulation process increases the size of the forwarded packet by 28 bytes. As a result, if the size of the encapsulated GRE packets are larger than the maximum transmission unit (MTU) of the network interface that will be used for forwarding the packet, the TCP/IP stack might need to perform fragmentation, creating two or more packets that are forwarded to the target stack. The target stack then reassembles the fragmented packets.

While fragmentation and reassembly processing is not unusual in an IP network, it is generally desirable to eliminate the need for this processing, thereby optimizing performance. In the case of fragmentation resulting from GRE encapsulation, the cost of the fragmentation and reassembly processing might become a concern if a large percentage of the incoming DVIPA packets to be forwarded require fragmentation. Fortunately, configuration options do exist that can help eliminate the need for this fragmentation and reassembly processing, including the following:

- Enable path MTU discovery on the client IP hosts (that is, client hosts sending packets to the DVIPA). This enables the client hosts to dynamically discover the smallest MTU along the path from the client to the server. In the case of forwarded DVIPA traffic, the path MTU is adjusted (reduced) by the length of

the GRE header, if the addition of this header would have resulted in fragmentation being required. For IPv6, path MTU discovery is automatically enabled for all hosts, and no explicit configuration should be required.

- Ensure that the MTU size of the routes over the network interfaces that are used to forward the DVIPA packets is large enough to account for the largest client packet plus the length of the GRE header. This might be an option if the clients are connected to networks with a smaller MTU size than what is available in the network paths between the z/OS hosts (that is, the TCP/IP stack forwarding the DVIPA packets and the target TCP/IP stack). Consider the following example:
  - The majority of the client hosts are connected to the network using Fast Ethernet, and as result use an MTU of 1492.
  - The route selected using the VIPAROUTE statement specifies a network path over OSA-Express Gigabit Ethernet between the two z/OS hosts. Gigabit Ethernet accommodates a much larger MTU size than Fast Ethernet (8992 versus 1492). This larger MTU size with Gigabit Ethernet is often referred to as jumbo frames.

  In this configuration, the z/OS hosts can be configured to take advantage of the larger MTU size when communicating with each other over the Gigabit Ethernet network. As a result, fragmentation is avoided for these forwarded DVIPA packets, as the larger MTU easily accommodates the increased packet size resulting from the GRE encapsulation. However, it is important to ensure that this larger MTU size is used only for communications among hosts where the entire network path supports the larger MTU size. Otherwise, packets sent from the z/OS hosts using the larger MTU size might need to be fragmented as they cross network boundaries that support only lower MTU sizes. As a result, when configuring larger MTU sizes, such as jumbo frames for Gigabit Ethernet, it is also important to consider enabling path MTU discovery on the hosts using the larger MTU size. This enables these hosts (in this example, the z/OS hosts) to use the larger MTU size only where appropriate, without introducing fragmentation. For more information on specifying MTU sizes on z/OS, see "Maximum transmission unit considerations" on page 95.

Dynamic port assignment

Sysplex distributor can also react dynamically to servers binding to the distributed DVIPA and creating a listening socket, adding a port to the list of ports for which connection workload balancing will occur. If the PORT parameter is omitted from the VIPADISTRIBUTE statement for the distributed DVIPA, any server that binds to the distributed DVIPA and a nonzero port will be eligible for workload distribution. If only one server binds to the distributed DVIPA and port and establishes a listening socket, that server will get all of the work. When the second server binds to the distributed DVIPA and the same port and establishes a listening socket, it will immediately become eligible to participate in connection workload balancing. TCP/IP will not enforce a limit on the number of ports that can participate in connection workload balancing per distributed DVIPA, other than the total number of allowable ports.

Sysplex-wide source VIPA

Sysplex distributor addresses the requirement of providing to clients outside a parallel sysplex a single-IP-address appearance to application instances spread across the sysplex, and also the distribution of the incoming work among the various instances. Many applications are part of a cooperative network of applications, and the sysplex applications that serve as clients to end users might also have to initiate (client-like) outbound connection requests to cooperating applications. The SOURCEVIPA feature allows applications to attain independence

of any physical adapter, but SOURCEVIPA is limited to statically defined VIPAs within a stack. Different instances of the same application using sysplex distributor, and thus having a single IP address for inbound connection requests, will use different IP addresses for their outbound connection requests.

These problems are resolved by allowing a single sysplex-wide VIPA to be used as the source IP address for TCP applications and to have the sysplex stacks collaborate on assigning ephemeral ports to prevent duplicate connection 4-tuples (combination of source and destination IP addresses and ports). These solutions are provided by SYSPLEXPORTS, in conjunction with either job-specific source IP addressing or sysplex-wide source VIPAs for TCP connections.

For information on job-specific or destination-specific source IP addressing using the SRCIP statement, see *z/OS Communications Server: IP Configuration Reference*.

Sysplex-wide source VIPAs for TCP connections

The TCPSTACKSOURCEVIPA keyword on the IPCONFIG or IPCONFIG6 statements allows users to specify a single VIPA, static or dynamic, to be used as a source IP address for TCP applications that initiate outbound connections on that stack. TCPSTACKSOURCEVIPA is only in effect when SOURCEVIPA is enabled and an application issues a connect() without a bind(). Applications that perform an explicit bind() do not use the TCPSTACKSOURCEVIPA address. Applications using the Pascal API TcpOpen() call have an explicit bind() performed for them.

Guideline: Because the SRCIP profile statement provides all of the functionality of the TCPSTACKSOURCEVIPA parameter and additional granularity, consider using the SRCIP statement instead of specifying the TCPSTACKSOURCEVIPA parameter. Specifying JOBNAME * in a SRCIP profile statement provides the same result as specifying the TCPSTACKSOURCEVIPA parameter for implicit bind scenarios, and also applies to applications that issue a bind to the IPv4 INADDR_ANY address or to the IPv6 unspecified address (in6addr_any).

Tip: The TCPSTACKSOURCEVIPA parameter overrides the VIPA IP addresses in the HOME list or the SOURCEVIPAINTERFACE specification, but the TCPSTACKSOURCEVIPA parameter can be overridden. For information about the hierarchy of various ways that the source IP address of an outbound connection is determined, see “Source IP address selection” on page 218.

If you specify TCPSTACKSOURCEVIPA and do not specify SOURCEVIPA in a profile, a warning message is issued and TCPSTACKSOURCEVIPA will not be enabled. The address specified does not need to be active on the stack at profile processing time. For example, a valid TCPSTACKSOURCEVIPA address can be an address that will be a target address on this stack for sysplex distribution.

If the TCPSTACKSOURCEVIPA address is not an active VIPA on the stack at the time a connect() is issued, the connect() call goes through normal source IP address selection. A warning message will be issued no more than once every five minutes (to avoid flooding the system console), indicating an attempt to use the address specified in TCPSTACKSOURCEVIPA failed.

TCPSTACKSOURCEVIPA can be coded on all target stacks. The target TCPSTACKSOURCEVIPA statements can specify individual unique addresses, or can be duplicates of those specified on the distributing stack (a target DVIPA). Specifying the same DVIPA address for TCPSTACKSOURCEVIPA on the distributor and all target stacks creates a sysplex-wide source VIPA and raises the concern for coordination of ephemeral ports across the sysplex.

For information on diagnosing sysplex-wide source VIPAs for TCP connections problems, see *z/OS Communications Server: IP Diagnosis Guide*.

SYSPLEXPORTS

Whenever two or more application instances use the same source IP address and initate connections to the same destination IP address and port, sysplex-wide coordination of assignment of ephemeral ports is required so that the 4-tuple for each connection remains unique. As long as the source IP address is on a single stack, this coordination is not a problem because the stack manages assignment of ephemeral ports. However, with sysplex distributor applications, multiple application instances might need to initiate connections using the same distributed DVIPA, potentially to the same destination IP address and port, so uniqueness of the connection 4-tuples cannot be guaranteed unless the stacks collaborate across the sysplex for ephemeral port assignment for distributed DVIPAs. This can be done by adding the optional SYSPLEXPORTS parameter to the VIPADISTRIBUTE statement.

You must specify the SYSPLEXPORTS parameter on the first VIPADISTRIBUTE statement processed for a particular DVIPA. SYSPLEXPORTS cannot be enabled after a DVIPA has been configured for distribution. After you have enabled SYSPLEXPORTS, you cannot disable it until you have deleted all distribution for the DVIPA. If you want to specify the SYSPLEXPORTS parameter on a VIPADISTRIBUTE statement in the data set referenced by a VARY TCPIP,,OBEYFILE command, you must delete the existing VIPADISTRIBUTE statement in one data set, and then add the statement back in a second data set. An example of the contents of a data set that deletes an existing distributed DVIPA is as follows:

```
VIPADYNAMIC
VIPADISTRIBUTE DELETE
10.1.1.1 PORT 20 21
DESTIP ALL
ENDVIPADYNAMIC
;
```

An example of the contents of a data set that adds SYSPLEXPORTS to this DVIPA is as follows:

```
VIPADYNAMIC
VIPADISTRIBUTE DEFINE SYSPLEXPORTS
10.1.1.1 PORT 20 21
DESTIP ALL
;
ENDVIPADYNAMIC
```

When a distributed DVIPA can be active on more than one target stack, SYSPLEXPORTS can be specified to cause the stacks to collaborate in the assignment of ephemeral ports for outbound initiated TCP connections. This ensures that two different connections do not end up with the same connection 4-tuple.

At profile processing time, a stack with a profile that contains a SYSPLEXPORTS parameter on a VIPADISTRIBUTE statement connects to the coupling facility SYSPLEXPORTS structure containing sysplex port assignment information. The name of this structure is in the format EZBEPORT*vvtt*, where *vv* is the 2-character VTAM group ID suffix specified on the XCFGRPID start option, and *tt* is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is specified, but a TCP/IP group ID suffix is specified, *vv* is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is

specified, *tt* is not present. If neither group ID suffix is specified, both *vv* and *tt* are not present. The structure will be a list structure with an entry for each DVIPA address that has a VIPADISTRIBUTE statement with SYSPLEXPORTS specified anywhere in the sysplex (or within the subplex, if subplexing is being used). The first stack to connect to the EZBEPORT*vvtt* structure for a particular DVIPA creates an entry for that DVIPA in the coupling facility. The stack creates and initializes, in the EZBEPORT*vvtt* structure, a sublist for this DVIPA of assigned ports for this stack. For more information about setting up EZBEPORT*vvtt*, see Setting up the sysplex environment for VTAM and TCP/IP functions in *z/OS Communications Server: SNA Network Implementation Guide*.

The stack also maintains a list of allowable ephemeral ports on this stack, which is basically any port number above 1023 that has not been reserved for TCP by a PORT or PORTRANGE statement. Only port number values in this list will be allocated for use by this stack for its SYSPLEXPORTS DVIPAs. Since this list is unique to a particular stack and determined by stack configuration, a port number that is not permissible for one stack because it has been reserved might be allowable for another stack, and could in fact be allocated for use by that stack for a SYSPLEXPORTS DVIPA.

Under the following conditions, the first time an application issues a TCP bind() with port 0 or a connect() request, TCP/IP will receive an unassigned group of ports from the coupling facility structure that are allowable as ephemeral ports on the stack (not otherwise reserved by PORT or PORTRANGE):

- The bind() or connect() request uses a distributed DVIPA as the source address (whether by the application explicitly binding the socket to the designated DVIPA or by the stack assigning the TCPSTACKSOURCEVIPA address).
- The distributed DVIPA is designated as SYSPLEXPORTS.

The stack will assign an ephemeral port from the obtained group as the source port for the TCP connection request, and the coupling facility structure will be updated to show the group of ports as assigned. The stack will assign ports from within this group for each subsequent equivalent bind() request. If all the ports within the group are used, the stack will obtain another group of ports from the coupling facility.

This means that the maximum number of simultaneously active outbound connections using sysplex-wide ephemeral port assignment is approximately 63000 for a particular distributed DVIPA, and is exactly equal to all port numbers between 1024 and 65535 that have not been reserved with a PORT or PORTRANGE configuration statement on all stacks at the same time. This is the same as for ephemeral port assignment within a single stack. That is, a single z/OS TCP stack supports no more than about 63000 simultaneously active, locally initiated TCP connections whose source ports are ephemeral ports assigned by the stack. If a stack is unable to successfully obtain an ephemeral port from the coupling facility for a SYSPLEXPORTS DVIPA, the connection request will be terminated with an error indication.

If you send a connection request to a distributed DVIPA that is enabled for SYSPLEXPORTS and a random ephemeral port with no associated listener, then this connection will time out.

For information on diagnosing SYSPLEXPORTS problems, see *z/OS Communications Server: IP Diagnosis Guide*.

GLOBALCONFIG EXPLICITBINDPORTRANGE

You must specify the EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG profile statement if you are using or intend to use either of the following:

- A distributed DVIPA as a source IP address in a DESTINATION rule in a SRCIP block
- A distributed DVIPA as a source IP address in a JOBNAME rule in a SRCIP block for an application that might use an IPv6 socket to connect to a mapped IPv4 destination address (this applies only if the stack is IPv6 enabled)

The EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement establishes a pool of ephemeral ports that is managed to guarantee the uniqueness of an assigned port across the sysplex (or subplex). This pool of ports is used to provide a sysplex-wide unique ephemeral port for any application that issues an explicit bind() to INADDR_ANY or the IPv6 unspecified address (in6addr_any) and port 0 before issuing a connect() request.

If an application uses an explicit bind() to INADDR_ANY or in6addr_any and port 0 before connecting, TCP assigns an ephemeral port from this pool to assure uniqueness across the sysplex, because it cannot be determined at the time of the explicit bind() whether the source IP address determined at connect() time might be a distributed DVIPA derived from a match on a JOBNAME or DESTINATION rule in the SRCIP block. Sysplex-wide coordination of the assigned ephemeral port value is required when the source IP address is a distributed DVIPA, so that each connection 4-tuple remains unique across the sysplex.

Restriction: The use of the EXPLICITBINDPORTRANGE pool of sysplex-wide unique ports is not supported in some common INET (CINET) configurations. It is supported if stack affinity is established, or if there is only one active TCP/IP stack for CINET to manage. In other cases, the parameter is accepted, but the results are unpredictable.

When EXPLICITBINDPORTRANGE is configured, selecting a distributed DVIPA during connect processing from a matching SRCIP JOBNAME or DESTINATION rule is also permitted when the application has explicitly bound the source port to either a port number less than 1024 or to an ephemeral port that is reserved for the job by a PORT or PORTRANGE profile statement. However, if the source port is bound to an ephemeral port that is not reserved for the job and the source address selected from a SRCIP rule during connect processing is a distributed DVIPA, the connect request will fail.

Rule: If the source port is either less than 1024 or a port that is reserved for this job and the specified source is a distributed DVIPA, ensure that multiple outbound connections to the same destination IP address and port cannot occur concurrently with the same source IP address and port.

When a profile is processed, a stack with a profile that contains a GLOBALCONFIG statement with an EXPLICITBINDPORTRANGE parameter does the following:

- Connects to the coupling facility SYSPLEXPORTS structure that contains sysplex port assignment information
- Associates the stack with the pool established by the EXPLICITBINDPORTRANGE parameter

The structure is a list structure with an entry for each DVIPA address that has a VIPADISTRIBUTE statement with the SYSPLEXPORTS parameter anywhere in the sysplex (or within the subplex, if subplexing is being used). List 0 contains entries to maintain the explicit bind port range pool. Each stack that associates itself with the pool sets the port range for that pool. The stack creates and initializes, in the structure, a sublist in list 0 of assigned ports for that stack.

Note: The name of this structure is in the format EZBEPORT*vvtt*, where the *vv* value is the 2-character VTAM group ID suffix specified on the XCFGRPID start option, and the *tt* value is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is specified, but a TCP/IP group ID suffix is specified, *vv* is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is specified, *tt* is not present. If neither group ID suffix is specified, both *vv* and *tt* are not present. For more information about setting up EZBEPORT*vvtt*, see setting up the sysplex environment for VTAM and TCP/IP functions in *z/OS Communications Server: SNA Network Implementation Guide*.

Guidelines:

- When the GLOBALCONFIG EXPLICITBINDPORTRANGE statement in the TCP/IP profile is processed, each stack sets the range for the pool established by the EXPLICITBINDPORTRANGE parameter for all the participating stacks in the sysplex. If each stack defines a different range, the last EXPLICITBINDPORTRANGE parameter processed supercedes any previously specified port ranges. To prevent the range from varying based on the order in which stacks complete their profile processing, specify the same port range for each stack that configures GLOBALCONFIG EXPLICITBINDPORTRANGE. You can do this by specifying the GLOBALCONFIG EXPLICITBINDPORTRANGE statement in a file that is included in each stack's TCP/IP profile using an INCLUDE statement.
- Avoid overlap of the explicit bind port range with other ports or port ranges reserved through the PORT or PORTRANGE profile statements. If a port in the pool established by the EXPLICITBINDPORTRANGE parameter is reserved on a TCP/IP stack through the PORT or PORTRANGE statements, the port cannot be allocated to that stack for EXPLICITBINDPORTRANGE processing. This might restrict the number of ports in the explicit bind port range that are actually available for EXPLICITBINDPORTRANGE processing. For example, if you have defined an explicit bind port range 40000 – 41000, and you have a PORTRANGE statement on that stack that reserves ports 40500 – 41000, only ports 40000 – 40499 are available to that stack for EXPLICITBINDPORTRANGE processing.

  If an application binds to a port in the explicit bind port range that has been reserved using a PORT or PORTRANGE statement, the bind is allowed, but the port is not treated as an EXPLICITBINDPORTRANGE port. It is not marked in the SYSPLEXPORTS coupling facility structure for coordination across the sysplex. This situation might cause connections to fail as a result of duplicate connection 4-tuples.

  If an application binds to a port in the explicit bind port range that has not been reserved using a PORT or PORTRANGE statement, the bind fails with errnojr JrExpBndPortRangeConflict (x734C).

To remove a stack's participation in the EXPLICITBINDPORTRANGE pool, specify the GLOBALCONFIG statement with the NOEXPLICITBINDPORTRANGE parameter using a VARY TCPIP,,OBEYFILE command. This causes that stack to disassociate itself from the EXPLICITBINDPORTRANGE pool. If you do this and

you have applications that issue an explicit bind() to INADDR_ANY or in6addr_any and port 0 on this stack that might match the following rules, you must ensure that no distributed DVIPAs are used as the source IP address on the matching rule.

- The DESTINATION rule of the SRCIP block on this stack
- A JOBNAME rule of the SRCIP block on this stack, where the application associated with the job name might use an IPv6 socket to connect to an IPv4 mapped destination address (this applies only to stacks that are IPv6 enabled)

Timed affinities

Sysplex distributor normally distributes each connection request, as it arrives to one of the candidate server instances, based on available capacity and policies in effect when the connection request arrives. In particular, each connection is assumed to be independent of all other existing and future connections, with respect to the server instance that will receive the incoming connection request.

Some applications, however, establish an affinity between a client and a particular server instance that needs to span multiple connections. TN3270E Telnet server printer sessions, for example, are based on a connection request from a Telnet client, and that printer session connection request needs to be routed to the same TN3270E Telnet server that is serving the LU2 session. Similarly, Web-based applications, such as shopping carts, might need to have all connections from a particular client come to the server instance that has the contents of the shopping cart stored as session state.

The TIMEDAFFINITY parameter on the VIPADISTRIBUTE statement indicates to sysplex distributor that connections to a particular distributed DVIPA need to take into account the client origin. Connections from the same client, as identified by IP address, need to be routed to the same server instance, even when multiple server instances are hosted by a single target stack.

If a nonzero value for the TIMEDAFFINITY parameter is specified on a VIPADISTRIBUTE statement, the first connection from a particular client is routed as normal to a target stack and listening application. At that time, both the sysplex distributor routing stack and the target stack establish an affinity to govern subsequent connection requests from the same client. This affinity maintains a connection count, initially one. As subsequent connection requests for the same distributed DVIPA and port come in from the same client IP address, they are routed to the same server instance and the affinity connection count is incremented. As affinity-based connections, including the first one, are closed, the connection count is decremented.

When the last existing connection is closed and the count gets to zero, a timer of the duration (in seconds) specified by the TIMEDAFFINITY parameter is started. If another connection request is received from the same client to the same distributed DVIPA and port, the timer is stopped and the connection request is routed to the designated server instance. If no connection request is received from that client for the designated distributed DVIPA and port before the timer expires, the affinity is removed from the sysplex distributor routing and target stacks. The next connection request from that client for the distributed DVIPA and port will be routed according to normal sysplex distributor considerations of relative capacity and policies.

Connection requests that map to an existing affinity are always routed to that target regardless of the distribution method being used. This also applies to

weighted active connection distribution. Although the established affinities are honored, distribution decisions for connection requests that have no affinity will include the active connections that were established as a result of an affinity relationship.

Using the VARY TCPIP,,OBEYFILE command with a profile containing a VIPADISTRIBUTE statement that specifies the TIMEDAFFINITY value as 0 prevents new affinities from being established. However, an existing affinity remains until all connections using the affinity end and the timer for the affinity expires. The timer value is not changed for an existing affinity by the new statement; instead, it continues to use the configured TIMEDAFFINITY value that was active when the affinity was established. To remove existing affinities, issue the VARY TCPIP,,OBEYFILE command with a profile containing a VIPADISTRIBUTE DELETE statement, followed by a VIPADISTRIBUTE DEFINE statement with a TIMEDAFFINITY value of 0.

Note that under some circumstances, a client's affinity with a specific target application server instance might be terminated prior to the specified time interval if key resources needed to satisfy new client TCP connection requests are not available. This includes the following scenarios:

- A target application server instance terminates, is quiesced for DVIPA sysplex distributor workload balancing, or is no longer listening on its specified port. Any affinities to the target application instance are terminated and new connections for that port are no longer routed to this server.

  One exception to this scenario occurs for configurations where multiple applications reside on the same system and TCP/IP stack, and also listen on the same port (that is, the set of applications comprises a shareport group). In this case, when one of the application instances in the shareport group terminates, is quiesced for DVIPA sysplex distributor workload balancing, or is no longer listening on the specified port, the routing stack continues to maintain any existing affinities, but only to this target system and TCP/IP stack, as long as at least one application instance in the shareport group is active, is not quiesced, and is listening to the specified port. When a new TCP connection is received from a client that previously had an affinity to the server that is no longer active, the request is routed to the same target system and TCP/IP stack. One of the other available servers in the shareport group is selected to process the request and a new affinity is established.
- A target system or TCP/IP stack is no longer available. All affinities associated with applications running on that system and TCP/IP stack are terminated.
- A target TCP/IP stack is no longer reachable across dynamic XCF links (that is, the dynamic XCF link to the target stack is no longer active). Any existing client affinities to applications residing on that target stack are terminated if new connection requests from these clients are received while the dynamic XCF link is not active. Note that this scenario only occurs if a dynamic XCF link becomes inactive and all attempts to automatically restart the link are unsuccessful.
- A target server is found to be unresponsive to accepting new connection requests. All affinities to the target server are terminated and new connections for that port are no longer routed to that server.
- A target server is unable to support new connections requests. Connections that are protected by IPSec UDP-encapsulated security associations that are negotiated with a peer behind a NAPT must be distributed to a V1R8 or later target. It is not always possible for the distributing stack to detect that a security association is being negotiated with a peer behind a NAPT. If an initial connection is distributed to a V1R7 target and an affinity to that target is

established, and during negotiation of a subsequent security association it is determined that the peer is behind a NAPT, the affinity to the target is terminated.

Note that sysplex distributor's notion of *client* is tied exclusively to source IP address on the connection request. This is not new, and is also true of other functions such as Policy Agent and IPSec. However, it can present problems in situations where many different connections from truly different client instances all appear with the same source IP address. Examples include the following:

- Proxy applications, such as a Web HTTP server proxy, that initiate secondary connections on behalf of a large number of different clients. The secondary connections into sysplex distributor all look as though they come from the same client, and any affinity for those connections directs all connection requests to the same server.
- Network address translation (NAT), which keeps connection tables so that it can map multiple client-side addresses into a single server-side source IP address.
- Clients on z/OS configured for SOURCEVIPA, or in general, many instances of a client on the same network node with one or very few IP addresses (as far as outbound connection requests are concerned).
- Clients running on the sysplex distributor routing stack, which is a special instance of the previous scenario. The source IP address for a client running on the sysplex distributor routing node is the distributed DVIPA, the same as the destination IP address. This is not new, and is true for any connection request issued for a server on the same stack, if the connection request socket was not bound to a particular IP address before issuing the connect() call.

In cases like this, distribution might be significantly less than optimal, because sysplex distributor has no way to distinguish among connection requests from different real clients all using the same source IP address. In the worst case, where all source IP addresses are the same (for example, where there is a single proxy instance in a firewall), there will be no load balancing at all as long as an affinity exists.

Essentially, timed affinity was created to allow connection workload distribution where it was not possible before, due to the client/server application model requiring a particular client to go to a particular server instance for some period of time. Such applications are not, at present, workload balanced. If a network configuration is such that a reasonable number of source IP addresses do not allow workload balancing, techniques to partition the work at the source must be implemented (configuring the clients to go to unique server addresses, or configuring the proxy to spread the workload among multiple servers, as the WebSphere HTTP server plug-in does). Where the anticipated number of different source IP addresses, and the connection request arrival rate, is large enough to provide reasonable balancing and reaction to changing sysplex workloads, this provides a reasonable solution while respecting affinities between clients and servers as required for the application. The main reason for configuring the affinity on the basis of each distributed DVIPA and port pair is that affinity requirements differ from application (port number) to application, and some applications do not need affinity at all. You must take into account your specific network configuration, and specifically the arrival rate of connections from different IP addresses, in determining whether timed affinity with sysplex distributor is appropriate for a particular application in your network.

Affinity information needs to be handled on the sysplex distributor routing stack, backup stacks, and target stacks. If a target stack is not z/OS V1R5 or later, server

application instances that are part of a shareport group on that stack will not work properly, and affinities for that target stack will not be communicated to the backup routing stack on failure of a primary routing stack. If a backup routing stack is not z/OS V1R5 or later, affinity information will not be sent to it from surviving target stacks if it takes over from a failed routing stack. Therefore, it is strongly recommended that all TCP/IP stacks participating in distribution for a distributed DVIPA with affinities be at least z/OS V1R5.

You can use the Netstat VCRT/-V report option with the DETAIL modifier to display the affinity related information for each connection, as follows:

```

```

The following notes apply to the preceding example.

Notes:

1. Affinity CRT entry for the three regular CRT entries that follow. If there is an affinity entry, it is shown before the regular CRT entries.
2. Three regular CRT entries, associated with the single preceding affinity entry.
3. Affinity CRT entry for the regular CRT entry that follows.

4. Regular CRT entry associated with the previous affinity entry.
5. An affinity CRT entry that has no connection associated with it. The use count is zero. There are 99 seconds affinity time left before this affinity entry is removed.
6. Regular CRT entry. There is no affinity associated with it.

Sysplex-wide security associations

To enable sysplex-wide security associations (SWSA) for IPv4 on a stack that has IP security enabled, add the subparameter DVIPSEC to the IPSEC keyword in the IPSEC statement block of the TCP/IP profile. To enable SWSA on a stack that has firewall support enabled, add the subparameter DVIPSEC to the FIREWALL parameter of the IPCONFIG statement.

Restriction: The FIREWALL parameter can be configured only on a stack that is at a V1R7 or earlier level.

To take advantage of the functions described here, you must add the DVIPSEC subparameter to your primary (including sysplex distributor hosts) and backup hosts. It is not necessary to add DVIPSEC to hosts that serve only as targets for sysplex distributor. For more information on configuring SWSA, see *z/OS Communications Server: IP Configuration Reference*.

SWSA also requires the use of a coupling facility structure with a name in the form EZBDVIPA*vvtt*, where *vv* is the 2-digit VTAM group ID suffix specified on the XCFGRPID start option, and *tt* is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is specified, but a TCP/IP group ID suffix is specified, *vv* is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is specified, *tt* is not present. If neither group ID suffix is specified, both *vv* and *tt* are not present. For information about setting up the sysplex environment and the use of the EZBDVIPA*vvtt* coupling facility structure, see *z/OS Communications Server: SNA Network Implementation Guide*.

Dynamic IPSec security associations (SA), negotiated by IKE, can use a DVIPA address as the SA endpoint. Manually configured SAs are not supported by SWSA. For more information on IPSec, see Chapter 19, “IP security,” on page 923.

When using SWSA, there are two possible configurations to consider:

- DVIPA takeover
- Sysplex distributor

To support IPSec in conjunction with DVIPA takeover and sysplex distributor, some IKE and IPSec configuration is required. Loss of access to the coupling facility is also discussed in the following subtopics.

IPv6 sysplex-wide security associations are not supported.

For information on diagnosing SWSA problems, see *z/OS Communications Server: IP Diagnosis Guide*.

DVIPA takeover

When a DVIPA is moved during DVIPA takeover (planned or unplanned), SWSA automatically reestablishes new IPSec SAs with the same security service characteristics as the SAs that existed on the host that previously owned the DVIPA. The SA reestablishment is transparent to the client that owns the other end

of the SA. That is, the SA reestablishment looks like a normal SA refresh. For example, as shown in Figure 41, during DVIPA takeover, DVIPA 192.168.253.4 is taken over by the backup host, and SAs are transparently reestablished between the client and the backup host.

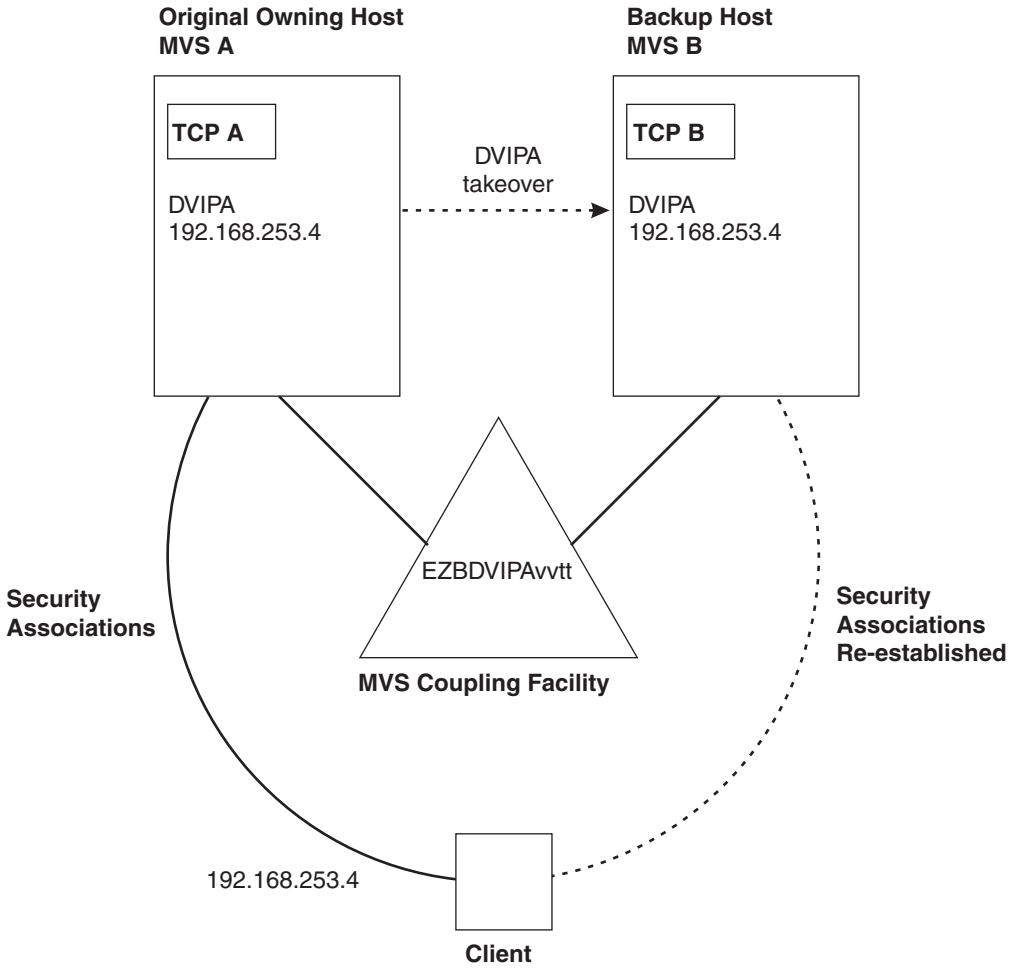

Figure 41. DVIPA takeover with SWSA

The IKE running on behalf of the TCP stack of the DVIPA owner is responsible for all IKE SA negotiations. The TCP stack owning the DVIPA is responsible for keeping the coupling facility updated with information needed to reestablish the SAs in the event of a DVIPA takeover. When a takeover occurs, the IKE on the backup host assumes responsibility for renegotiating new SAs based on the stored information read from the coupling facility during the takeover by the TCP stack of the new DVIPA owner.

Sysplex distributor

TCP traffic protected by an IPSec SA with a sysplex-distributed DVIPA endpoint can be distributed to target hosts. IPSec cryptography for inbound traffic is performed on the target host whenever possible. If not possible, the distributor performs the cryptography before forwarding the packet to the target stack. IPSec cryptography for outbound traffic is performed on the target host, and then sent directly into the network without being routed through the distributor. Figure 42 on page 390 shows the target stack performing the cryptography for the inbound and outbound traffic.

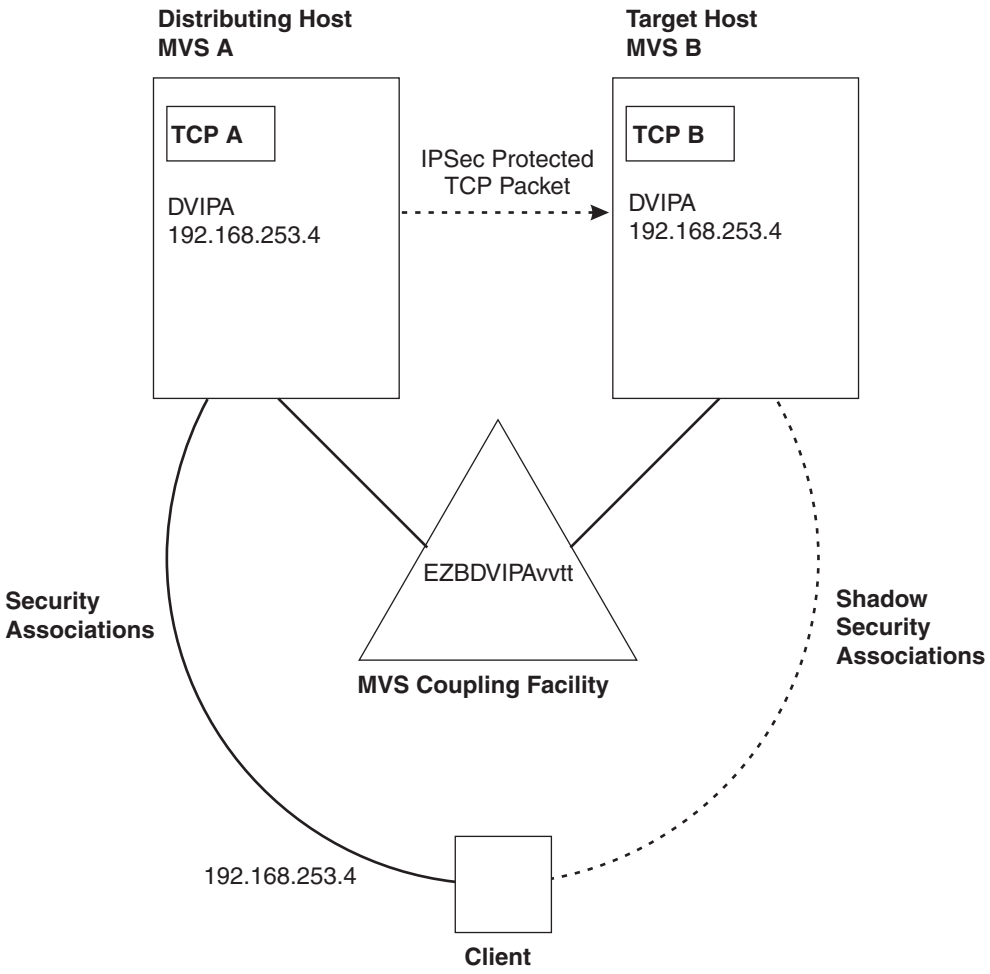

Figure 42. Sysplex distributor with SWSA

The IKE running on behalf of the distributor TCP stack (the DVIPA owner) is responsible for all IKE SA negotiations. The distributor stack keeps the master copy of the SA associated with the DVIPA. Whenever a new SA is negotiated or refreshed and the SA is installed in the distributor stack, a copy (shadow) of the SA, which contains information necessary to perform IPSec cryptography, is sent within the sysplex to the target hosts. The shadow SAs enable the distribution of cryptography to the target stacks. The coupling facility is used as a central repository for SA replay protection sequence numbers used for outbound operations. The SA lifesizes (bytes sent and received over an SA) are maintained in the master SA.

Using IPSec with DVIPAs and sysplex distributor

To support IPSec in conjunction with DVIPA takeover and sysplex distributor, some IKE and IPSec configuration on the original or distributing host must be replicated onto all systems that can either serve as a backup host for a VIPA takeover or a target host for sysplex distributor. This includes IP Security policy that affects traffic using distributed DVIPA (from an IKE definition perspective).

- From a stack perspective, all anchor rules that are applicable to distributed DVIPA traffic must be identical on all systems. In addition, the ordering of the rules must allow for consistent application of security policy on all systems.
- To be considered a sysplex-wide SA, the SA negotiated that applies to DVIPAs must be at a granularity no coarser than host for the local address. That is, a

dynamic SA cannot use a subnet or range that encompasses a DVIPA address. This rule ensures that on a DVIPA Giveback the SA can be moved from host to host without concerns about an SA being applicable to both the backup and primary host simultaneously. If such a dynamic SA is negotiated, the IPSec traffic using it cannot be distributed or recovered through the DVIPA takeover support.

Loss of access to coupling facility

If access is lost to the coupling facility containing the DVIPA structure EZBDVIPA*vvtt*, it is possible the TCP connections using this DVIPA could terminate and new connections needing IPsec will fail to establish. Loss of access could be caused by any of the following:

- A disconnect from the coupling facility structure.
- The structure is rebuilt.
- The structure encounters a critical storage shortage.

Loss of coupling facility access should affect only sysplex distributor connections that are being encrypted or authenticated. When access to EZBDVIPA*vvtt* is restored, the sessions can be re-established.

Resolution of dynamic VIPA conflicts

The same dynamic VIPA can exist on more than one stack in the sysplex, playing different roles on the different stacks. The TCP/IP stacks collaborate to prevent conflicting definitions. For example, at any given time only one stack will advertise a given dynamic VIPA to the routers.

Potentially conflicting dynamic VIPA definitions can arise during profile processing or as the result of changes within the sysplex due to a stack or application failure or as the result of movement of workload to a different stack. The following scenarios are examples of dynamic VIPA conflict resolution handled automatically by the TCP/IP stacks. For a summary of dynamic VIPA conflict identification and resolution, see "Dynamic VIPA creation results" on page 396.

Restart of the original VIPADEFINE TCP/IP after an outage

When a dynamic VIPA is defined using VIPADEFINE on one TCP/IP, and other stacks are designated as backup using VIPABACKUP statements for the same dynamic VIPA, the stack with the highest backup rank for that DVIPA will activate it if or when the VIPADEFINE stack fails.

If the failed stack is later restarted with the same VIPADEFINE profile statement, it is likely that connections to that DVIPA will exist on the backup stack that now has the DVIPA activated and advertised to the routers. How and when ownership of the DVIPA is returned to the restarted stack is determined by how the DVIPA was originally configured.

VIPADEFINE MOVEABLE IMMEDIATE

If the DVIPA is an IPv6 DVIPA, or is an IPv4 DVIPA that was originally configured with MOVEABLE IMMEDIATE, the following occurs:

- The DVIPA ownership is immediately transferred to the restarting stack which adds the DVIPA to its HOME list and the routers are dynamically notified. The restarted stack receives all new connections for that DVIPA. The stack also can receive packets for existing connections, and it routes these to the backup stack to preserve those connections.

- At the same time, the backup stack notifies the routers that it no longer is the owner of the DVIPA.
  - If there are no current connections to the DVIPA, it is removed from the HOME list on the backup stack and it reverts to backup status.
  - If there are any existing connections, the DVIPA remains in the HOME list of the backup stack and the DVIPA is put into *Moving* status until the last existing connection is terminated. At that time, the DVIPA is removed from the HOME list and reverts to backup status.

IBM recommends this form of a planned DVIPA takeback occur only during low periods of connection activity. This gives the attached routers time to update their routing tables and avoid connections being reset due to receiving an ICMP_HOST_UNREACH or ICMP6_DST_UNREACH from the router.

Tip: If OMPROUTE is used, it is recommended that GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN be configured. This causes DVIPA takeback to be delayed until OMPROUTE is active and able to advertise DVIPAs on the takeback stack. For more information on using DELAYJOIN, see "Sysplex problem detection and recovery" on page 449.

Notes:

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.
2. MOVEABLE IMMEDIATE is the default for IPv4 DVIPAs, and the only behavior for IPv6 DVIPAs.

VIPADEFINE MOVEABLE WHENIDLE

If an IPv4 DVIPA was originally configured with MOVEABLE WHENIDLE, the following occurs:

- If it appears that there are no active connections to the DVIPA on the backup stack:
  - The DVIPA is removed from the HOME list on the backup stack and reverts to backup status.
  - The restarted stack assumes ownership of the DVIPA by adding it to its HOME list and notifying the routers.
- If there are existing connections to the DVIPA on the backup stack:
  - Ownership of the DVIPA remains with the backup stack. The DVIPA on the restarting stack is placed in backup status at the head of the backup list for the DVIPA.
  - The backup stack periodically checks to see if it has any active connections to the DVIPA.

    When or if it appears that there are no active connections for the DVIPA, the following occurs:

    - The DVIPA is removed from the HOME list on the backup stack and reverts to backup status.
    - The restarted stack assumes ownership of the DVIPA by adding it to its HOME list and notifying the routers.

    Notes:

    1. WHENIDLE is supported only for IPv4 DVIPAs.

2. A small period of time exists between the check for connections and the movement of the dynamic VIPA to the restarted stack. If connections are made to the old host (the backup stack) in this interval, they will be broken.
3. During the time that TCP/IP is periodically checking for connections, TCP/IP does *not* refuse new connections because this would be the same as an outage. If moving the work back to the restarted stack is more important than maintaining uninterrupted service to all clients, then the system operator can use the VARY TCPIP,,OBEYFILE command to delete the dynamic VIPA on the backup stack with the VIPADELETE profile statement. This causes the restarted stack to immediately activate the DVIPA. Optionally, the data set specified on the command can contain a VIPABACKUP statement following the VIPADELETE statement. This will restore the stack as a backup stack.

Movement of unique application-instance (BIND)

A dynamic VIPA is created when any application binds to a nonexistent, specific IP address falling within a configured VIPARANGE on that stack.

In the case of a stack failure, the same application could be started on another stack and (assuming the new stack also has an appropriate VIPARANGE configured) when the application binds to the same IP address, the dynamic VIPA is created on the second stack. Future client connections to that IP address are routed to the second stack where the application is now running.

However, if the same (or a different) application is started on a second stack and attempts to create the same dynamic VIPA using a bind() while it exists on the first stack, the end result is determined by how the VIPARANGE was configured on the stack where the first bind() occurred.

VIPARANGE (DEFINE) MOVEABLE NONDISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE NONDISRUPTIVE, the following occurs:

- If the RACF profile EZB.BINDDVIPARANGE.*sysname.tcpname* has been defined, the application issuing the bind() must be permitted to the profile.

  Note: If the RACF profile is not defined but the same VIPARANGE is configured on another stack, any application on that stack can cause the DVIPA to move there by issuing a BIND() to that DVIPA.
- The DVIPA ownership is immediately transferred to the second stack which adds the DVIPA to its HOME list and dynamically notifies the routers. This stack will now receive all new connections for the DVIPA.
- At the same time, the first stack notifies the routers that it no longer is the owner of the DVIPA, and puts the DVIPA into *moving* status. The DVIPA remains in *moving* status (and in the first stacks HOME list) until the application closes the socket.
- Existing connections on the first stack are preserved. If the second stack receives packets intended for existing connections, it routes the packets to the first stack.

Notes:

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.

2. NONDISRUPTIVE is the default for V2R10 and later, and is the only option supported for IPv6.
3. Both stacks must be running V2R10 or later to get non-disruptive behavior. If either stack is running V2R8, the result will be as described in "VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE."

VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE DISRUPTIVE (or if either stack is running V2R8), the following occurs:

- The bind() request for the application on the second stack will fail.
- The DVIPA on the first stack is not affected.

Notes:

1. If movement of the application from the first to the second stack is intended, the application must be ended on the first stack before it is started on the second stack.
2. DISRUPTIVE is supported only for IPv4 DVIPAs.

Defining a RACF profile for VIPARANGE

A RACF SERVAUTH class profile can control which applications can bind() to define a DVIPA using VIPARANGE. To restrict applications that can bind() to a DVIPA within a VIPARANGE, define the EZB.BINDDVIPARANGE.*sysname*.*tcpname* profile in RACF, and permit the applications that are allowed to bind() as shown in the following example. If the profile is not defined, then the bind() will be processed.

To restrict access to all the IP addresses in the VIPARANGE definitions, you can define a RACF profile using the following example:

```
RDEFINE SERVAUTH (EZB.BINDDVIPARANGE.sysname.tcpname)
   UACC(NONE)

PERMIT EZB.BINDDVIPARANGE.sysname.tcpname
   ACCESS(READ) CLASS(SERVAUTH) ID(userid)
```

In this example, *sysname* is the name of the MVS system, *userid* is the user ID that the application is running on, and *tcpname* is the job name of the TCP/IP started task.

The job name for started tasks, such as TCP/IP, is derived depending on how it is started:

- If the START command is issued with the name of a member in a cataloged procedure library (for example, S TCPIPX), the job name will be the member name (for example, TCPIPX).
- If the member name on the START command is qualified by a started task identifier (for example, S TCPIPX.ABC), the job name will be the started task identifier (for example, ABC). The started task identifier is not visible to all MVS components, but TCP/IP uses it to build the RACF resource name.
- The JOBNAME parameter can also be used on the START command to identify the job name (for example, S TCPIPX,JOBNAME=XYZ).
- The JOBNAME can also be included on the JOB card.

If this RACF profile is created, the user ID must be permitted to access this profile, or bind() requests will fail with a permission denied error, regardless of superuser authority.

Note also that before the RACF profiles take effect, a refresh of these profiles might be required. This can be accomplished by the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Movement of a unique APF-authorized application instance (ioctl)

APF-authorized applications running under a user ID with superuser authority (or that have access through the MODDVIPA security profile) have the ability to activate a dynamic VIPA with the SIOCSVIPA or SIOCSVIPA6 ioctl command, either within the application itself or by invoking the MODDVIPA utility. Because this is a controlled environment, it is assumed configuration errors are minimized or avoided and the usage is correct. Thus, even if the requested DVIPA is currently active on another TCP/IP stack via BIND() or ioctl(), the DVIPA will be immediately activated on this stack. What happens on the other stack is determined by how the VIPARANGE was configured on that stack.

VIPARANGE (DEFINE) MOVEABLE NONDISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE NONDISRUPTIVE, the following occurs:

- The DVIPA ownership is immediately transferred to the second stack which adds the DVIPA to its HOME list and dynamically notifies the routers.
- At the same time, the first stack notifies the routers that it no longer is the owner of the DVIPA, and puts the DVIPA into *moving* status. The DVIPA remains in *moving* status (and in the first stack's HOME list) until the DVIPA is deleted on that stack with the VIPADELETE profile statement or the SIOCSVIPA or SIOCSVIPA6 ioctl DELETE option.
- Existing connections on the first stack are preserved. If the second stack receives packets intended for existing connections, it will route the packets to the first stack.

Notes:

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.
2. NONDISRUPTIVE is the default for V2R10 and later.
3. Both stacks must be running V2R10 or later to get non-disruptive behavior. If either stack is running V2R8, the result will be as described in "VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE."

VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE DISRUPTIVE (or if either stack is running V2R8), the following occurs:

- The ioctl request for the application on the second stack succeeds. The DVIPA is added to the HOME list on the second stack, and the routers are dynamically notified.
- The DVIPA on the first stack is deleted.

Notes:

1. Any existing connections to the DVIPA on the first stack are broken.
2. DISRUPTIVE is IPv4 only.

Same dynamic VIPA for VIPADEFINE and BIND(), SIOCSVIPA or SIOCSVIPA6 ioctl, or MODDVIPA utility

Regardless of careful implementation, it is possible that the same IP address is inadvertently selected for VIPADEFINE and for use with BIND(), SIOCSVIPA or SIOCSVIPA6 ioctl, or the MODDVIPA utility. Because the application scenarios are quite different, this must be an error.

If this duplicate DVIPA address conflict occurs on the same TCP/IP, the second attempt might fail. If an IP address is specified in a VIPADEFINE, and that same IP address has already been activated on the TCP/IP by an application using BIND(), the SIOCSVIPA or SIOCSVIPA6 ioctl, or the MODDVIPA utility, the VIPADEFINE will be rejected during VARY TCPIP,,OBEYFILE command processing. If an IP address is activated with VIPADEFINE, and the application does a BIND(), ioctl(), or the MODDVIPA utility is used, the BIND() will succeed, but the ioctl() will fail with a nonzero errno and the MODDVIPA utility will set a nonzero condition to indicate that the IP address already exists.

The same situation could also occur on two different TCP/IPs in the sysplex. Because the TCP/IPs are exchanging information among themselves, if the two attempts are far enough apart in time, the second attempt will be caught immediately and rejected. However, it is possible that the attempt will be made almost simultaneously on two different TCP/IPs, such that neither TCP/IP is yet aware of the attempt on the other TCP/IP. If both attempt such an activation, and the exchange of information then shows a conflict, the internal sysplex time stamps are used to determine which attempt was really first. The one that appears to be first is allowed to continue, and the dynamic VIPA is deleted from the *later* TCP/IP. While such a simultaneous attempt is somewhat unpredictable in respect to which one will succeed, the dynamic VIPA will remain active on only one TCP/IP, and examination of messages will indicate which TCP/IP successfully created the DVIPA and on which TCP/IP it was rejected.

Dynamic VIPA creation results

Table 19 on page 397 summarizes the results of attempting to create a dynamic VIPA when it (or the same IP address for HOME statement) already exists in the sysplex.

Table 19. Summary of dynamic VIPA creation results

First action	Second action	Result if second action is on the same stack	Result if the second action is on a different stack within the sysplex
bind()	bind()	Second bind() succeeds, but no new VIPA is created.	If both stacks are running V2R10 or later, and the first BIND DVIPA was created with MOVEABLE NONDISRUPTIVE: • On stack 2, bind() succeeds • On stack 1, the BIND VIPA remains in the HOME list (unadvertised) and any existing connections are preserved • New connections to that IP address go to the application on stack 2. Otherwise, second bind fails.
bind()	ioctl()	ioctl() fails with warning condition code, but the application associated with the ioctl is still able to use the dynamic VIPA.	ioctl() succeeds, bind is deleted (even if BIND DVIPA was created as MOVEABLE NONDISRUPTIVE)
bind()	VIPADEFINE	VIPADEFINE fails.	VIPADEFINE fails.
bind()	VIPABACKUP	VIPABACKUP fails.	VIPABACKUP fails.
bind()	HOME	See note.	See note.
ioctl()	bind()	bind() succeeds, no new VIPA is created.	bind() fails.
ioctl()	ioctl()	Second ioctl() fails with warning condition code, but the application associated with the ioctl is still able to use the dynamic VIPA.	Second ioctl() succeeds. If both stacks are running V2R10 or later, and the ioctl DVIPA on stack 1 was created with MOVEABLE NONDISRUPTIVE, the DVIPA on stack 1 remains in the HOME list (unadvertised) and any existing connections are preserved. Otherwise, the ioctl DVIPA on stack 1 is deleted and any existing connections are broken.
ioctl()	VIPADEFINE	VIPADEFINE fails.	VIPADEFINE fails.
ioctl()	VIPABACKUP	VIPABACKUP fails.	VIPABACKUP fails.
ioctl()	HOME	See note.	See note.
VIPADEFINE	bind()	bind() succeeds, but no new VIPA is created.	bind() fails.

Table 19. Summary of dynamic VIPA creation results (continued)

First action	Second action	Result if second action is on the same stack	Result if the second action is on a different stack within the sysplex
VIPADEFINE	ioctl()	ioctl() fails.	ioctl() fails.
VIPADEFINE	VIPADEFINE	If the second VIPADEFINE statement is an exact duplicate of the first, the second VIPADEFINE is ignored with no error message. For IPv4, the second VIPADEFINE fails if it has different options or a different mask than the first VIPADEFINE specified. For IPv6, the second VIPADEFINE fails if the interface name is already defined with a different address or the address is already defined for a different interface name.	For IPv4, the second VIPADEFINE succeeds but activation on stack 2 might be deferred. If both stacks are running V2R10 or later, and the DVIPA was created on stack 1 as MOVEABLE IMMEDIATE: • Second VIPADEFINE is activated immediately • Any connections to the DVIPA on stack 1 are preserved. (DVIPA stays in HOME list unadvertised) Otherwise, the second VIPADEFINE activation is deferred until there are no connections on stack 1, at which point, stack 1 reverts to backup status. For IPv6, if both the interface name and address on the second VIPADEFINE match the first VIPADEFINE, the DVIPA is activated on stack 2. Any connections to the DVIPA on stack 1 are preserved. If either the interface name or address is the same but the other is not, the second VIPADEFINE fails.
VIPADEFINE	VIPABACKUP	VIPABACKUP fails.	Both succeed.
VIPADEFINE	HOME	See note.	See note.
VIPABACKUP	bind()	bind() fails.	If the IP address is already active on the bind() stack, the bind() will succeed. Otherwise, the bind() fails.
VIPABACKUP	ioctl()	ioctl() fails.	ioctl() fails.

Table 19. Summary of dynamic VIPA creation results (continued)

First action	Second action	Result if second action is on the same stack	Result if the second action is on a different stack within the sysplex
VIPABACKUP is backup status	VIPADEFINE	VIPADEFINE succeeds, replaces the VIPABACKUP. For IPv6, both the interface name and the address on the VIPADEFINE must match the VIPABACKUP. If one matches and the other does not match, the VIPADEFINE fails.	VIPADEFINE succeeds. For IPv6, both the interface name and the address on the VIPADEFINE must match the VIPABACKUP. If one matches and the other does not match, the VIPADEFINE fails.
VIPABACKUP in active status (after takeover)	VIPADEFINE	VIPADEFINE rejected	For IPv4, the VIPABACKUP DVIPA is MOVEABLE IMMEDIATE or WHENIDLE depending how the original VIPADEFINE DVIPA was created. If both stacks are running V2R10 or later, and the VIPABACKUP DVIPA is MOVEABLE IMMEDIATE: • The VIPADEFINE is activated immediately. • Any connections to the DVIPA on stack 1 are preserved (DVIPA stays in HOME list unadvertised). • When there are no more connections, stack 1 reverts to backup status. Otherwise, the VIPADEFINE activation on stack 2 is deferred until there are no active connections on stack 1, at which point stack 1 reverts to backup status. For IPv6, if both the interface name and the address on the VIPADEFINE match the VIPABACKUP, the DVIPA is activated on stack 2. Any connections to stack 1 are preserved. If only one matches, the VIPADEFINE fails.

Table 19. Summary of dynamic VIPA creation results (continued)

First action	Second action	Result if second action is on the same stack	Result if the second action is on a different stack within the sysplex
VIPABACKUP	VIPABACKUP	If the DVIPA is in backup status on this stack, the second VIPABACKUP succeeds. If the DVIPA is in active status on this stack (for example, after a takeover), a VIPABACKUP with a different rank will be rejected. For IPv6, both the interface name and address must match the first VIPABACKUP. If one matches and the other is different, the second VIPABACKUP fails.	Second VIPABACKUP succeeds. For IPv6, both the interface name and address must match the first VIPABACKUP. If one matches and the other is different, the second VIPABACKUP fails.
VIPABACKUP	HOME	See note.	See note.
HOME	bind()	bind() succeeds, but no new VIPA is created.	bind() fails.
HOME	ioctl()	ioctl() fails.	ioctl() fails.
HOME	VIPADEFINE	VIPADEFINE fails.	VIPADEFINE fails.
HOME	VIPABACKUP	VIPABACKUP fails.	VIPABACKUP fails.
Note: Defining the same IP address in the HOME list as an existing dynamic VIPA will not be rejected by the TCP/IP stack, but it is likely to cause routing problems.			

TIER1, TIER2, and CPCSCOPE keyword DVIPA contention resolution

Sysplex distributor supports load balancing across z/OS images in a sysplex and to non-z/OS targets, as described in "Sysplex distribution optimizations for multi-tier z/OS workloads" on page 485 and "Sysplex distribution with DataPower" on page 491; the TIER1, TIER2, and CPCSCOPE keywords are used with this support. Use the following guidelines to define dynamic VIPAs (DVIPAs) that use these keywords.

Guidelines:

- If you want to change the TIER1, TIER2, or CPCSCOPE definition for a DVIPA, delete the existing definition of the DVIPA from the sysplex first; the keyword usage for a DVIPA must be the same throughout the sysplex. For example:
  - If there is an existing VIPADEFINE or VIPABACKUP statement for DVIPA1 using the TIER2 keyword, use a VIPADELETE statement to remove this DVIPA before using a VIPADEFINE TIER1 statement for DVIPA1.
  - If there is an existing VIPADEFINE or VIPABACKUP statement for DVIPA1 that does not use the TIER1, TIER2, or CPCSCOPE keywords, use a VIPADELETE statement to remove this DVIPA before defining DVIPA1 with one of these keywords.
- When you are defining a DVIPA with the CPCSCOPE keyword, and the DVIPA exists in a different central processor complex (CPC), delete it from that CPC

first; a DVIPA with the CPCSCOPE keyword can exist only on stacks in the same CPC. For example, if DVIPA1 was defined using a VIPABACKUP CPCSCOPE statement on a stack in CPC1, use a VIPADELETE statement to remove this DVIPA before using a VIPABACKUP CPCSCOPE statement for a stack in CPC2.

If you do not follow these guidelines, the changes to DVIPA creation results that occur when the TIER1, TIER2, or CPCSCOPE keyword is changed, added, or removed from a DVIPA that already exists in the sysplex are described in Table 20, Table 21 on page 402, and Table 22 on page 403.

If you create a new definition for an existing DVIPA on the same stack, either in the same profile or later using the VARY TCPIP,,OBEYFILE command, see Table 20. When the new definition is processed, it cannot change the TIER1, TIER2, or CPCSCOPE usage; if this is attempted, the new definition is rejected.

Table 20. DVIPA contention resolution for DVIPA definitions on the same stack

Original definition	Later definition	Result
VIPADEFINE or VIPABACKUP DVIPA1 TIER1	VIPADEFINE or VIPABACKUP DVIPA1 TIER1	Later definition replaces the original definition
VIPADEFINE or VIPABACKUP DVIPA1 TIER2	VIPADEFINE or VIPABACKUP DVIPA1 TIER2	
VIPADEFINE or VIPABACKUP DVIPA1 TIER2 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 TIER2 CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 TIER1	VIPADEFINE or VIPABACKUP DVIPA1 TIER2 or CPCSCOPE	Configuration mismatch; later definitions are rejected
VIPADEFINE or VIPABACKUP DVIPA1 TIER2	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or TIER2	
VIPADEFINE or VIPABACKUP DVIPA1	VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1	

When two stacks define the same DVIPA, contention resolution is as follows:

- If there is a TIER1, TIER2, or CPCSCOPE mismatch for the DVIPA, the stack with the later timestamp cannot change the keyword usage, and either rejects its own definition during profile processing or deletes its definition when it learns of the DVIPA definition with the earlier timestamp.
- If there is a mismatch between a DVIPA definition that uses a TIER1, TIER2, or CPCSCOPE keyword and a DVIPA definition that does not use any of these keywords, possible outcomes are as follows:
  - If the second stack has already received the mismatched DVIPA definition from the first stack prior to profile processing, contention resolution depends on the release level of stack 2:
    - If stack 2 is V1R11 or later, the earlier timestamp wins and stack 2 rejects all DVIPA1 definitions (including the VIPADISTRIBUTE statement)

- If stack 2 is V1R10 or earlier, it is not aware of the new keywords and the mismatch and it defines the DVIPA; stack 1 deletes its definition when it learns that stack 2 defined the DVIPA

– After two stacks have successfully defined DVIPAs with mismatching definitions, the stack that uses the keywords deletes all of its definitions for that DVIPA, because the stack that uses no keywords might be using V1R10 or earlier.

Table 21 summarizes DVIPA contention resolution between stacks in the same CPC.

Table 21. DVIPA contention resolution between stacks in the same CPC

Stack 1 — Earlier timestamp	**Stack 2 — Later timestamp**	**Result**
VIPADEFINE DVIPA1 TIER1	VIPADEFINE DVIPA1 TIER1	Later timestamp wins and stack 1 becomes a backup for DVIPA1
VIPADEFINE DVIPA1 TIER2	VIPADEFINE DVIPA1 TIER2	
VIPADEFINE DVIPA1 TIER2 CPCSCOPE	VIPADEFINE DVIPA1 TIER2 CPCSCOPE	
VIPADEFINE DVIPA1 CPCSCOPE	VIPADEFINE DVIPA1 CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 TIER1	VIPADEFINE or VIPABACKUP DVIPA1 TIER2 or CPCSCOPE	Configuration mismatch; earlier timestamp wins and stack 2 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)
VIPADEFINE or VIPABACKUP DVIPA1 TIER2	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or TIER2	
VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1	Configuration mismatch during profile processing for stack 2: • If stack 2 is V1R11 or later, the earlier timestamp wins and stack 2 rejects all DVIPA1 definitions (including the VIPADISTRIBUTE statement) • If stack 2 is V1R10 or earlier, it is not aware of the new keywords and the mismatch and it defines the DVIPA; stack 1 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement) when it learns that stack 2 defined the DVIPA

Table 21. DVIPA contention resolution between stacks in the same CPC (continued)

Stack 1 — Earlier timestamp	Stack 2 — Later timestamp	Result
VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1	Configuration mismatch after profile processing for stack 2 completes; definition with no keywords wins and stack 1 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)
VIPADEFINE or VIPABACKUP DVIPA1	VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	Configuration mismatch after profile processing for stack 2 completes; definition with no keywords wins and stack 2 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)

Table 22 summarizes additional contention resolution rules used when the stacks are in different CPCs.

Table 22. DVIPA contention resolution between stacks in different CPCs

Stack 1 CPC 1 — Earlier timestamp	Stack 2 CPC 2 — Later timestamp	Result
VIPADEFINE DVIPA1 TIER1	VIPADEFINE DVIPA1 TIER1	Later timestamp wins and stack 1 becomes a backup for DVIPA1
VIPADEFINE DVIPA1 TIER2	VIPADEFINE DVIPA1 TIER2	
VIPADEFINE or VIPABACKUP DVIPA1 TIER2 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 TIER2 CPCSCOPE	Earliest Timestamp wins and stack 2 deletes its VIPADEFINE or VIPABACKUP statement because the DVIPA can have VIPADEFINE and VIPABACKUP definitions only on stacks in the same CPC
VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 TIER1	VIPADEFINE or VIPABACKUP DVIPA1 TIER2 or CPCSCOPE	Configuration mismatch; earlier timestamp wins and stack 2 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)
VIPADEFINE or VIPABACKUP DVIPA1 TIER2	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or CPCSCOPE	
VIPADEFINE or VIPABACKUP DVIPA1 CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1 TIER1 or TIER2	

Table 22. DVIPA contention resolution between stacks in different CPCs (continued)

Stack 1 CPC 1 — Earlier timestamp	Stack 2 CPC 2 — Later timestamp	Result
VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1	Configuration mismatch during profile processing for stack 2: • If stack 2 is V1R11 or later, the earlier timestamp wins and stack 2 rejects all DVIPA1 definitions (including the VIPADISTRIBUTE statement) • If stack 2 is V1R10 or earlier, it is not aware of the new keywords and the mismatch and it defines the DVIPA; stack 1 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement) when it learns that stack 2 defined the DVIPA
VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	VIPADEFINE or VIPABACKUP DVIPA1	Configuration mismatch after profile processing for stack 2 completes; definition with no keywords wins and stack 1 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)
VIPADEFINE or VIPABACKUP DVIPA1	VIPADEFINE or VIPABACKUP DVIPA1 TIER1, TIER2, or CPCSCOPE	Configuration mismatch after profile processing for stack 2 completes; definition with no keywords wins and stack 2 deletes all DVIPA1 definitions (including the VIPADISTRIBUTE statement)

IPv6 considerations

This topic discusses special considerations for IPv6.

VIPARANGE

MOVeable DISTRUPTive is not supported for IPv6. To prevent an unauthorized application from creating a dynamic VIPA with a bind() call, a RACF profile (called EZB.BINDDVIPARANGE.*sysname*.*tcpname*) can be added. If the RACF check fails, the bind() request fails, and if the RACF check is successful, the bind() request is accepted.

VIPADEFINE and VIPABACKUP

VIPABACKUP must specify an interface name and IPv6 address. The interface name and IPv6 address pair must match any preexisting dynamic VIPA definitions for either that interface name or IPv6 address. If using VIPABACKUP for an initial DVIPA activation, neither the interface name nor the IPv6 address can preexist. Furthermore, for the takeover and backup functions to succeed, if a corresponding VIPADEFINE is to be subsequently activated, the interface name and IPv6 address on the VIPADEFINE statement must match the VIPABACKUP statement.

Unique application-instance scenario and IPv6-enabled applications

A single instance of an IPv6-enabled TCP application can typically handle communications with IPv4 or IPv6 partner applications. IPv6-enabled TCP server applications usually accomplish this by using a single AF_INET6 socket to accept connections from both IPv4 and IPv6 clients. As a result, IPv6-enabled applications have some additional configuration considerations when compared to IPv4-only applications, as they require both an IPv4 DVIPA and an IPv6 DVIPA to be configured. If the application is using the MODDVIPA utility or the SIOCSVIPA IOCTL to define the DVIPA, it needs to be modified as follows:

- If using the MODDVIPA utility, an additional set of invocations for this utility is needed to define and delete the IPv6 DVIPA to be associated with the application.
- If the application is using the SIOCSVIPA IOCTL, it needs to be modified to also issue the SIOCSVIPA6 IOCTL to define and delete the IPv6 DVIPA to be associated with the application.

Applications that are currently relying on defining the DVIPA dynamically using the bind() socket API or the BIND parameter on the PORT reservation statement have some additional considerations, as a single socket cannot be bound to more than one IP address.

Following are some of the options that can help alleviate this issue:

- Instead of relying on the bind to trigger the DVIPA definition, the application or configuration can be modified to allow the application to bind to the IPv6 unspecified address (in6addr_any). The MODDVIPA utility can then be used to define and delete both the IPv4 and IPv6 DVIPAs associated with the application. Another similar alternative would be for the application to issue the SIOCSVIPA or SIOCSVIPA6 IOCTL for both of these DVIPAs, but this is probably less desirable since it involves application changes.
- Start two instances of the application, one binding to the IPv4 DVIPA and the other binding to the IPv6 DVIPA. This assumes that multiple instances of the same application can be started within the same MVS image or across different images in the sysplex. This configuration allows IPv4 clients to reach the application instance bound to the IPv4 DVIPA and IPv6 clients to reach the application instance bound to the IPv6 DVIPA.
- In some cases it might be possible to modify the application so that it can create two sockets, one for IPv6 communications and one for IPv4 communications. Each socket could then be bound to the IPv4 or IPv6 DVIPA as appropriate, and a single instance of the application could handle both IPv4 and IPv6 clients. This solution might be less desirable since it also involves application code changes.

VIPAs, OSA-Express QDIO, and Spanning Tree Protocol

Spanning Tree Protocol (STP) can potentially impact environments where both OSA-Express QDIO and VIPA are deployed.

With dynamic VIPA, a TCP/IP address takeover occurs when a TCP/IP stack fails, or a static or dynamic VIPA is manually moved by operator intervention. In either case, when a static or dynamic VIPA moves, the IP address and respective workloads are taken over by another TCP/IP stack through other OSA-Express Ethernet devices running on a different server. When the original TCP/IP stack and respective OSA-Express QDIO devices are returned to operation, both the IP address and respective workload traffic are taken back by the recovered TCP/IP stack.

If the network bridge or switch is not configured properly, packets can get lost in the network or be blocked by the networking equipment. This is a result of a physical looping condition identified by the STP, or expired OSA-Express QDIO timers due to the increased latencies associated with blocked ports or delayed packets. In these cases, static or dynamic VIPA connectivity can fail.

When configuring STP, use care in the bridge or switch configuration to avoid or minimize potential loop conditions. For example, if the STP is not an integral component of the overall network, disabling the STP on all of the Virtual LANs (VLANs) that connect to OSA-Express QDIO devices will help avoid the problem.

Also, some networking switches provide a mechanism for suppressing the STP's listening and learning states on specific switch ports. For example, Cisco Systems provides an STP configuration feature called PortFast that can place specific switch ports into forwarding state as soon as a link is detected. Without PortFast enabled, a switch port has to transition through the listening and learning stages (30 seconds total) of Spanning Tree reconvergence before the switch port can actually pass valid traffic. For PortFast capable Cisco switches, enabling PortFast on all switch ports that OSA-Express QDIO is connected into allows network administrators to both preserve their original Spanning Tree configuration by not having to change it, while also providing a viable mechanism to avoid potential static or dynamic VIPA problems.

For more information on configuring STP and immediate port forwarding, see the bridge or switch operational manual.

Mixture of types of dynamic VIPAs within subnets

Any particular IP address can be used in only one way as a dynamic VIPA. A dynamic VIPA can be defined either with VIPADEFINE or by application action within a valid VIPARANGE, but not both. However, within a subnet defined as a VIPARANGE, some IP addresses can be used for VIPADEFINE, and others may be assigned to unique application instances, without conflict, as long as the limit of a total of 1024 active and backup dynamic VIPAs on a single TCP/IP is not exceeded. TCP/IP will make no attempt to reject a VIPADEFINE dynamic VIPA that also falls within a VIPARANGE. This allows installations with limited availability of IP addresses to assign individual addresses to either application scenario, without having to define separate subnets and use up additional IP addresses in that manner.

MVS failure and sysplex failure management

The TCP/IPs in a sysplex use MVS XCF messaging to exchange information about dynamic VIPAs. When a TCP/IP fails or is ended by operator command, but the underlying MVS remains active, the other TCP/IPs are immediately notified, and takeover of VIPADEFINE dynamic VIPAs is automated and very fast. In addition, each TCP/IP stack monitors for local problem conditions that might cause it to leave the TCP/IP sysplex group, at which point the other TCP/IPs will be immediately notified. For more information, see "Sysplex problem detection and recovery" on page 449.

However, when an MVS fails, there is normally an operator message on the console requiring a response (WTOR). Until this response is made by an operator or automation, the other MVS systems do not notify the remaining TCP/IPs in the sysplex of the failure of the TCP/IP on the failing MVS. This can delay automated backup of dynamic VIPAs defined with VIPADEFINE. Sysplex Failure Management (SFM) can be used to automate the required response to the console message of the failing MVS. See *z/OS MVS Setting Up a Sysplex* for information on how to set up SFM to avoid the requirement for a manual response and speed backup of dynamic VIPAs defined with VIPADEFINE.

For more information, see *z/OS Communications Server: IP Diagnosis Guide*.

Applications and dynamic VIPAs

While most applications support multiple instances in a sysplex, very few applications expect IP addresses to move around under them. TCP applications use TCP connections to form a relationship between particular client and server instances to exchange data over an extended period. They rely on notification of TCP connection termination to initiate recovery and to reestablish a new relationship (possibly from a client to a different server). Conversely, most UDP applications do the equivalent function at the application layer. Movement of an IP address to a different server could be confusing to the client, unless the new server also is aware of the state of the client work.

UDP applications whose interactions consist of atomic interactions (a single request followed by one or more responses, with no state information maintained at the server between requests) can use dynamic VIPAs in the multiple application-instance scenario. However, if the server application maintains state information between interactions (for example, NFS), then moving a dynamic VIPA to another server might not work unless the client/server application protocol can detect the discontinuity. In that case, the unique application-instance scenario might apply, which would require the restart of the server instance on another TCP/IP.

In addition, the following types of work are not appropriate for distribution with distributed dynamic VIPA:

- Applications that establish affinity with a particular TCP/IP stack, such as SNMP.
- FTP servers that receive the PASV or EPSV command for a distributed DVIPA that did not specify SYSPLEXPORTS. The PASV and EPSV commands are supported when SYSPLEXPORTS was specified on the VIPADISTRIBUTE statement of the distributed DVIPA that is the destination IP address being used by the FTP server. These commands request that the FTP server bind() on a data port that is not the default data port, or the one specified on the

VIPADISTRIBUTE statement, and to wait for a connection rather than initiate one on receipt of a transfer command (for example, RETR). Because SYSPLEXPORTS cannot be specified for a non-distributed dynamic VIPA, passive mode FTP connections made to a non-distributed dynamic VIPA cannot be recovered when the VIPA is moved through a planned takeover. The control connection remains on the original stack, but attempts to create new data connections for control connections that existed prior to the move will fail. When SYSPLEXPORTS is used with a distributed dynamic VIPA, new data connections are always sent to the same stack containing their control connection. For more information on using the SYSPLEXPORTS parameter in the VIPADYNAMIC block, see *z/OS Communications Server: IP Configuration Reference*.

- FTP servers that accept connections on an IPv6 distributed DVIPA that does not have SYSPLEXPORTS specified. The FTP server expects an EPSV command for data transfers to or from an IPv6 address, and use of the EPSV command is supported only when SYSPLEXPORTS was specified on the VIPADISTRIBUTE statement of the distributed DVIPA that is the destination IP address being used by the FTP server.

Configuring VIPAs for activation with VIPABACKUP

When adding a dynamic VIPA to a functioning sysplex, the normal order is to add VIPABACKUP statements to backup stacks, and then add a VIPADEFINE statement to the TCP/IP stack where the VIPA should normally reside, at which time the VIPA would be activated and ready for use. A VIPADISTRIBUTE statement could be added at the same time, along with the VIPASMPARMS statement if the SERVICEMGR parameter is coded on the VIPADEFINE statement. The VIPA would only be activated when the VIPADEFINE was processed on the TCP/IP that would normally own it, and not when a VIPABACKUP is processed on another stack. This is, in part, because parameters on the VIPADEFINE that are needed to activate the VIPA were not found on the VIPABACKUP statement.

However, on the rare occasion that a disaster occurs, it might be necessary to IPL all of the systems in a sysplex. Assuming that many dynamic VIPAs are in use and the VIPADEFINE statements are spread across the available TCP/IP stacks in the sysplex, most of the dynamic VIPAs have a lengthy wait before the owning operating system, TCP/IP, and application are started and fully operational. The intent of dynamic VIPAs defined with VIPADEFINE and VIPABACKUP is to move the dynamic VIPAs under a functioning application as soon as possible. Therefore, optional parameters have been added to the VIPABACKUP statement to allow the dynamic VIPA to be activated when the VIPABACKUP is processed at TCP/IP initialization or VARY TCPIP,,OBEYFILE command processing. If the MOVEABLE IMMEDIATE or MOVEABLE WHENIDLE parameter is specified on a VIPABACKUP profile statement, along with required address mask and optional SERVICEMGR parameters for an IPv4 DVIPA, the dynamic VIPA will be activated when the profile statement is processed, if it is not active elsewhere in the sysplex already. The following notes apply to this case:

- If the MOVEABLE parameter is specified, the address mask must also be specified. For an IPv4 DVIPA, the SERVICEMGR parameter on a VIPABACKUP statement is optional. The address mask and SERVICEMGR parameters can only be specified on a VIPABACKUP statement if the MOVEABLE parameter has also been specified.
- The first started VIPABACKUP TCP/IP stack that is configured to start a particular dynamic VIPA with VIPABACKUP will activate the dynamic VIPA and own it until the VIPADEFINE stack is started. As long as the first activating VIPABACKUP stack remains operational, starting another stack with a

VIPABACKUP statement will not cause the dynamic VIPA to move, even if the second stack has a higher backup rank. Only the initialization of the VIPADEFINE stack will cause the VIPA to move automatically.

- When the VIPADEFINE is eventually processed, its parameters will override the values specified on the VIPABACKUP that activated the dynamic VIPA, if the VIPADEFINE has parameters that are different from those specified on the VIPABACKUP.

It is always a good idea, when able to specify a parameter on both primary and backup, to specify exactly the same values for each. When all the parameters common to VIPADEFINE and VIPABACKUP are specified the same on both for a particular DVIPA, the behavior exhibited when the VIPADEFINE stack comes up will be the same as when the DVIPA is activated first by a VIPABACKUP stack. However, for IPv4, there are several parameters that could be specified inconsistently on the VIPABACKUP and VIPADEFINE statements. If they are specified inconsistently, following are some of the implications by parameter:

- SERVICEMGR: If the Cisco forwarding agents are not configured to participate, then it does not matter whether or not SERVICEMGR is specified. If the Cisco forwarding agents are configured to participate, the following apply if SERVICEMGR is specified differently on participating stacks:
  - If SERVICEMGR is not specified on the VIPABACKUP stack, the Cisco forwarding agents will send all packets through normal IP forwarding to the stack owning the DVIPA (the VIPABACKUP stack until the VIPADEFINE stack comes up). When the VIPADEFINE stack comes up with SERVICEMGR, it will inform the forwarding agents and normal function will continue, even for existing connections. In other words, nothing fails, including existing connections, but optimal routing is not achieved unless all participating stacks code SERVICEMGR.
  - If SERVICEMGR is specified on the VIPABACKUP stack, things will operate normally for MNLB integration until the VIPADEFINE stack is activated. When that happens, no new updates will be sent to the Cisco forwarding agents, meaning that existing connections will be routed optimally for a while, but all packets for new connections will be sent to the VIPADEFINE stack for routing. After the 15-minute timeout for connection routes in the forwarding agents, the existing connections will have all packets sent to the VIPADEFINE stack. Once again, nothing fails, including existing connections, but optimal routing is not achieved unless all participating stacks code SERVICEMGR.
- MOVEABLE: If there is any doubt, this parameter should be coded as MOVEABLE IMMEDIATE on the VIPABACKUP stack, so that the stack will maintain connection information to be sent to the VIPADEFINE stack when it comes up. Subsequent operation in the sysplex will be determined by the coding (or defaulting) of MOVEABLE on the VIPADEFINE statement, regardless of what was coded on the VIPABACKUP of the stack that first activated the DVIPA. This is true even if that same stack later takes over the DVIPA from the VIPADEFINE or another stack. (This is the reason MOVEABLE was chosen as the way to activate the new function on VIPABACKUP stacks, rather than a new keyword, to force consideration of the setting of the MOVEABLE parameter for VIPABACKUP stacks.)
- address_mask: The address_mask is used to build BSDROUTINGPARMS statements. If the attached routing daemon is OMPROUTE and there is no corresponding interface definition with the subnet mask parameter in OMPROUTE configuration, OMPROUTE might send a different address mask from the VIPADEFINE stack than it will for the VIPABACKUP stack, which

might confuse the routing network. The address_mask should be the same on VIPABACKUP and VIPADEFINE statements for a particular DVIPA.

Result: Incorrect OMPROUTE configuration, such as missing interface definitions for RIPv1, RIPv2, or OSPF, can lead to unexpected results, especially if OMPROUTE uses defaults for the address mask.

Assuming that dynamic VIPAs are spread across the sysplex, and that critical applications are as well, the first stack to be activated might activate most, if not all, DVIPAs, and might therefore assume a considerable amount of the workload. For any particular application, all of the workload is directed to the first stack supporting that application to be activated, regardless of what other workload will be executing on that same stack or LPAR.

Recommendation: Consider the planned sysplex TCP/IP activation sequence, and have only those DVIPAs for critical applications activating on TCP/IP stacks early in the sequence, so that less important work does not interfere with the business-critical applications during sysplex startups.

Example of configuring dynamic and distributed VIPAs

The TCP/IP profiles needed to implement dynamic VIPA (DVIPA) on multiple systems in a sysplex are shown in the following examples. The VIPADEFINE and VIPABACKUP statements allow automatic dynamic VIPA takeover to occur if needed (see "Configuring the multiple application-instance scenario" on page 363), and the VIPARANGE statements allow dynamic VIPAs to be dynamically created by an application or by the MODDVIPA utility (see "Configuring the unique application-instance scenario" on page 364). The VIPADISTRIBUTE statements allow a single VIPA to be shared among several TCP/IPs. Including the SOURCEVIPA and TCPSTACKSOURCEVIPA parameters on the IPCONFIG and IPCONFIG6 statements, on each target stack with the same dynamic VIPA specified, enables a single DVIPA address to be used as a sysplex-wide source DVIPA address for outbound TCP connections. The following examples show both IPv4 and IPv6 DVIPAs, and the output is shown in the IPv6-enabled, or long, format.

 DYNAMICXCF 193.9.200.6 255.255.255.240 1
IPCONFIG6 DYNAMICXCF 2001:0DB8::151:0006
 SOURCEVIPA TCPSTACKSOURCEVIPA DVIPA1

TCPCS6 does not have dynamic VIPAs defined so it does not
contain a VIPADYNAMIC definition.  It has DYNAMICXCF specified
for IPv4 and IPv6 to enable XCF dynamic support and to allow
TCPCS6 to be a target for dynamic VIPA distribution.
```

Start TCP/IP on each system as shown.

- On system1, start TCPCS and TCPCS2.
- On system2, start TCPCS3, on system3 start TCPCS6.
- On system1, run the MODDVIPA utility to define the DVIPA 201.2.10.193.

```
  //TCPDVP   PROC
  //*
  //*
  //TCPDVP  EXEC PGM=MODDVIPA ,REGION=0K,TIME=1440,                       x
  //             PARM='POSIX(ON) ALL31(ON)/-p TCPCS -c 201.2.10.193'
  //SYSPRINT DD SYSOUT=*,DCB=(RECFM=FB,LRECL=132,BLKSIZE=132)
  //SYSERR   DD SYSOUT=*
  //SYSERROR DD SYSOUT=*
  //SYSDEBUG DD SYSOUT=*
  //SYSUDUMP DD SYSOUT=A
  //SYSABEND DD SYSOUT=*
  //*
  //*Run program here
```

```
//*
//TCPDVP  EXEC PGM=MODDVIPA ,REGION=0K,TIME=1440,                      x
//             PARM='POSIX(ON) ALL31(ON)/-p TCPCS -d 201.2.10.193'
```

The PARM field can be **-c** for create or **-d** for delete. This example will create DVIPA 201.2.10.193 for the TCP/IP named TCPCS. After intermediate program has completed (and the comment character is removed), the DVIPA will be deleted.

- On system 1, deactivate DVIPA 201.2.10.23 by issuing the following command on the MVS console:

  ```
  V TCPIP,TCPCS,SYSPLEX,DEACTIVATE,DVIPA=201.2.10.23
  ```

Verifying the DVIPAs in a sysplex

The following display command can be used to display dynamic VIPAs in a sysplex:

```
d tcpip,tcpname,sysplex,vipadyn
```

In the following example taken from stack TCPCS, the ORIGIN lines show that 201.2.10.11, 201.2.10.12, 201.2.10.14, 201.2.10.15, DVIPA1, and DVIPA2 were all created by VIPADEFINE on this stack. 201.2.10.13, 201.2.10.21, and 201.2.10.22 were created by VIPABACKUP statements. (Note that the deactivated DVIPA 201.2.10.23 does not appear in this display.)

The ORIGIN line indicates how the DVIPA is configured on the stack specified by `tcpname`. Each stack (TCPNAME) for each system (MVSNAME) is shown with its status (STATUS). Two other status values not shown in the following example are:

QUIESCING
: This DVIPA has been deactivated, or it was a target for distribution and has been removed as a target. However, it is still servicing one or more connections for this DVIPA. The DVIPA will be removed when all connections complete.

MOVING
: This DVIPA was active on this stack and has been moved to another stack. Connections on this stack for this DVIPA prior to the move will still be serviced by this stack until completion.

The rank (RANK) indicates which of the stacks is eligible to take over if the stack on which the DVIPA is active stops. The stack with the highest rank is the one that will take over the DVIPA.

Using Netstat support to verify dynamic VIPA configuration

You can use the Netstat VIPADCFG/-F report option to display the dynamic VIPA configuration for a particular TCP/IP stack. Use the DETAIL modifier on the distributing stack to verify all the options configured on the VIPADISTRIBUTE statements.

Guideline: Use the Netstat CONFIG/-f report option to verify the rest of the stack configuration, including SOURCEVIPA, TCPSTACKSOURCEVIPA, and SYSPLEXROUTING; use the Netstat SRCIP/-J report option to verify the SRCIP profile statement for particular jobs or destinations.

The dynamic VIPA information section is only displayed when there are DVIPAs configured on this stack. The VIPA Range section, displayed only if a VIPARANGE statement was processed in this stack's initial profile (or in a data set referenced by a VARY TCPIP,,OBEYFILE command), indicates only that a range was configured. It does not indicate whether any ioctl or BIND has actually created a DVIPA in the specified range. The VIPA distribute section is displayed only if there are VIPADISTRIBUTE statements configured on this stack. The deactivated dynamic VIPA information section is displayed only when there are DVIPAs that have been deactivated on this stack.

Netstat CONFIG/-F DETAIL output from stack TCPCS:

```
# netstat -p tcpcs -F DETAIL
MVS TCP/IP NETSTAT CS V1R12       TCPIP Name: TCPCS           18:23:46

Verifying sysplex distributor workload

You can use the Netstat VDPT/-O and VCRT/-V report options to verify sysplex distributor workload. See *z/OS Communications Server: IP System Administrator's Commands* for more information on these commands.

Use the Netstat VDPT/-O report option with the DETAIL modifier on the distributing stack to confirm that there are target stacks available with server applications ready. This display will only show target stacks that are currently up and have joined the sysplex. The RDY field indicates how many, if any, applications the target TCP/IP, identified by its DestXCF Addr, has bound to DPort. If none, then this target TCP/IP will not receive any connection workload. The TotalConn field indicates how many connections this distributing TCP/IP has forwarded to the target TCP/IP. The ActiveConn field indicates how many connections the distributing TCP/IP has forwarded to the target TCP/IP that are currently active.

Tip: TotalConn is an historical count and will wrap.

The following Netstat display command on the distributing stack, TCPCS, shows which target stacks are available with the server applications ready.

```

```

- The target stack is identified by its dynamic XCF address (DESTXCF).
- The RDY field indicates how many applications on that target stack have bound to the DEST port.
- TOTALCONN is the number of all connections the distributing stack, TCPCS, has routed to the target stack.
- The ACTIVECONN value is the number of currently active connections that the distributing stack, TCPCS, has routed to the target stack. The active connections include all TCP connections that the target TCP/IP stack is still aware of, even if the connections are in the process of terminating. For example, connections in FIN_WAIT2 or TIMEWAIT states are also included in this count.

- The ABNORM value is the rate of abnormal terminations for this server. This field affects the WLM weight and the operation of the OPTLOCAL distributor setting.
- The HEALTH value is the health indicator for this server. This field affects the WLM weight and the operation of the OPTLOCAL distributor setting.
- WLM is the normalized workload manager weight value for the target TCP/IP stack.
- Weight is the raw composite weight for the target TCP/IP stack. The composite weight is based on the application's general CPU utilization, the System z Application Assist Processor (zAAP) utilization, and the System z Integrated Information Processor (zIIP) utilization, as shown in Table 23.

Table 23. Weight determination

Processor	DISTMETHOD BASEWLM	DISTMETHOD SERVERWLM
CP	The `Raw` value is the raw WLM system general CP weight. The `Proportional` value is the `Raw` value modified by the expected CP utilization proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.	The `Raw` value is the raw WLM server-specific general CP weight. The `Proportional` value is the `Raw` value modified by the proportion of CP capacity that is currently being consumed by the application's workload, as compared to the other processors (zIIP and zAAP).
zAAP	The `Raw` value is the raw WLM system zAAP weight. The `Proportional` value is the `Raw` value modified by the expected zAAP utilization proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.	The `Raw` value is the raw WLM server-specific zAAP weight. The `Proportional` value is the `Raw` value modified by the proportion of zAAP capacity that is currently being consumed by the application's workload, as compared to the other processors (CP and zIIP).
zIIP	The `Raw` value is the raw WLM system zIIP weight. The `Proportional` value is the `Raw` value modified by the expected zIIP utilization proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.	The `Raw` value is the raw WLM server-specific zIIP weight. The `Proportional` value is the `Raw` value modified by the proportion of zIIP capacity that is currently being consumed by the application's workload, as compared to the other processors (CP and zAAP).

- FLG is a flag field indicating how the connection was distributed. For example, the value DYNAMIC indicates this DVIPA is being distributed by the dynamic port assignment function.
- The target server responsiveness (TSR) field indicates how well a target server is accepting TCP connection setup requests. A value of 100 indicates that the target

server is accepting all TCP connection setup requests successfully. A value of 0 indicates that the target server is accepting no TCP connection setup requests successfully. A value between 100 and 0 indicates the relative success rate of TCP connection setup requests for this target server.

When weighted active distribution is being used, the configured active connection weight for each target is shown as the WLM value in the Netstat VDPT/-O display. By using the DETAIL modifier on the display, the active connection counts are shown. The distributor balances incoming connection requests across the targets with a goal of having the number of active connections on each target proportionally equivalent to the configured active connection weight of each target.

For more details, see *z/OS Communications Server: IP System Administrator's Commands*.

Dynamic VIPAs and routing protocols

With dynamic VIPAs, IP addresses may move from one stack to another. These changes need to be communicated to the network. Therefore, dynamic routing should be implemented when dynamic VIPAs are being used.

IPv4 considerations for OMPROUTE

The names of dynamic VIPA interfaces are assigned dynamically by the stack when a dynamic VIPA interface is created. Therefore, the Name field set on the Interface or OSPF_Interface statement for a dynamic VIPA will be ignored by OMPROUTE.

It is recommended that a host have an Interface or OSPF_Interface definition for every dynamic VIPA address which that host might own. Because this could be a large number of interfaces, additional wildcard capabilities have been added to OMPROUTE, for dynamic VIPA interfaces only.

Ranges of dynamic VIPA interfaces can be defined using the subnet mask parameter on the OSPF_Interface or Interface statement. The range defined will be all the IP addresses that fall within the subnet defined by the mask and the IP address. The IP address parameter must be the subnet number of the range being defined, not a host address within that range. The following example defines a range of dynamic VIPA addresses from 10.138.165.81 to 10.138.165.94:

```
OSPF_Interface
   IP_address = 10.138.165.80
   Name = dummy_name (see note)
   Subnet_mask = 255.255.255.240;
```

Tips:

- The *Name* parameter is required and must be unique, but it is not actually used for dynamic VIPAs.
- When defining ranges, it is not necessary or desirable to code a destination address. OMPROUTE will automatically set the destination address of a dynamic VIPA to its IP address.
- There is nothing in the interface definition statements that informs OMPROUTE that a particular interface definition statement is for a dynamic VIPA or a range of dynamic VIPAs. Rather, OMPROUTE learns this information from the stack when these interfaces are created or taken over.
- Because dynamic VIPAs can move between z/OS hosts, you should configure a router ID that specifies a physical interface or a static VIPA and not a dynamic VIPA.

The MTU size defined on OSPF_INTERFACE statements limits the size of advertisements that can be sent or received over OMPROUTE interfaces. OMPROUTE cannot build an advertisement whose size would exceed the largest MTU size of all its interfaces. Also, OMPROUTE cannot receive an advertisement that is larger than the largest MTU size defined for all its interfaces. In either of these cases, you will see the following message:

```
EZZ7967I ADVERTISEMENT DISCARDED, OVERFLOWS BUFFER: LS
   TYPE x ID x.x.x.x ORG y.y.y.y
```

When this happens on an originating host, that host will not be able to send router Link State Advertisements (LSAs), and therefore other hosts will not be able to calculate routes to any destinations (for example, VIPAs) owned by the originating host. OMPROUTE will terminate if it encounters this condition. If it cannot send its router LSA, it is useless as a router. When this happens on a receiving host, that

host will not be able to compute routes to any destinations advertised in the discarded LSA. Also note that other OSPF implementations might have similar or stricter limitations, in which case they would be unable to receive or propagate large router LSAs received from OMPROUTE. These scenarios can severely affect network connectivity and routing capability. If large numbers of VIPA interfaces are going to be used, we recommend you examine OSPF MTU sizes throughout your network to ensure that large router LSAs can be propagated.

Normally, large router LSAs would not be a problem, as LSAs seldom exceed their allowed MTU sizes. However, if a large number of VIPA or dynamic VIPA interfaces are defined on a host, this can become a consideration. The size of the router LSA will include 52 bytes for headers, plus the number of bytes required to advertise the host's owned interfaces. The number of bytes required for each interface is:

VIPA	12 bytes, plus 12 bytes for each VIPA subnet (see the following example)
Point-to-point	24 bytes
Point-to-multipoint	12 bytes, plus 12 bytes for each neighbor on the interface
All other types	12 bytes

For owned VIPA interfaces, OMPROUTE normally advertises both host and subnet routes. The size of router LSAs required can be minimized by careful subnet planning. For example, assume the following definition exists in the OMPROUTE configuration file:

```
OSPF_Interface
   IP_Address=3.3.3.*
   Name = VIPA1A
   Subnet_Mask=255.255.255.252
   Attaches_To_Area=1.1.1.1
   MTU=1024
   Cost0 = 1;
```

If 101 VIPA interfaces, numbered 3.3.3.1 to 3.3.3.101, are activated, in addition to the headers and any other owned interfaces, OMPROUTE would need 1512 bytes to advertise 126 links in its router LSA (1 host route to each of the VIPAs, plus 25 subnet routes since each subnet contains only four addresses).

By contrast, assume the following definition exists in the OMPROUTE configuration file:

```
OSPF_Interface
   IP_Address=3.3.3.*
   Name = VIPA1A
   Subnet_Mask=255.255.255.0
   Attaches_To_Area=1.1.1.1
   MTU=1024
   Cost0 = 1;
```

If the same 101 VIPA interfaces are activated, OMPROUTE would advertise 102 links in its router LSA (1 host route to each VIPA, plus 1 subnet route since all the VIPAs are in the same subnet). This would only require 1224 bytes to advertise the VIPAs. If the MTU size on the network is 1500, this can make the difference between being able to send or receive a router LSA or not being able to send or receive a router LSA. This limitiation can further be circumvented by suppressing VIPA host routes by coding the Advertise_VIPA_Routes or Subnet parameters on

the OSPF_INTERFACE statement for the VIPA interfaces. However, there are limits on when this can be done. For details, see the *z/OS Communications Server: IP Configuration Reference*.

Ensure that all members of a sysplex are defined to be in the same OSPF area. Failure to do this causes routing problems during the transition of ownership of a DVIPA from a member in one area to a member in another area. It can also disrupt sysplex distributor operation for clients within the sysplex.

IPv4 considerations for Routing Information Protocol

If using Routing Information Protocol (RIP) services and Host Route advertising is not supported by adjacent routers (that is, inability to learn host routes), the following restrictions for VIPA addresses must be applied to benefit from fault tolerance support:

- If you use subnetting and VIPA addresses are in the same network as the physical IP addresses, the subnetwork portion of any VIPA addresses must not be the subnetwork portion of any physical IP addresses in the network. In this case, assign a new subnetwork for the VIPA address.
- If subnetting is not used on any physical interface, the network portion of any VIPA addresses must not be the network portion of any physical IP addresses in the network. In this case, assign a new network for the VIPA address, preferably a class C network address.

If using RIP services and Host Route advertising is supported by adjacent routers, the network or subnetwork portions of VIPA addresses can be the same across multiple z/OS TCP/IP stacks in the network. To enable Host Route advertising in OMPROUTE, configure RIP_Interface Send_Host_Routes=YES.

IPv6 considerations

For IPv6, all interfaces are defined to OMPROUTE by name only, and name wildcards are supported. This greatly simplifies definition considerations for OMPROUTE and VIPA interfaces.

To define IPv6 interfaces to OMPROUTE, you must know their names. Unlike IPv4, in which VIPA link names are generated by the stack, you specify link names to TCP/IP when defining IPv6 dynamic VIPA interfaces. These link names should be used when defining the same interfaces to OMPROUTE.

Tip: Using consistent naming conventions and name wildcards can make this task easier. For example, if you require that all IPv6 VIPA link names start with the letter V, and do not allow other interface types to have link names starting with V, a single definition can define all IPv6 VIPA interfaces to OMPROUTE as follows:

```
IPV6_OSPF_INTERFACE
      NAME=V*;
```

Unlike IPv4, there are no size limitations on the number of IPv6 dynamic VIPA addresses that OMPROUTE can advertise. In IPv6 OSPF, OMPROUTE will advertise all host and prefix addresses associated with owned interfaces, including VIPAs and dynamic VIPAs. In IPv6 RIP, sending and receiving of host routes should be turned on to allow host addresses associated with VIPAs to be advertised.

Chapter 8. TCP/IP in a sysplex

The increasing demands of network servers, and in particular System z servers, has led to the creation of different techniques to address performance requirements when a single server is not capable of providing the availability and scalability demands placed on it by its clients. Specifically, network solutions make use of what is referred to as the clustering technique, whereby multiple servers are associated together into a cluster to provide sufficient processing power and availability characteristics to handle the demands of the clients.

In the scope of this topic, this cluster functionality is provided by the sysplex. That is, the sysplex provides the necessary capability to cluster together a number of System z servers that cooperate with one another to deliver the processing power needed to service the demands required of a particular service environment.

Solutions utilizing the clustering approach to increase server availability and processing capability attempt to provide mechanisms by which they ensure the viability of the cluster in an environment containing a large number of clients generating a potentially high number of requests. To do so, the cluster technique can provide for two main objectives, high availability and load balancing. In some cases, clustering techniques address only high availability, as is the case with dynamic VIPA that provides for availability in spite of potential TCP/IP stack or z/OS image failures. In other cases, the intent is to provide for both high availability and load balancing, as is done by sysplex distributor.

In general, load balancing refers to the ability to utilize different systems within the cluster simultaneously, thereby taking advantage of the additional computational function of each. Further, clustering techniques addressing load balancing lead to other system requirements, such as that of a single systemwide image (one identity by which clients access the system), horizontal growth, and ease of management.

The traditional view of a single server has been primarily a single machine with perhaps a few network interfaces (IP addresses). This tends to lead to many potential points of failure within the server: the machine itself (hardware), the operating system (including TCP/IP stack) kernel executing on the machine, or a network interface (and the IP address associated with it). Static Virtual IP Addresses (VIPAs) exclude the network interface as a point of failure while dynamic VIPAs additionally aid with server (image) or kernel failure. In this way, high availability is seen as the availability of the entire server cluster and the service it provides. Furthermore, VIPAs can be used in conjunction with the sysplex distributor load balancing solution.

Clustering techniques that address the load balancing of connections requests also typically provide for some high availability. That is, these techniques dispatch connections to target servers and can exclude failed servers from the list of target servers that can receive connections. In this way, the dispatching function avoids routing connections and requests to a server incapable of satisfying such requests.

Load balancing is the ability for a cluster to spread workload evenly (or based on some policy) to target servers comprising the cluster. Usually, this load balancing is measured by some notion of perceived load on each of the target servers. This

topic describes load balancing using the sysplex distributor, which identifies the target System z servers willing to receive client connections based on some specification.

By providing load balancing, clustering techniques must also provide for other system requirements in addition to the dispatching of connections. These include the ability to advertise some single systemwide image or identity so that clients can uniquely and easily identify the service. Additionally, clustering techniques should also provide for horizontal growth of the system and ease of management.

It is also sometimes useful to arrange the members in the sysplex into subsets of members that communicate through XCF only amongst themselves. This is called subplexing. Each member of a subplex joins a unique set of sysplex groups and communicates through XCF with only other members that have joined the same unique set of sysplex groups. Each TCP/IP stack can participate in one and only one subplex. For more information, see "Sysplex subplexing."

Note: This information applies to both IPv4 and IPv6, unless otherwise noted.

Connectivity in a sysplex

With dynamic VIPAs, IP addresses may move from one stack to another. These changes need to be communicated to the network. Therefore, dynamic routing should be implemented when dynamic VIPAs are being used. See "Dynamic VIPAs and routing protocols" on page 425 for more detailed information.

Sysplex subplexing

A subplex is a subset of a sysplex that consists of all the members in the sysplex that communicate through cross-system coupling facility (XCF) groups with each other, and not with members outside the subset.

Defining multiple subplex scopes within a sysplex can be useful in scenarios where multiple networks with different security or functional attributes are attached to specific systems in the sysplex. For example, consider the scenario where some systems in the sysplex are connected to an internal enterprise network and other systems in the sysplex are connected to external networks that have different security attributes. In this example, you might want to be able to partition the sysplex into two subplexes from a sysplex network function perspective; one that includes the systems connected to the internal network and another for the systems that are connected to the external networks. By defining these separate subplexes, users can still exploit some of the sysplex network functions while preserving the isolation of the networks (that is, without automatically enabling dynamic XCF connectivity across the entire sysplex).

TCP/IP and VTAM subplex concepts and example

To enable partitioning of the TCP/IP stacks and VTAM nodes in a sysplex into subplexes, the values specified by the following VTAM start option and TCP/IP profile GLOBALCONFIG parameter are used as suffixes for XCF group names and coupling facility structure names.

- VTAM

  Use the XCFGRPID start option. For a description of sysplex subplexing and how the XCFGRPID start option modifies VTAM group names and VTAM structure names, see *z/OS Communications Server: SNA Network Implementation Guide*.
- TCP/IP

Use the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile.

For TCP/IP, both the VTAM group ID suffix and the TCP group ID suffix can be used to modify the group name that a TCP/IP stack uses when it joins the sysplex. The group name used is in the form EZBT*vvtt*, where *vv* is the 2-digit VTAM group ID suffix specified on the XCFGRPID start option, and *tt* is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. By using these suffixes to modify the XCF group name, the sysplex is effectively partitioned into subsets referred to as subplexes.

Only those TCP/IP stacks joining the unique group name generated using the specified suffixes are aware of each other in the sysplex; they communicate with each other through dynamic XCF. If the VTAM node is stopped and restarted with a new value for its XCFGRPID start option, the TCP/IP stacks using that VTAM node must be stopped and restarted to access the new VTAM suffix.

Figure 43 shows an example of TCP/IP and VTAM subplexes.

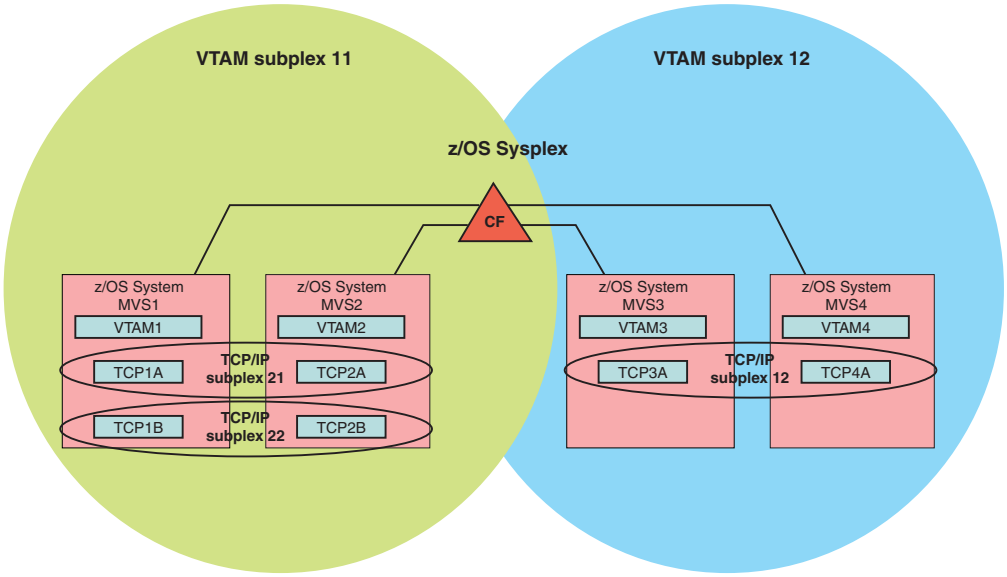

Figure 43. An example of TCP/IP and VTAM subplexes

In Figure 43, the following subplexes are defined:

- Two VTAM subplexes (11 and 12) have been defined by starting VTAM1 and VTAM2 with a start option of XCFGRPID 11, and starting VTAM3 and VTAM4 with a start option of XCFGRPID 12.
- Three TCP/IP subplexes have been defined by starting TCP1A and TCP2A with the statement GLOBALCONFIG XCFGRPID 21, TCP1B and TCP2B with the statement GLOBALCONFIG XCFGRPID 22, and TCP3A and TCP4A with the statement GLOBALCONFIG XCFGRPID 12.

The following conditions exist in the sysplex shown in Figure 43:

- TCP/IP stacks TCP1A and TCP2A join XCF group EZBT1121. TCP1A is aware of only TCP2A in the sysplex, and TCP2A is aware of only TCP1A in the sysplex.
- TCP/IP stacks TCP1B and TCP2B join XCF group EZBT1122. TCP1B is aware of only TCP2B in the sysplex, and TCP2B is aware of only TCP1B in the sysplex.

- TCP/IP stacks TCP3A and TCP4A join XCF group EZBT1212. TCP3A is aware of only TCP4A in the sysplex, and TCP4A is aware of only TCP3A in the sysplex.

Note: Even if TCP3A and TCP4A had been started with a GLOBALCONFIG 21 value, they would still be in a separate group from TCP1A and TCP2A, because they are in different VTAM subplexes.

Rule: Because TCP/IP stacks use VTAM XCF support for their dynamic XCF connectivity, TCP/IP subplexes cannot span multiple VTAM subplexes.

To preserve separation between the subplexes, the TCP and VTAM coupling facility structures accessed must also be unique for each subplex. For the TCP structures EZBDVIPA, used for SWSA support, and EZBEPORT, used for SYSPLEXPORTS support, this is accomplished by appending the VTAM and TCP XCF group ID suffixes to the end of the structure names, or EZBDVIPA*vvtt* and EZBEPORT*vvtt* respectively. Thus, in the example, TCP1A and TCP2A access EZBDVIPA1121 and EZBEPORT1121, while TCP1B and TCP2B access EZBDVIPA1122 and EZBEPORT1122.

To access the TCP structures, the structure names, including the suffixes, must be defined in the sysplex CFRM policy. In Figure 43 on page 431, the CFRM policy for the sysplex must have structure definitions for EZBDVIPA1121, EZBDVIPA1122, EZBDVIPA1212, EZBEPORT1121, EZBEPORT1122, and EZBEPORT1212, if all of the stacks expect to access these structures.

- If no VTAM suffix is specified, a value of CP is used for *vv* when creating the TCP sysplex group name, and a value of 01 is used for *vv* when creating the structure names.
- If a VTAM suffix is specified, but no TCP suffix is specified, a value of CS is used for *tt* when creating the TCP sysplex group name, and a null value is used for *tt* when creating the structure names. Thus, in Figure 43 on page 431, if TCP1B and TCP2B are started without an XCFGRPID parameter on their GLOBALCONFIG statements, the sysplex group they join is EZBT11CS, and the structures they can access are EZBDVIPA11 and EZBEPORT11.

To estimate the coupling facility size requirements for each of these structures, use the CFSizer Web site at http://www.ibm.com/servers/eserver/zseries/cfsizer/.

To isolate communication between different subplexes within a sysplex, dynamic XCF connectivity between TCP/IP stacks in different subplexes on separate MVS images is blocked. In addition, IUTSAMEH connectivity for dynamic XCF between stacks in different subplexes on the same MVS image is also blocked.

When using HiperSockets to establish dynamic XCF connectivity between TCP/IP stacks in the same CPC using the same HiperSockets CHPID, to preserve subplex isolation, specify the IQDVLANID parameter on the GLOBALCONFIG statement as follows:

- TCP/IP stacks in the same subplex that share the same CPC and specify the same HiperSockets CHPID must specify the same VLAN ID value on the IQDVLANID parameter.
- TCP/IP stacks in different subplexes that share the same CPC and specify the same HiperSockets CHPID must specify different VLAN ID values on the IQDVLANID parameter.
- If subplexing is not being used within the sysplex, do not specify the IQDVLANID parameter on the GLOBALCONFIG statement.

Static XCF, user-defined IUTSAMEH, or user-defined HiperSockets connectivity between TCP stacks in different TCP subplexes within the same VTAM subplex are not blocked, because you have control over the definition and activation of these connections.

No steps are explicitly taken to block any other network connectivity available through LANs and WANs that might be shared by different subplexes, including scenarios where the same OSA-Express adapter is shared across systems in different subplexes. If complete network isolation between subplexes is required, other mechanisms, such as physical network isolation or logical separation through firewall technologies, should be deployed.

Subplex support applies to TCP/IP and VTAM sysplex functions that make explicit use of XCF communications and coupling facility structures. For TCP/IP, this includes functions such as dynamic XCF, dynamic VIPAs, sysplex distributor, SYSPLEXPORTS, and SWSA. The scope of these functions is typically the entire sysplex. Automated domain name registration (ADNR) does not have explicit support for subplexing, but if ADNR is used in a subplexing environment, the scope of ADNR might be restricted to a subplex when the different subplexes are used to isolate network connectivity. In this case, an instance of ADNR must be started for each subplex in the sysplex that will use ADNR functions. ADNR needs to have affinity to one of the stacks in the subplex when ADNR is started on a system that is running multiple stacks. See adnrproc.sample for an example of the JCL.

In the remainder of this information, references to the sysplex or the sysplex group can refer to the entire sysplex and sysplex group EZBTCPCS, if subplexing is not being used, or to a specific subplex and a specific instance of the sysplex group EZBT*vvtt*, if subplexing is in effect.

Setting up a subplex

Setting up TCP/IP and VTAM subplexes within a sysplex requires some preparation.

Steps for preparing your sysplex for subplexing: Steps 2 and 3 depend on the level of isolation you require for your subplexes within the sysplex. You do not need to perform those two steps if the following are true:

- You do not use HiperSockets in support of dynamic XCF connectivity
- You do not need to isolate the subplexes for HiperSockets connectivity (if, for example, you only need to restrict sysplex distributor distribution between subplexes)
- You can configure your systems such that TCP/IP stacks that are in separate subplexes and reside on the same CPC use a CHPID that is unique to the subplex

Requirement: A z890 GA2 or z990 GA2 hardware level is required to support VLAN IDs on HiperSockets.

Perform the following steps to prepare your sysplex for subplexing.

1. Plan how many subplexes are needed and assign a TCP/IP XCF group ID and a VTAM XCF group ID for each anticipated subplex in the sysplex:
   - All TCP/IP stacks in the same TCP/IP subplex must have the same TCP/IP XCF group ID.

- All VTAM nodes in the same VTAM subplex must have the same VTAM XCF group ID.

2. Ensure that all TCP/IP stacks and VTAM nodes in the sysplex are at z/OS V1R8 or later.
3. If HiperSockets is enabled and there are TCP/IP stacks in the sysplex that reside on the same CPC and use the same HiperSockets CHPID, assign a VLAN ID to each anticipated subplex in the sysplex. Also, assign a VLAN ID to the default subplex (that is, the subset of sysplex TCP/IP stacks that uses the default sysplex group name, EZBTCPCS). All TCP/IP stacks in the same subplex must have the same VLAN ID, if they reside on the same CPC and use the same HiperSockets CHPID.

Steps for partitioning a set of TCP/IP stacks in a sysplex into a subplex:
Perform the following steps to partition a set of TCP/IP stacks in a sysplex into a subplex that is functionally isolated from the other TCP/IP stacks in the sysplex.

1. If TCP/IP coupling facility structures for SYSPLEXPORTS or sysplex-wide security associations (SWSA) are to be used, ensure that all the structures are defined to MVS and are specified in the active CFRM policy using their fully suffixed names. For example, if SYSPLEXPORTS is to be used with the base structure name of EZBEPORT, two VTAM subplexes are to be configured (11 and 12), and within each VTAM subplex, two TCP/IP subplexes are defined (21 and 22), ensure that the EZBEPORT1121, EZBEPORT1122, EZBEPORT1221, and EZBEPORT1222 structures are defined to MVS and specified in the active CFRM policy.
2. If the VTAM nodes are to be partitioned into subplexes, reconfigure each VTAM node in the VTAM subplex that will support the new TCP/IP subplex. For a description of how to set up VTAM subplexing, see *z/OS Communications Server: SNA Network Implementation Guide*.
3. As each VTAM is being reconfigured, for each TCP/IP stack that you want to place in a new subplex, perform the following steps:
   a. Stop the stack.
   b. Change the GLOBALCONFIG statement in the TCP/IP profile to include the XCFGRPID parameter with the group ID for the new subplex.
   c. If HiperSockets is enabled and there are TCP/IP stacks that reside on the same CPC as this stack and that use the same HiperSockets CHPID, change the GLOBALCONFIG statement in the TCP/IP profile to include the IQDVLANID parameter with the selected VLAN ID for the new subplex.

      Tip: This step depends on the level of isolation you require for your subplexes within the sysplex. If you do not need to isolate the subplexes for HiperSockets connectivity (if, for example, you only need to restrict sysplex distributor distribution between subplexes), you do not need to perform this step.
   d. Start the TCP/IP stack, specifying the updated TCP/IP profile.
   e. Continue until all the TCP/IP stacks in the new subplex have been reconfigured.

Dynamic XCF

For most point-to-point links, a unique pair of IP addresses is needed for each stack within a sysplex. This requirement tends to use more IP addresses, and IP addresses can be saved by using dynamic XCF. Dynamic XCF creates a single IP address by which all other stacks in a sysplex can reach a stack. Dynamic XCF

creates trusted, internal links to other stacks within a sysplex, generating dynamic definitions for TCP/IP stacks that reside on another z/OS host in a sysplex or for TCP/IP stacks that reside on the same z/OS host.

Dynamic XCF automatically generates the appropriate DEVICE, LINK, HOME, INTERFACE, BSDROUTINGPARMS, and BEGINROUTES definitions, and activates the devices to enable a stack to communicate with other stacks in the sysplex. Dynamic XCF devices and links, when activated, appear to the stack as though they had been defined in the TCP/IP profile, and can be displayed using standard commands.

Dynamic XCF support is available for both IPv4 and IPv6, and is enabled with the DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statement, respectively. Though not specifically mentioned throughout this topic, unless otherwise noted, this information applies to IPv6 as well as IPv4.

Notes:

1. Dynamic XCF (non-IUTSAMEH and non-IQDIO) interface definitions to a particular LPAR are stopped and deleted when the last stack on a given LPAR is removed from the sysplex.
2. If you are using policy-based routing, by default dynamic XCF does not generate the corresponding policy-based routing RouteTable definitions. Determine whether it is appropriate for these routes to be added to each of your policy-based route tables. Use the DynamicXCFRoutes parameter on the RouteTable statement that defines a policy-based route table to indicate whether the routes should be added to that table. For information about the RouteTable statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

Getting started with dynamic XCF

The minimum requirements for TCP/IP stacks to use dynamic XCF differ based on whether same host or inter-host communication is being used. To generate definitions for two TCP/IP stacks that reside on different MVS hosts:

- Both MVS hosts must belong to the same sysplex.
- VTAM must have XCF communications enabled by specifying the XCFINIT=YES or XCFINIT=DEFINE start option, or by activating the VTAM XCF local SNA major node, ISTLSXCF. For details about configuration, see *z/OS Communications Server: SNA Network Implementation Guide*.
- DYNAMICXCF must be specified in the TCP/IP profile of each stack.

With this configuration, both same host and inter-host communication can be performed using dynamic XCF.

To generate definitions for two TCP/IP stacks that reside on the same MVS host, you must specify DYNAMICXCF in the TCP/IP profile of each stack.

At initialization, each TCP/IP stack configured for XCF joins a well-known XCF group. When other stacks in the group discover the new stack, the definitions are created automatically, the links are activated, and the remote IP address for each link is added to the routing table. After the remote IP address has been added, IP traffic proceeds as usual.

In VTAM, you must activate the XCF local SNA major node. You can do this using the start option XCFINIT=YES or XCFINIT=DEFINE. If dynamically defined XCF definitions have been created for another VTAM in the sysplex that has since

stopped and restarted with a different CPName, dynamic XCF recognizes this situation and automatically modifies existing definitions to accommodate the CPName change. If the XCF local SNA major node is inactive when TCP/IP is started and is not activated until after TCP/IP has finished initialization, TCP/IP does not generate any dynamic definitions for other TCP/IP hosts already started in the sysplex until either:

- A new TCP/IP host is detected
- A profile related operator command is issued (such as the VARY TCPIP,,OBEYFILE, VARY TCPIP,,START, or VARY TCPIP,,STOP commands)

Dynamic XCF for IPv4 addresses: To request dynamics for XCF or same host connections, enter the following in the IPCONFIG statement:

```
DYNAMICXCF IPAddress SubnetMask CostMetric
```

The internal definitions that are created depend on your configuration.

Scenario number 1:

- TCP/IP detects another instance of TCP/IP on the same z/OS
- No device exists with the name IUTSAMEH
- No link exists with the name EZASAMEMVS

This scenario creates internal definitions equivalent to the following:

DEVICE IUTSAMEH MPCPTP AUTORESTART
: Device definition to obtain the most efficient stack-to-stack communications within the same MVS image.

LINK EZASAMEMVS MPCPTP IUTSAMEH
: Link definition for the IUTSAMEH device.

HOME IPAddress EZASAMEMVS
: Associates the IP address with the IUTSAMEH link.

BSDROUTINGPARMS EZASAMEMVS 65535 CostMetric SubnetMask DestIPAddress
: Defines the link characteristics for EZASAMEMVS.

  Note: The DestIPAddress is always 0.

START IUTSAMEH
: Starts the IUTSAMEH device.

Scenario number 2:

- TCP/IP detects another instance of TCP/IP in the sysplex
- No device with the name of the CPName of the remote VTAM exists
- No HiperSockets connectivity between the two images exists
- No link exists with the name EZAXCF*nn*, where *nn* is the value of the MVS system symbol (SYSCLONE) for the MVS hosting the VTAM with the device name

This scenario creates internal definitions equivalent to the following:

DEVICE CPName MPCPTP AUTORESTART
: Device definition to communicate with TCP/IP stacks hosted by the remote VTAM.

LINK EZAXCF*nn* MPCPTP CPName
Link definition for the device, where *nn* is the SYSCLONE value for the remote VTAM and MVS.

HOME IPAddress EZAXCF*nn*
Associates the IP address with the dynamic XCF link.

BSDROUTINGPARMS EZAXCF*nn* 55296 CostMetric SubnetMask DestIPAddress
Defines the link characteristics for EZAXCF*nn*.

START CPName
Starts the specified device.

Notes:

1. If EZAXCF*nn* is already defined as a link name, or the CP name is already defined as a device name, then dynamic XCF definition EZAXCF*nn* and the CP name are not generated for discovery of another stack in the same sysplex.
2. The DestIPAddress is always zero.

Scenario number 3:

- TCP/IP detects another instance of TCP/IP in the sysplex
- The images reside on the same CPC
- HiperSockets connectivity between the two images exists
- The host processor supports HiperSockets and z/OS Communications Server is properly configured
- No link exists with the name IQDIOLNK*nnnnnnnn* (where *nnnnnnnn* is the hexadecimal representation of the IP address specified on the IPCONFIG DYNAMICXCF statement)

This scenario creates internal definitions equivalent to the following:

DEVICE IUTIQDIO MPCIPA AUTORESTART
Device definition to communicate with TCP/IP stacks hosted by the remote VTAM.

LINK IQDIOLNK*nnnnnnnn* IPAQIDIO IUTIQDIO
Link definition for the device, where *nnnnnnnn* is the hexadecimal representation of the IP address specified on the IPCONFIG DYNAMICXCF statement (that is, IPAddress).

HOME IPAddress IQDIOLNK*nnnnnnnn*
Associates the IP address with the dynamic XCF link.

BSDROUTINGPARMS IQDIOLNK*nnnnnnnn* 57344 CostMetric SubnetMask DestIPAddress
Defines the link characteristics for IQDIOLNK*nnnnnnnn*.

START IUTIQDIO
Starts the specified device.

Notes:

1. If IQDIOLNK*nnnnnnnn* is already defined as a link name, or IUTIQD*xx* (where *xx* is the CHPID of the HiperSockets LAN that is defined or specified by default on the VTAM start option IQDCHPID) is already defined as a device name, dynamic XCF IQDIOLNK*nnnnnnnn* and IUTIQDIO definitions are not generated for discovery of another stack in the same CPC.
2. The DestIPAddress is always zero.

For details about these XCF-related statements, see *z/OS Communications Server: IP Configuration Reference*. For information about changes to Netstat displays of dynamic XCF settings, see *z/OS Communications Server: IP System Administrator's Commands*.

Dynamic XCF for IPv6 addresses: To request dynamics for XCF or same host connections, enter the following in the IPCONFIG6 statement:

```
DYNAMICXCF IP6Address
```

The internal definitions that are created depend on your configuration.

Scenario number 1:

- TCP/IP detects another instance of TCP/IP on the same z/OS
- No device exists with the name IUTSAMEH
- No link exists with the name EZ6SAMEMVS

This scenario creates internal definitions equivalent to the following:

INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAME IUTSAMEH IPADDR IP6Address
Interface definition for EZ6SAMEMVS.

START EZ6SAMEMVS
Starts the EZ6SAMEMVS interface.

Scenario number 2:

- TCP/IP detects another instance of TCP/IP in the sysplex
- No device with the name of the CPName of the remote VTAM exists
- No HiperSockets connectivity between the two images exists
- No link exists with the name EZ6XCF*nn*, where *nn* is the value of the MVS system symbol (SYSCLONE) for the MVS hosting the VTAM with the device name

This scenario creates internal definitions equivalent to the following:

INTERFACE EZ6XCF*nn* DEFINE MPCPTP6 TRLENAME CPName IPADDR IP6Address
Interface definition, where *nn* is the SYSCLONE value for the remote VTAM and MVS.

START EZ6XCF*nn*
Starts the specified interface.

Notes:

1. If EZ6XCF*nn* is already defined as a link name, or the CP name is already defined as a device name, then dynamic XCF definition EZ6XCF*nn* and CP name are not generated for discovery of another stack in the same sysplex.
2. The DestIPAddress is always zero.

For details about these XCF-related statements, see *z/OS Communications Server: IP Configuration Reference*. For information about changes to Netstat displays of dynamic XCF settings, see *z/OS Communications Server: IP System Administrator's Commands*.

IUTSAMEH

Communications Server provides internal links between TCP/IP stacks that are running within the same MVS image. This support is referred to as a Same Host (IUTSAMEH) link. If DYNAMICXCF is defined, TCP/IP always creates and activates a same host (IUTSAMEH) device and link (unless a static IUTSAMEH device is already defined) even if this is the only stack on the MVS image. When TCP/IP activates the IUTSAMEH device, VTAM dynamically builds the IUTSAMEH TRLE. The generated device name is IUTSAMEH, the generated link name is EZASAMEMVS (IPv4), and the generated interface name is EZ6SAMEMVS (IPv6). As other stacks are brought up within the same MVS image, a host route is created to each of these stacks across the same host link. It is recommended that users do not configure a static device for IUTSAMEH (allow TCP/IP to dynamically create the device and link). Communications Server also uses the IUTSAMEH link for Enterprise Extender support.

The IUTSAMEH DEVICE and LINK (IPv4) or INTERFACE (IPv6) do not become active and remain in SENT SETUP status until either another TCP/IP stack or Enterprise Extender connection is activated on this MVS image.

```
DEVNAME: IUTSAMEH        DEVTYPE: MPCPTP
DEVSTATUS: SENT SETUP
LNKNAME: EZASAMEMVS      LNKTYPE: MPCPTP      LNKSTATUS: NOT ACTIVE
:
INTFNAME: EZ6SAMEMVS     INTFTYPE: MPCPTP6     INTFSTATUS: NOT ACTIVE
```

In the case where IUTSAMEH is active solely because of Enterprise Extender and the IUTSAMEH is subsequently stopped, to restart the IUTSAMEH for Enterprise Extender, the XCA major node must be recycled. Otherwise, it might require manual reactivation of the Enterprise Extender LINEs and PUs, and manual redials.

XCF

When a subsequent stack within the sysplex is started that is not within the same MVS image, TCP/IP creates and activates an XCF device and link (unless an XCF device is already defined). The XCF links connect using the sysplex coupling facility or CTC links. A new device and link are created for every other VTAM node in the sysplex with at least one TCP/IP stack active on the same system with DYNAMICXCF specified. The generated device name is the CP name (for APPN) or SSCP name (for subarea-only nodes) of the remote VTAM. The generated link name is EZAXCF*nn* (IPv4), and the generated interface name is EZ6XCF*nn* (IPv6), where *nn* is the 2-character &SYSCLONE value. A host route across the XCF link is created when the XCF link is successfully activated.

Examples of definitions generated by dynamic XCF

This topic contains examples of definitions generated by dynamic XCF in both IPv4 and IPv6 environments. The notes following the examples pertain to both environments.

IPv4 example 1:

This configuration consists of two MVS systems (MVS1,MVS2) that are members of the same sysplex. Each MVS host has one TCP/IP stack (TCPIP1 and TCPIP2, respectively). From the syntax descriptions, the following information is needed to generate the dynamic definitions:

- MVS sysclone value
- VTAM CPName
- Status of XCF in VTAM

- The values specified on the IPCONFIG DYNAMICXCF keyword

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3

MVS2:
Sysclone = B2 VTAM
Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.2 255.255.255.248 2
```

After both TCPIP1 and TCPIP2 have been started, the following definitions will be generated.

TCPIP1 will generate the equivalent of these definitions:.

```
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.1 EZAXCFB2
BSDROUTINGPARMS EZAXCFB2 55296 3 255.255.255.248 0
START VTAM2
```

TCPIP2 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
HOME 9.1.1.2 EZAXCFA1
BSDROUTINGPARMS EZAXCFA1 55296 2 255.255.255.248 0
START VTAM1
```

When an XCF link becomes active, each TCPIP will generate a route to the other TCPIP over the XCF link. In this example, when the XCF link becomes active, TCPIP1 will generate a route to TCPIP2 over the XCF link and vice versa.

IPv4 example 2:

The configuration is the same as Example 1 except a second TCP/IP stack (TCPIP1A) was added to MVS1.

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3
TCPIP1A: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0

MVS2:
Sysclone = B2
VTAM Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.2 255.255.255.248 2
```

After both TCPIP1 and TCPIP2 have been started, the following definitions will be generated, as in Example 1.

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.1 EZAXCFB2
BSDROUTINGPARMS EZAXCFB2 55296 3 255.255.255.248 0
START VTAM2
```

TCPIP2 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
HOME 9.1.1.2 EZAXCFA1
BSDROUTINGPARMS EZAXCFA1 55296 2 255.255.255.248 0
START VTAM1
```

Now, TCPIP1A is started. TCPIP1 and TCPIP2 recognize that TCPIP1A has started. TCPIP1A will generate definitions for both TCPIP1 and TCPIP2. TCPIP1 will generate IUTSAMEH definitions for TCPIP1A. However, TCPIP2 does not need to generate and will not generate any new definitions except for routing information for TCPIP1A. New definitions do not need to be created because the DEVICE and LINK definitions are based on the discovery of a new VTAM node in the sysplex. (The DEVICE name is the VTAM CPName.)

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.1 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 3 255.255.255.248 0
START IUTSAMEH
```

When the IUTSAMEH connection becomes active, each TCPIP will generate a route to the other TCPIP over the IUTSAMEH connection.

TCPIP2 does not generate anything.

TCPIP1A will generate:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.3 EZAXCFB2
HOME 9.1.1.3 EZASAMEMVS
BSDROUTINGPARMS EZAXCFB2 55296 0 255.255.255.248 0
BSDROUTINGPARMS EZASAMEMVS 65535 0 255.255.255.248 0
START IUTSAMEH
START VTAM2
```

When the IUTSAMEH connection becomes active, each TCPIP will generate a route to the other TCPIP over the IUTSAMEH connection.

IPv4 example 3:

To continue Example 2, add another MVS host (MVS3) with a VTAM node (VTAM3) with one TCP/IP stack (TCPIP3).

```
MVS3:
Sysclone = C3
VTAM Cpname = VTAM3
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP3: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0
```

In this example, the previously active TCP/IP stacks will generate definitions for TCPIP3 because a new VTAM stack has become active in the sysplex. TCPIP3 will generate definitions for definitions for TCPIP1/TCPIP1A and TCPIP2.

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.1 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 3 255.255.255.248 0
START VTAM3
```

TCPIP2 will generate:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.2 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 2 255.255.255.248 0
START VTAM3
```

TCPIP1A will generate:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.3 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 0 255.255.255.248 0
START VTAM3
```

TCPIP3 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.3 EZAXCFA1
HOME 9.1.1.3 EZAXCFB2
BSDROUTINGPARMS EZAXCFA1 55296 0 255.255.255.248 0
BSDROUTINGPARMS EZAXCFB2 55296 0 255.255.255.248 0
START VTAM1
START VTAM2
```

IPv4 example 4:

This example illustrates how dynamic XCF can generate IUTSAMEH definitions without VTAM having its XCF enabled.

```
MVS1:
Sysclone = A1  (not used in this example)
VTAM Cpname = VTAM1  (not used in this example)
VTAM has XCFINIT=NO specified and has not activated the major node ISTLSXCF.
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3
TCPIP1A: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0
```

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.1 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 3 255.255.255.248 0
START IUTSAMEH
```

TCPIP1A will generate:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.3 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 0 255.255.255.248 0
START IUTSAMEH
```

IPv6 example 1:

This configuration consists of two MVS systems (MVS1,MVS2) that are members of the same sysplex. Each MVS host has one TCP/IP stack (TCPIP1 and TCPIP2, respectively). From the syntax descriptions, the following information is needed to generate the dynamic definitions:

- MVS sysclone value
- VTAM CPName
- Status of XCF in VTAM
- The values specified on the IPCONFIG6 DYNAMICXCF keyword

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
MVS2:
Sysclone = B2
Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::222:f001
```

After both TCPIP1 and TCPIP2 are started, the following definitions are generated.

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE  EZ6XCFB2 DEFINE MPCPTP6 TRLENAME VTAM2 IPADDR 2001:0DB8::111:f001
START EZ6XCFB2
```

TCPIP2 generates:

```
INTERFACE  EZ6XCFA1 DEFINE MPCPTP6 TRLENAME VTAM1 IPADDR 2001:0DB8::222:f001
START EZ6XCFA1
```

The INTERFACE statement combines the definitions of DEVICE, LINK, and HOME into a single statement for IPv6. When an XCF interface becomes active, each TCP/IP generates a route to the other TCP/IP over the XCF interface. In this example, when the XCF interface becomes active, TCPIP1 generates a route to TCPIP2 over the XCF interface, and TCPIP2 generates a route to TCPIP1 over the XCF interface.

IPv6 example 2:

The configuration is the same as Example 1 except a second TCP/IP stack (TCPIP1A) is added to MVS1.

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
TCPIP1A: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f002
MVS2:
Sysclone = B2
```

```
VTAM Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::222:f001
```

After both TCPIP1 and TCPIP2 are started, the following definitions are generated, as in Example 1.

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE  EZ6XCFB2 DEFINE MPCPTP6 TRLENAME VTAM2 IPADDR 2001:0DB8::111:f001
START EZ6XCFB2
```

TCPIP2 generates:

```
INTERFACE  EZ6XCFA1 DEFINE MPCPTP6 TRLENAME  VTAM1 IPADDR 2001:0DB8::222:f001
START EZ6XCFA1
```

Now, TCPIP1A is started. TCPIP1 and TCPIP2 recognize that TCPIP1A has started. TCPIP1A generates definitions for both TCPIP1 and TCPIP2. TCPIP1 generates IUTSAMEH definitions for TCPIP1A. However, TCPIP2 does not need to generate and does not generate any new definitions, except for routing information, for TCPIP1A. New definitions do not need to be created because the INTERFACE definition is based on the discovery of a new VTAM node in the sysplex. (The TRLENAME is the VTAM CPName.)

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE  EZ6SAMEMVS DEFINE MPCPTP6 TRLENAME  IUTSAMEH IPADDR 2001:0DB8::111:f001
START EZ6SAMEMVS
```

When the IUTSAMEH connection becomes active, each TCP/IP generates a route to the other TCP/IP over the IUTSAMEH connection.

TCPIP2 does not generate anything.

TCPIP1A generates:

```
INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAME VTAM2 IPADDR 2001:0DB8::111:f002
START EZ6XCFB2
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAME IUTSAMEH IPADDR 2001:0DB8::111:f002
START EZ6SAMEMVS
```

When an XCF interface becomes active, each TCP/IP generates a route to the other TCP/IP over the XCF interface. In this example, when the XCF interface becomes active, TCPIP1A generates a route to TCPIP2 over the XCF interface, and TCPIP2 generates a route to TCPIP1A over the XCF interface. When the IUTSAMEH connection becomes active, each TCP/IP generates a route to the other TCP/IP over the IUTSAMEH connection.

IPv6 example 3:

To continue Example 2, add another MVS host (MVS3) with a VTAM node (VTAM3) with one TCP/IP stack (TCPIP3).

```
MVS3:
Sysclone = C3
VTAM Cpname = VTAM3
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP3: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::333:f001
```

In this example, the previously active TCP/IP stacks generate definitions for TCPIP3 because a new VTAM stack has become active in the sysplex. TCPIP3 generates definitions for TCPIP1, TCPIP1A, and TCPIP2.

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE  EZ6XCFC3 DEFINE MPCPTP6 TRLENAME VTAM3 IPADDR 2001:0DB8::111:f001
START EZ6XCFC3
```

TCPIP2 generates:

```
 INTERFACE  EZ6XCFC3 DEFINE MPCPTP6 TRLENAME VTAM3 IPADDR 2001:0DB8::222:f001
 START EZ6XCFC3
```

TCPIP1A generates:

```
INTERFACE  EZ6XCFC3 DEFINE MPCPTP6 TRLENAME VTAM3 IPADDR 2001:0DB8::111:f002
START EZ6XCFC3
```

TCPIP3 generates:

```
INTERFACE EZ6XCFA1 DEFINE MPCPTP6 TRLENAME VTAM1 IPADDR 2001:0DB8::333:f001
START EZ6XCFA1
INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAME VTAM2 IPADDR 2001:0DB8::333:f001
START EZ6XCFB2
```

IPv6 example 4:

This example illustrates how dynamic XCF can generate IUTSAMEH definitions without VTAM having its XCF enabled.

```
MVS1:
Sysclone = A1  (not used in this example)
VTAM Cpname = VTAM1  (not used in this example)
VTAM has XCFINIT=NO specified and has not activated the major node ISTLSXCF.
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
TCPIP1A: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f002
```

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAME IUTSAMEH IPADDR 2001:0DB8::111:f001
START EZ6SAMEMVS
```

TCPIP1A generates:

```
 INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAME IUTSAMEH IPADDR 2001:0DB8::111:f002
 START EZ6SAMEMVS
```

Notes:

1. Because the interfaces generated by dynamic XCF use a single IP address, the output of the SIOCGIFCONF ioctl() contains multiple entries with the same IP address. If an application is using the SIOCGIFCONF output to issue bind() to all the entries returned, the application could receive EADDRINUSE on a bind() if there are multiple XCF devices defined by dynamic XCF in the list.
2. If you want to define a static route to a link which is generated by dynamic XCF, you must wait until the dynamic devices are started and then use the VARY TCPIP,,OBEYFILE command. For IPv4, the GATEWAY or BEGINROUTES statement that refers to a dynamically defined linkname must be in a separate data set from the data set used to define the dynamic devices (either the initial profile data set or the data set referenced by a VARY TCPIP,,OBEYFILE command). For IPv6, the ROUTE statement that refers to a dynamically defined interface name must be in a separate data set from the data set used to define the dynamic interfaces (either the initial profile data set or the data set referenced by a VARY TCPIP,,OBEYFILE command).
3. Even though the HOME, BSDROUTINGPARMS and BEGINROUTES definitions are full replacement statements, the definitions generated by dynamic XCF will not replace any existing definitions. Likewise, user-defined

HOME, BSDROUTINGPARMS and BEGINROUTES definitions will not affect existing or future definitions generated by dynamic XCF.

4. A mix of static and dynamic IPv4 and IPv6 definitions for a device is not allowed. For example, if a static IUTSAMEH IPv4 device and link is defined, an IPv6 dynamic definition for IUTSAMEH will not be created. If a static IUTSAMEH IPv6 interface is defined, an IPv4 dynamic definition for IUTSAMEH will not be created. The same logic also applies for XCF links; a mix of static and dynamic IPv4 and IPv6 definitions is not allowed for an XCF link.
5. The address specified on the IPCONFIG6 DYNAMICXCF statement cannot be an existing, statically defined, interface address. If a profile contains an IPv6 interface statement for an address that is also used in the IPCONFIG6 DYNAMICXCF statement, the IPCONFIG6 DYNAMICXCF statement is ignored.

Deleting dynamically defined XCF devices: You can delete dynamically defined XCF devices and links by first stopping the devices to be deleted and then issuing a VARY TCPIP,,OBEYFILE command that references a data set containing a DELETE LINK EZAXCF*nn* and DELETE DEVICE. Because the HOME statement processing does not affect dynamically defined XCF HOME list entries, the HOME *xx.xx.xx.xx* EZAXCF*nn* entry is automatically deleted by DELETE LINK.

For IPv6, you can delete dynamically defined XCF interfaces by first stopping the interface previously defined in an INTERFACE statement and then issuing a VARY TCPIP,,OBEYFILE command that references a data set containing an INTERFACE *interfacename* DELETE statement.

HiperSockets

HiperSockets is a System z hardware feature that provides high performance internal communications between LPARs within the same central processor complex (CPC) without the use of any additional or external hardware equipment (for example, channel adapters, LANs, and so on).

If the host processor supports HiperSockets and Communications Server is properly configured, Communications Server will attempt to create XCF connectivity between LPARs in the same CPC using a HiperSockets link or interface. When the HiperSockets link or interface cannot be activated, TCP/IP creates a normal XCF link or interface. However, if the HiperSockets link or interface is successfully activated, but is then later stopped, TCP/IP does not create an XCF link or interface.

The HiperSockets for DYNAMICXCF device and link or interface are dynamically built and the device or interface is started during TCP/IP DYNAMICXCF stack initialization. The HiperSockets for DYNAMICXCF device and link and interface cannot be configured. The generated device name is IUTIQDIO. The generated IPv4 link name is IQDIOLNK*nnnnnnnn*, where *nnnnnnnn* is the character representation of the hexadecimal version of the DYNAMICXCF IP address. The generated IPv6 interface name is IQDIOINTF6. In general, where an XCF link or interface would normally have been used (for intra-CPC), a HiperSockets link or interface will be used.

Similar to IUTSAMEH, VTAM will dynamically build the TRLE for IUTIQDIO when the IUTIQDIO device is started. The TRLE statement is not configured (defined) by the user.

Although HiperSockets for DYNAMICXCF is not configured with TCP/IP DEVICE and LINK or INTERFACE statements, and the TRLE is not defined by the user, the following steps must be taken to define the HiperSockets subchannel devices and IQD CHPID:

1. Using HCD or IOCP, the system administrator must define (create the IOCDS) the HiperSockets IQD CHPID (channel path ID) and subchannel devices to the applicable LPARs. To dynamically build the HiperSockets TRLE, VTAM requires a minimum of 3 subchannel devices configured with each IQD CHPID within HCD. The maximum number of subchannel devices that VTAM will use (associate with each TRLE or MPC group) is 10. For additional details regarding configuring the HiperSockets subchannel devices and IQD CHPID, see *z/OS HCD Planning* and Appendix D, "Using HCD," on page 1493.
2. When more than one IQD CHPID is configured to a specific LPAR, VTAM start option IQDCHPID must be used to specify which specific IQD CHPID this LPAR should use. The VTAM start option controls which IQD CHPID (and related subchannel devices) VTAM selects to include in the HiperSockets MPC group (IUTIQDIO) when it is dynamically built for HiperSockets for DYNAMICXCF connectivity. Start option IQDCHPID controls the VTAM IQD CHPID selection for the HiperSockets for DYNAMICXCF device IUTIQDIO (MPC group) only. It does not control IQD CHPID selection for a user defined HiperSockets device (MPCIPA). However, a user defined HiperSockets device (IQD CHPID) cannot use (conflict with) the same IQD CHPID that the HiperSockets for DYNAMICXCF device is currently using.

   For example, if IQD CHPID 'FE'x is currently in use by DYNAMICXCF due to one of the following:

   a. VTAM start option IQDCHPID=FE is currently specified
   b. VTAM start option IQDCHPID=ANY is currently specified, but the HiperSockets for DYNAMICXCF device IUTIQDIO is currently using the 'FE' CHPID

   then an attempt to configure and start a user defined HiperSockets device IUTIQDFE will not be allowed (IQD CHPIDs conflict). This option can also be modified with a VTAM modify command. In most cases, the default setting will be sufficient. For additional details regarding this start option, see *z/OS Communications Server: SNA Resource Definition Reference*.

For additional details regarding HiperSockets, see "HiperSockets concepts and connectivity" on page 81.

Network interfaces monitoring

Sysplex distributor and other dynamic VIPA (DVIPA) functions depend on an available network path to the TCP/IP stack that owns and advertises a dynamic VIPA. If connectivity is disrupted, clients might not be able to access the applications represented by the DVIPA, impacting their operations. Dynamic XCF interfaces can be configured to provide for a backup network path for DVIPAs. If the dynamic XCF interfaces fail for a given system, the sysplex autonomics function might automatically initiate a recovery action, resulting in the local TCP/IP stack leaving the sysplex and enabling other TCP/IP stacks to assume ownership of the DVIPAs.

However, there are some configurations in which it is not optimal to configure dynamic XCF interfaces as eligible backup network paths for TCP/IP stacks that own and advertise DVIPAs. In these configurations, incoming network traffic for the DVIPAs is expected to arrive over one or more external network interfaces. If these external interfaces fail, or the networks they are attached to experience a

failure, the DVIPAs owned by the local TCP/IP stack can become isolated. Client traffic destined for these DVIPAs cannot reach the local TCP/IP stack; the DVIPA is unreachable.

The network interfaces monitoring function enhances the sysplex autonomics function by enabling you to specify key network interfaces that should be monitored by TCP/IP stacks. If a failure occurs on all specified interfaces, sysplex autonomics recovery can be triggered so other TCP/IP stacks in the sysplex can take over responsibilities for the DVIPAs owned by the local stack.

This level of monitoring is not only useful for TCP/IP stacks that currently own and advertise distributed and non-distributed DVIPAs, but also for TCP/IP stacks that are eligible backup stacks for these DVIPAs. This can help ensure that any backup TCP/IP stacks that are experiencing network connectivity problems do not attempt to perform DVIPA takeover activities if the primary DVIPA owner is stopped or fails. By being proactive and detecting these network connectivity problems, the backup stack can remove itself from the sysplex, enabling other healthy backup stacks to perform the takeover activities. While this monitoring function can also be enabled on TCP/IP stacks that act only as targets for distributed DVIPAs, the benefits for this configuration are minimal, as sysplex distributor already automatically monitors the ability of target TCP/IP stacks to communicate with distributed DVIPA clients.

The following functions are provided by the network interfaces monitoring function:

- You can identify which links and interfaces are critical for inbound network connectivity for a distributed DVIPA or DVIPA-owning TCP/IP stack. Specify which links and interfaces are to be monitored by sysplex autonomics using the MONSYSPLEX parameter on the LINK and INTERFACE statements.
- You have the option of enabling the TCP/IP stack to monitor the status of these interfaces through the MONINTERFACE keyword on the GLOBALCONFIG SYSPLEXMONITOR statement. If the MONINTERFACE keyword is specified, by default the TCP/IP stack also monitors the presence of dynamic routes over these interfaces. To override monitoring of dynamic routes, specify the MONINTERFACE NODYNROUTE keyword on the GLOBALCONFIG SYSPLEXMONITOR statement. The monitoring of dynamic routes enables TCP/IP to extend its monitoring beyond the status of the actual network interface, to also include the status of any routers that are connected to the local area network to which these interfaces are attached. Because a dynamic routing protocol is usually required for DVIPAs, by checking for the presence of dynamic routes, TCP/IP can determine whether the local OMPROUTE daemon is successfully communicating with these routers using dynamic routing protocols. If these network interfaces and dynamic routes become unavailable or experience network connectivity failures, the sysplex autonomics function can automatically initiate a recovery action.

If network interfaces monitoring is enabled, you must be aware of the following scenarios where the monitoring function can create problems:

- Monitored interfaces are deleted

  To delete interfaces, the devices or interfaces must first be stopped. When the devices or interfaces are stopped, the interface becomes inactive. If the TCP/IP stack detects that all monitored interfaces are inactive as a result of stopping devices or interfaces, the TCP/IP stack can issue messages regarding the problem and possibly trigger a recovery action. You can disable monitoring of these interfaces before stopping the devices or interfaces, using the VARY

TCPIP,,OBEYFILE command and specifying the NOMONSYSPLEX keyword for the LINK or INTERFACE statement. For more information about DEVICE and LINK statements and INTERFACE statements, see *z/OS Communications Server: IP Configuration Reference*.

- The first hop routers are brought down for maintenance

  If the MONINTERFACE keyword or MONINTERFACE DYNROUTE option is configured on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and the first hop routers are brought down for maintenance, an inadvertent recovery action might be triggered. You can temporarily disable the monitoring of dynamic routes using the VARY TCPIP,,OBEYFILE command and specifying MONINTERFACE NODYNROUTE on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement.

For more information about sysplex autonomics, see "Sysplex problem detection and recovery."

Sysplex problem detection and recovery

Each sysplex member monitors itself and can automatically leave the sysplex if it determines that it is no longer able to function correctly as a router, target, backup, or owner of a DVIPA. Through a variety of methods, it monitors:

- Internal resources and conditions, such as timely execution of sysplex functions, available private storage, and common storage
- External resources, such as availability of VTAM, or OMPROUTE if it is being used

As long as the TCP/IP stack is a member of a TCP/IP sysplex group, the sysplex monitor gets control periodically. The time period is determined from the TIMERSECS value specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in PROFILE.TCPIP. The default TIMERSECS value is 60 seconds.

Once a problem is detected, further actions depend on whether RECOVERY or NORECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. NORECOVERY is the default value.

Joining the TCP/IP sysplex group can be delayed until certain network routing and connectivity availability conditions are met. Those conditions can include any combination of the following:

- OMPROUTE is active
- Monitored interfaces are active
- Dynamic routes over those monitored interfaces are present

The first condition is activated using the DELAYJOIN option on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. The other two conditions are activated using the MONINTERFACE or MONINTERFACE DYNROUTE option on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. No sysplex-related definitions within the TCP/IP profile (that is, VIPADYNAMIC and DYAMICXCF statements) are processed until the sysplex group is joined.

Tips:

- To determine whether the stack has joined a sysplex group, issue the DISPLAY TCPIP,,SYSPLEX,GROUP command.

- If you have procedures specified on the AUTOLOG profile statement that bind to a dynamic VIPA, specify the optional DELAYSTART parameter with the optional DVIPA subparameter for these procedures on the AUTOLOG statement. With the DELAYSTART DVIPA subparameter, the procedures will not start until the TCP/IP stack has joined the sysplex group and has processed the dynamic VIPA configuration.

During a planned or unplanned outage, the DVIPAs and distributed DVIPAs for a TCP/IP stack are taken over by backup TCP/IP stacks. When the primary TCP/IP stack is restarted, the DVIPAs and distributed DVIPAs are taken back from the backup TCP/IP stacks. If dynamic routing is used to advertise routes to these DVIPAs, and specified network routing and connectivity availability conditions are not met on the primary TCP/IP stack, existing connections to these DVIPAs might be reset and new connect requests to these DVIPAs might fail. By using the GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN and MONINTERFACE DYNROUTE configuration statements in the TCP/IP profile on the primary TCP/IP stack, it is possible to delay taking back the DVIPAs and distributed DVIPAs until specified network routing and connectivity availability conditions are met. New and existing connections continue to be serviced by the backup TCP/IP stacks until OMPROUTE is active and monitored interfaces and dynamic routes over those monitored interfaces are present on the primary TCP/IP stack.

For more information about the GLOBALCONFIG statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

Problem detection

If this stack is not the only member of the TCP/IP sysplex group and it is advertising DVIPAs (owns a DVIPA or is the primary routing node for a Distributed DVIPA), the following resource checks are made by the monitor:

- VTAM address space availability

  If the VTAM address space is not currently active and the elapsed time since VTAM was last detected as active has exceeded the TIMERSECS value, message EZZ9671E is issued.
- Route availability

  If there are no routes available to all partners, given the configured method chosen for forwarding data (VIPAROUTE statement or dynamic XCF interfaces), there are at least two other MVS systems in the sysplex, and the elapsed time since an active route was detected has exceeded the TIMERSECS value, message EZZ9673E or EZD1172E is issued.

If OMPROUTE was successfully initialized, it periodically sends a heartbeat to the stack, so the monitor can always make the following resource checks:

- If the elapsed time since a heartbeat was received has exceeded half of the TIMERSECS value, message EZZ9672E is issued as a warning and no other actions occur.
- If the stack is not the only member of a TCP/IP sysplex group, is advertising DVIPAs, and the elapsed time since a heartbeat was received has exceeded the TIMERSECS value, message EZZ9678E is issued.

If the network monitoring function is enabled, at least one monitored interface is configured, the TCP/IP stack is not the only member of this sysplex group, and the TCP/IP stack participates in sysplex distribution (as a distributor or target) or acts as an owner or a backup for DVIPAs, the following network connectivity checks are made by the monitor:

- Critical interfaces are active

  If the MONINTERFACE option is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, all monitored interfaces become inactive, and the elapsed time since at least one active monitored interface was detected has exceeded the TIMERSECS value, message EZD1209E is issued.
- Presence of dynamic routes available over critical interfaces

  If the MONINTERFACE or MONINTERFACE DYNROUTE option is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, there are no available dynamic routes found over any of the monitored interfaces, and the elapsed time since at least one dynamic route over the monitored interfaces was detected has exceeded the TIMERSECS value, message EZD1210E is issued.

Ensure that the WLM policy for the OMPROUTE address space receives sufficient priority in relationship to other work managed by WLM on the system, so that OMPROUTE receives the CPU cycles necessary for this task. For more information on this topic, see "Sysplex autonomics" on page 277.

If this stack is advertising DVIPAs or is a sysplex distributor target, the following checks are made:

- The monitor checks for CSM storage availability. If CSM storage is continuously critical for greater than the TIMERSECS value, message EZZ9679E is issued.
- If TCP/IP ECSA storage limits are defined on the ECSALIMIT parameter of the GLOBALCONFIG statement, monitoring of this storage is similar to CSM monitoring. If TCP/IP ECSA storage is continuously critical for a time greater than the TIMERSECS value, message EZD1187E is issued. If there are no TCP/IP ECSA storage limits defined on the GLOBALCONFIG statement and a storage request cannot be satisfied, message EZD1170E is issued. These messages indicate that there is a TCP/IP problem with ECSA storage.
- If TCP/IP private storage limits are defined on the POOLLIMIT parameter of the GLOBALCONFIG statement, monitoring of this storage is similar to CSM monitoring. If TCP/IP private storage is continuously critical for a time greater than the TIMERSECS value, message EZD1187E is issued. If there are no TCP/IP private storage limits defined on the GLOBALCONFIG statement and a storage request cannot be satisfied, message EZD1170E is issued. These messages indicate that there is a TCP/IP problem with private storage.

Note, however, that if all DVIPAs on this stack have a status of MOVING and the stack is not a DVIPA target, these checks are not made.

In addition to the sysplex monitor, when the stack joins the TCP/IP sysplex group it requests that XCF monitor the TCP/IP sysplex component on the local stack. The XCF component performs this function by monitoring a status field updated by the TCP/IP sysplex component. If XCF detects that the sysplex functions have not been responsive for the TIMERSECS value, it schedules a TCP/IP routine that issues message EZZ9674E.

If TCP/IP encounters a nonrecoverable sysplex error, it issues the eventual action message EZZ9670E.

If five TCP/IP abends occur in less than 1 minute, eventual action message EZD1973E is issued.

All of these messages are eventual action messages. If the detected problem condition is corrected (for example, VTAM is started), the eventual action message

is cleared. For more information about these eventual action messages, see *z/OS Communications Server: IP Messages Volume 2 (EZB, EZD)* and *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*.

Recovery

Recovery actions occur if RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. If the default setting, SYSPLEXMONITOR NORECOVERY, is active, other than issuing the message, no further actions occur if the problem is not corrected.

The VARY TCPIP,,SYSPLEX,LEAVEGROUP command can be used to manually force the sysplex member to leave the TCP/IP sysplex group. As a stack leaves the TCP/IP sysplex group, message EZZ9670E is cleared, as well as message EZD1170E. All other outstanding eventual action messages are cleared when the condition is cleared (for example, starting VTAM). For information on the VARY TCPIP,,SYSPLEX command, see *z/OS Communications Server: IP System Administrator's Commands*.

If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in the TCP/IP profile, and this stack is not the only member of the TCP/IP sysplex group, the stack leaves the TCP/IP sysplex group when one of the messages is issued. The one exception to this is EZZ9672E, which is only issued as an OMPROUTE warning message. No actions occur unless the corresponding EZZ9678E OMPROUTE message is subsequently issued.

To determine whether the stack is currently joined to a TCP/IP sysplex group, issue the DISPLAY TCPIP,,SYSPLEX,GROUP command. If the stack is not currently joined to a TCP/IP sysplex group, this command displays the following message:

```
EZZ8269I tcpstackname mvsname NOT A MEMBER OF A SYSPLEX GROUP
```

If the stack is currently joined, the name of the TCP/IP XCF group is displayed.

From any member of the sysplex, use the D XCF,GROUP,*groupname* command to see the systems currently in the sysplex group, where *groupname* is EZBTCPCS, or if subplexing is being used, EZBT*vvtt*, where *vv* is the VTAM XCF group ID suffix and *tt* is the TCP group ID suffix..

If the RECOVERY option is specified and a TCP/IP stack initiates an automated recovery action by leaving the TCP/IP sysplex group, all local DVIPAs are inactivated and all the VIPADYNAMIC block definitions are saved. Any applications bound to dynamically created DVIPAs (VIPARANGE or MODDVIPA) will receive an asynchronous error, `EUNATCH (3448) - the protocol required to support the address family is unavailable`.

If internal problems prevent the removal of these resources, eventual action message EZZ9675E is issued, and restarting the stack is necessary to be able to become part of the TCP/IP sysplex group. If all DVIPAs are successfully removed, eventual action message EZZ9676E is issued, indicating that sysplex problem detection cleanup has succeeded. There are two ways for the stack to rejoin the sysplex group and clear this message after a successful cleanup has occurred:

- If AUTOREJOIN was configured on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, the stack automatically rejoins the group and reprocesses its saved VIPADYNAMIC configuration when all detected problems have been relieved. The AUTOREJOIN option is the recommended setting when the RECOVERY option is configured.

- Issue the VARY TCPIP,,SYSPLEX,JOINGROUP command to cause the stack to rejoin the group, and reprocess its VIPADYNAMIC configuration.

Recovery is the preferred method of operation, since this allows other members of the TCP/IP sysplex to automatically take over the functions of a member with no actions needed by an operator. IBM Health Checker for z/OS can be used to check whether the RECOVERY parameter has been specified when the IPCONFIG DYNAMICXCF or the IPCONFIG6 DYNAMICXCF statement has been specified. For more details about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide*.

There are, however, some environments and scenarios where this automated recovery action might not be desirable and perhaps should not be enabled:

- DVIPAs or Distributed DVIPAs are defined, but no backup TCP/IP stacks are identified or no provisions are made to move the DVIPAs in cases of failure.

  The basic premise of the automated recovery actions is that one or more other TCP/IP stacks in the system can pick up ownership responsibilities for any DVIPAs owned by the failing TCP/IP stack. If this is not the case, it is suggested that you carefully evaluate the benefits of designating backup TCP/IP stacks and implement a configuration that includes backup capabilities. If this is not possible or desirable, RECOVERY should not be specified. If RECOVERY is not specified, automated recovery actions are disabled by default.

  For example, one such configuration is if you are only using DVIPAs that are always bound to a specific TCP/IP stack (that is, in lieu of static VIPAs). In this scenario, since there is no possibility of having ownership of these DVIPAs transferred automatically, there is no value in triggering the automated recovery action and you should consider not enabling the automated recovery function or using static VIPAs (since static VIPAs are not affected by the automated recovery actions).
- Test environments where individual system images have very limited resources (CPU, storage, and so on).

  This can include environments where you are running z/OS as a second level guest under z/VM, or in LPARs with shared processors and very limited resources. Not enabling the automated recovery actions in these environments can help prevent unwanted recovery actions that are triggered by false positive conditions, such as scenarios where artificial severe resource shortages are detected.
- Environments where VTAM or OMPROUTE are stopped for intervals longer than the TIMERSECS value specified on the SYSPLEXMONITOR parameter.

  If your current operations procedures have provisions for stopping VTAM or OMPROUTE for extended periods of time, you should consider disabling and re-enabling the automated recovery processing around the periods of time where you stop and restart these components. This can be accomplished using the VARY TCPIP,,OBEYFILE command.

  An alternative solution could be to increase the TIMERSECS value to accommodate the longest period of time you would expect VTAM or OMPROUTE to be inactive during normal operating procedures. One potential drawback of this approach is that the monitoring of other conditions and triggering of automatic recovery functions is less responsive.

Setting TIMERSECS

As discussed, the responsiveness of the self-monitoring and automated recovery actions is governed by the TIMERSECS value specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. The default value is 60 seconds. You

should evaluate whether this default value is appropriate in your environment and, if not, specify a value that is better suited to your environment. Following are some of the considerations that should be evaluated in selecting an appropriate value:

- Specifying a smaller TIMERSECS value increases the responsiveness of the self-monitoring functions.

  The monitor periodically performs its checks for problem conditions, every 60 seconds or every quarter of the TIMERSECS interval (TIMERSECS/4), whichever is less. Therefore, when a smaller TIMERSECS value is specified, operator message alerts are issued sooner if a problem condition is detected. Automated recovery actions are also triggered sooner if the RECOVERY option is in effect.

  While this might be desirable, care should be taken to not specify a timer interval value that is small enough to trigger recovery actions for conditions that are transient in nature. For example, the value specified should probably be larger than the spin loop timeout interval for the system (SPINTIME parameter in the EXSPAT*xx* parmlib member). Otherwise, a spin loop timeout condition that might be recoverable could trigger an unnecessary TCP/IP sysplex recovery action, as a result of the TCP/IP sysplex monitor not being able to be dispatched temporarily before any spin loop timeout recovery actions can take place. A good rule of thumb is to specify a TIMERSECS value that is at least two times larger than the spin loop timeout interval in effect for the system.
- Specifying a longer TIMERSECS value has the opposite effect, and the self-monitoring and automated recovery actions are less responsive.

  In addition, a longer TIMERSECS value can cause disruptions to existing TCP connections when problem conditions are detected, even if automated recovery actions are initiated. For example, if the problem condition persists for a long enough interval and it impacts the delivery of data on existing TCP connections, the remote TCP/IP hosts might terminate these connections before a recovery action is initiated.
- Review your current settings for the sysplex failure detection interval (INTERVAL keyword in COUPLE*xx*) and the ISOLATETIME value specified in your SFM policy, if defined. These values indicate how responsive the XCF component should be in removing systems from the sysplex when a status update missing condition occurs. As a result, these settings can provide a reasonable reference point for the setting of the TIMERSECS value. For more information on these intervals, see *z/OS MVS Setting Up a Sysplex*.

Summary of problems monitored and actions taken

When the sysplex monitor detects a problem, an operator message is issued. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in the TCP/IP profile, the stack leaves the sysplex group, deletes all its dynamic VIPAs, and inactivates all its VIPADYNAMIC definitions. When the detected problem is relieved, the operator message is deleted. If AUTOREJOIN was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, the stack might or might not rejoin the sysplex group, depending on the severity of the problem.

Table 24 on page 455 summarizes the various problems that are monitored and the specific actions that are taken for each detected problem.

Table 24. Sysplex problem monitoring

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
VTAM address space is not active	DVIPAs advertised and VTAM address space has been inactive greater than TIMERSECS interval	1. Issue EZZ9671E, VTAM inactive for at least TIMERSECS interval. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when VTAM is started.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration
Dynamic or static XCF route, or VIPAROUTE not active	DVIPAs advertised, acting as forwarder for a DVIPA, two other MVS systems in the sysplex, and either XCF routes (when VIPAROUTE is not specified) or all IP routes (when VIPAROUTE is enabled) to all sysplex partners are not available for TIMERSECS interval	1. If VIPAROUTE is not enabled, issue message EZZ9673E , dynamic XCF connectivity to all partners not available for at least TIMERSECS interval. 2. If VIPAROUTE is enabled, issue message EZD1172E , dynamic XCF connectivity and IP routes to all partners are not available for at least TIMERSECS interval. 3. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 4. Delete the operator message when any VIPAROUTE or XCF route becomes active.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
Network connectivity – critical interfaces are not active	• MONINTERFACE is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement and at least one interface is configured with the MONSYSPLEX keyword. • The TCP/IP stack participates in sysplex distribution (as a distributor or target) or acts as an owner or a backup for DVIPAs. • Another TCP/IP member exists in the sysplex. • All monitored interfaces become inactive for the TIMERSECS interval.	1. Issue message EZD1209E when all monitored interfaces become inactive for at least the TIMERSECS interval. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, leave the sysplex group and delete all VIPADYNAMIC block definitions. 3. Delete the operator message when any monitored interface becomes active.	
Network connectivity – dynamic routes are not present over critical interfaces	• MONINTERFACE or MONINTERFACE DYNROUTE is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and at least one interface is configured with the MONSYSPLEX keyword. • The TCP/IP stack participates in sysplex distribution (as a distributor or target) or acts as an owner or a backup for DVIPAs. • Another TCP/IP member exists in the sysplex. • No dynamic routes are found over critical interfaces for the TIMERSECS interval.	1. Issue message EZD1210E when no dynamic routes over critical interfaces are found for at least the TIMERSECS interval 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, leave the sysplex group and delete all VIPADYNAMIC block definitions. 3. Delete the operator message when any dynamic route over a critical interface is found.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
OMPROUTE heartbeats are no longer being received	First heartbeat received, and no heartbeat received for half of the TIMERSECS interval	1. Issue message EZZ9672E, the OMPROUTE not responsive warning message. 2. Delete the operator message when heartbeat received, or when message EZZ9678E is issued due to OMPROUTE not responding for at least TIMERSECS interval.	Not applicable
OMPROUTE heartbeats are no longer being received	First heartbeat received, DVIPAs advertised, and no heartbeat received for TIMERSECS interval	1. Issue message EZZ9678E, OMPROUTE not responsive for at least TIMERSECS interval. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. If a last heartbeat was not received (OMPROUTE did not terminate properly), abend and dump the TCP/IP and OMPROUTE address space. 3. Delete the operator message when heartbeat received.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
TCP/IP private storage allocation failures, when POOLLIMIT is not coded on the GLOBALCONFIG statement	DVIPAs advertised or this is a DVIPA target, and TCP private storage allocation fails	1. Issue message EZD1170E, TCP/IP private storage allocation failed message. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when TCP/IP private allocation requests are successful for a full monitor interval (1/4 of the TIMERSECS interval or 1 minute, whichever is less), or delete the operator message when the stack leaves the TCP/IP sysplex group.	Stack does not rejoin the sysplex group. Use of the VARY TCPIP,,SYSPLEX,JOINGROUP command is required to rejoin the sysplex and restore the saved VIPADYNAMIC configuration.
TCP/IP private critical storage limits reached, when POOLLIMIT values are specified on the GLOBALCONFIG statement	DVIPAs advertised or this is a DVIPA target, and TCP/IP private pool is critical for TIMERSECS interval. If TCP/IP private storage allocation request from MVS fails before the TCP/IP private pool is critical for TIMERSECS interval, the problem is treated as if no POOLLIMIT values were specified.	1. Issue message EZD1187E, TCP/IP private storage is critical. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when TCP/IP private pool storage exits the critical state.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
TCP/IP ECSA critical storage limits reached, when TCP/IP ECSA storage limits are specified on the GLOBALCONFIG statement	DVIPAs advertised or this is a DVIPA target, and TCP/IP ECSA is critical for TIMERSECS interval. If TCP/IP ECSA storage allocation request from MVS fails before TCP/IP is critical for TIMERSECS interval, the problem is treated as if no TCP/IP limits were specified.	1. Issue message EZD1187E, TCP/IP ECSA storage is critical. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when TCP/IP ECSA critical state is exited.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration
TCP/IP ECSA storage allocation failures, when no TCP/IP ECSA storage limits are specified on the GLOBALCONFIG statement	DVIPAs advertised or this is a DVIPA target, and TCP/IP ECSA storage allocation request fails	1. Issue message EZD1170E, TCP/IP ECSA storage allocation failed message. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when TCP/IP ECSA allocation requests are successful for a full monitor interval (1/4 of the TIMERSECS interval or 1 minute, whichever is less), or delete the operator message when the stack leaves the TCP/IP sysplex group.	Stack does not rejoin the sysplex group. Use of the VARY TCPIP,,SYSPLEX,JOINGROUP command is required to rejoin the sysplex and restore the saved VIPADYNAMIC configuration.

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
CSM storage critical	DVIPAs advertised or this is a DVIPA target, and CSM critical for greater than TIMERSECS interval	1. Issue message EZZ9679E, CSM critical message. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when CSM critical state exited.	Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration
XCF status is not being updated	Status not updated for TIMERSECS interval	1. Issue message EZZ9674E, sysplex processing not responsive message. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave the sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when the monitor is able to run, or delete the operator message when the stack leaves the TCP/IP sysplex group.	Stack does not rejoin the sysplex group. Use of the VARY TCPIP,,SYSPLEX,JOINGROUP command is required to rejoin the sysplex and restore the saved VIPADYNAMIC configuration.

Table 24. Sysplex problem monitoring (continued)

Type of check	When problem is monitored	Action taken when problem detected	Action taken if AUTOREJOIN coded and problem is cleared
Abend in sysplex code		1. Issue message EZZ9670E, sysplex processing encountered nonrecoverable error. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when the stack leaves the TCP/IP sysplex group.	Stack does not rejoin the sysplex group. Use of the VARY TCPIP,,SYSPLEX,JOINGROUP command is required to rejoin the sysplex and restore the saved VIPADYNAMIC configuration.
Five abends in less than 1 minute		1. Issue message EZD1973E, multiple nonrecoverable errors are adversely affecting sysplex processing. 2. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and this TCP/IP stack is not the only member of the TCP/IP sysplex group, leave sysplex group, inactivate all DVIPAs, and save all VIPADYNAMIC block definitions. 3. Delete the operator message when the stack leaves the TCP/IP sysplex group.	Stack does not rejoin the sysplex group. Use of the VARY TCPIP,,SYSPLEX,JOINGROUP command is required to rejoin the sysplex and restore the saved VIPADYNAMIC configuration.

Target server connection setup responsiveness monitoring

Sysplex distributor measures the responsiveness of target servers in accepting new TCP connection requests at intervals of approximately 1 minute. Target server responsiveness (TSR) values calculated from these measurements are used to modify the weight when using WLM system weight distribution, WLM server-specific weight distribution, or weighted active distribution, to favor those servers that are more successfully accepting new TCP connection setup requests.

TSR

TSR values are displayed as a percentage. Thus, a value of 100 indicates full responsiveness and a value of 0 indicates no responsiveness in setting up new TCP connections. A value of 0 for the TSR causes this target server to be bypassed when new TCP connection setup requests are distributed to target servers for a DVIPA and port, even if the distribution method is round-robin. Periodically, the

distributor sends a new connection request to a target with a TSR of 0, to check whether the responsiveness of that target has improved.

The calculated TSR values are applied to the WLM weights only if there are no stacks participating in the distribution of connections for this DVIPA that are at a release level earlier than z/OS V1R7. The TSRs are calculated by combining two factors, the target connectivity success rate (TCSR) and the Servers' accept Efficiency Fraction (SEF). These factors are defined as follows:

TCSR The target connectivity success rate is the measure of how many new TCP connection setup requests (SYNs) sent by the distributing stack to a target stack are received by the target stack. A low value could indicate a problem with the connectivity between the distributing stack and the target stack.

SEF The Servers' accept Efficiency Fraction measures how well a target server is accepting new TCP connection setup requests and managing its backlog queue.

CER

The connection establishment rate (CER) measures how many TCP connection setup requests received by the target stack become established (that is, how many enter the ESTAB state). The CER value is displayed as a percentage; 100 indicates that all of the connection setup requests that were received entered the established state. A lower value could indicate a routing problem in the network. The CER value is shown only as a diagnostic aid, and its value has no affect on the WLM weight.

Workload balancing

Load balancing is the ability for a cluster to spread workload evenly (or based on some policy) to target servers comprising the cluster. Usually, this load balancing is calculated based on the perceived load on each of the target servers. Various techniques are available to perform IP load balancing for a System z sysplex. These techniques typically fall into the following categories:

- Internal load balancing solutions

  These solutions typically rely on a component executing within the z/OS sysplex to perform the load balancing with very few dependencies on the external network. Because they are executing within the sysplex environment, these solutions typically have access to information that can be used to optimize load balancing, such as system capacity and current load information. An example of this technique is the sysplex distributor.
- Sysplex-aware external load balancing solutions

  These solutions are typically comprised of an external load balancer that relies on components inside the z/OS sysplex for advice on how workload should be distributed. As a result, these solutions usually provide for load balancing that is optimized for a z/OS sysplex environment. Examples of these solutions include the IBM Network Dispatcher and any external load balancing solution that supports the Server/Application State Protocol (SASP) provided by the z/OS Load Balancing Advisor (for example, the CISCO Content Switching Module).
- External load balancing solutions

  These solutions are usually comprised of load balancing components that execute outside of the z/OS sysplex, typically on one or more hosts or routers in the network, with little or no specific awareness of the z/OS sysplex environment. Several vendors provide such load balancing solutions.

This information describes and compares these three load balancing techniques and selected associated solutions. Each solution identifies the target System z servers that can receive client connections based on some specification.

By providing load balancing, clustering techniques must also provide for other system requirements in addition to the dispatching of connections. These include the ability to advertise some single systemwide image or identity so that clients can uniquely and easily identify the service. Additionally, clustering techniques should also provide for horizontal growth of the system and ease of management.

Single systemwide image

Clients connecting to a cluster should not be aware of the internal makeup of a cluster. More specifically, clients should not even be aware that the service they are requesting is actually being serviced by a collection or cluster of servers. Instead, clients must be provided with some single image identifier to be used when connecting to the service. For example, most of the load balancing solutions (internal or external) discussed in this information use a single IP address to represent a cluster of servers to clients. The clients simply use this IP address to establish connections and are not aware that the load balancing solution directs requests to a specific instance of the server.

Horizontal growth

As the clients' demands on the service increase, clusters must provide a way to expand the cluster of servers to accommodate for such growing demand. Put in another way, the cluster must provide a mechanism by which to add servers without disrupting the operation of the cluster. To this end, the service is made available to clients at all times and can grow horizontally to accommodate for increased demand placed on the cluster by the clients.

Ease of management

The administrative burden associated with the cluster (sysplex) should not increase as you add servers to the cluster. You should use the same configurations for many systems in the cluster. Within a sysplex, servers are homogenous, because a sysplex is comprised solely of System z servers. As such, many of the configurations can be shared among the different System z servers, which reduces the administrative burden associated with the sysplex. Additionally, as the size of the cluster increases, the administrative overhead in adding systems to the cluster should be as low as possible.

Administrative activities required to maintain a load balancing solution are highly dependent on the type of load balancing solution deployed. For example, administrative tasks associated with the maintenance of internal load balancing solutions typically consist of administrative tasks within the z/OS sysplex, such as changing z/OS configuration files. External load balancing solutions typically require administrative tasks performed on the external load balancing components, while sysplex-aware external load balancing solutions might require administrative tasks on both internal and external load balancing components. Depending on your environment and organizational structure, the administrative scope required by the various load balancing solutions can play a key role in your selection process. For example, do you need to deploy a solution that requires only administrative tasks on z/OS, or can you make required updates to network components as necessary?

Internal load balancing solutions

Internal load balancing solutions typically rely on components that reside within the z/OS sysplex to perform the load balancing. While other components might be required in the network, after the solution is configured, minimal changes should be needed from network components outside of the sysplex. An example of an internal load balancing solution is the sysplex distributor. For information about the sysplex distributor, see "Sysplex distributor" on page 469.

Sysplex-aware external load balancing solutions

Sysplex-aware external load balancing solutions are typically comprised of an external load balancing solution that communicates with components within the z/OS sysplex, to optimize load balancing based on the current conditions and workloads in the sysplex environment. Examples of these solutions include:

- External load balancers that use the Server/Application State Protocol (SASP) to obtain recommendations and topology information related to applications and systems within a sysplex environment.
- The IBM Network Dispatcher can obtain WLM recommendations from z/OS, and uses these recommendations to determine how workload requests are routed.

External load balancers can obtain detailed information regarding the state of target z/OS applications and systems by communicating with the z/OS Load Balancing Advisor using the SASP protocol. Using SASP, external load balancers can also obtain detailed recommendations on how workload should be distributed within the sysplex environment.

A key component of these recommendations is derived from the z/OS Workload Manager (WLM). The WLM information reflects the current available system capacity for target systems, and can also reflect how well individual server applications are performing compared to the WLM policy goals specified for that application. These recommendations are also influenced by how well the applications are performing from a TCP/IP perspective. For example, are the applications processing new requests quickly enough? Or are new requests filling up the backlog queues that TCP/IP maintains for each application?

Using SASP, external load balancers can perform load balancing that is optimized for your sysplex environment, based on the current configuration and workload conditions. SASP supports TLS/SSL for secure authentication, access control, and encryption of data. For more information on SASP and the z/OS Load Balancing Advisor, see Chapter 23, "z/OS Load Balancing Advisor," on page 1219.

External IP workload balancing solutions

IBM's Network Dispatcher (part of WebSphere Edge Server) and Cisco's Content Switching Module (CSM) are examples of external IP workload balancing solutions. Such solutions exist outside the sysplex, but can direct work into the sysplex. External IP workload balancing solutions typically define a single IP address representing all instances of the server, and then balance new work requests (for example, new TCP connection requests) among available servers.

External load balancers typically use a cluster IP address to represent the set of applications being load balanced. Client applications use this cluster IP address as the destination IP address for all their requests. External load balancers might be capable of using different methods for forwarding packets to their destinations.

Various load balancing solutions might use different terms when describing these methods. In this discussion, dispatch mode and directed mode are discussed as two examples of these methods.

When a load balancer uses dispatch mode, the destination IP addresses for incoming IP packets is not changed. Instead, the load balancer forwards the packet to a target z/OS system by using the MAC address of a network adapter on that system. This technique works well when the target systems and the load balancer are attached to the same network (that is, there are no intervening routers). The receiving z/OS system inspects the destination IP address of the packet, and if it matches one of the IP addresses in its HOME list, it accepts the packet. As a result, with dispatch mode, all target z/OS systems must have the load balancer's cluster IP address defined in their HOME list. It is important, however, that these addresses are not advertised externally through dynamic routing protocols. One way to accomplish this is by defining these IP addresses as loopback addresses on z/OS.

Dispatch mode also has special considerations when the load balancer is more than one hop away from the target systems (that is, a packet must be routed to the target), or when multiple z/OS target systems share the same OSA-Express adapter. In these scenarios, you can use the following techniques to route packets to the proper target system:

- VMAC addresses

  Causes the OSA to route packets using a MAC address that is exclusively owned by the target system.
- GRE tunnels

  Causes the OSA to route packets using an IP address that is exclusively owned by the target system.

On the other hand, when a load balancer uses directed mode, the load balancer converts the destination IP address (that is, the cluster IP address) to an IP address owned by the target z/OS system, using technologies such as network address translation (NAT). When IP packets for these connections are sent back to clients, the load balancer converts the source IP address (that is, the target z/OS system's IP address) back to the cluster IP address that the application had used on its request.

Some load balancer configurations might also perform NAT on the client's IP address. The client's IP address can be replaced with an IP address owned by the load balancing device. This might be necessary to ensure that all outgoing packets from a target system traverse the load balancing device, so that NAT can be performed to change the server's IP address back to the cluster IP address that the client had originally used. Therefore, it is important to note that with directed mode solutions, the IP addresses of load balanced connections reaching the sysplex might not reflect the real IP addresses of the clients making the requests. This can be an important consideration if any definitions or configuration within the sysplex rely on the client's IP address being visible on incoming connections.

External load balancing solutions might provide several configuration options that influence how workload is distributed, such as round-robin, weighted round-robin, and so on. Some of the solutions might also obtain recommendations from components inside the z/OS sysplex that might affect their workload balancing decisions. For more information, see “Sysplex-aware external load balancing solutions” on page 464.

Choosing a load balancing solution

Several load balancing solutions are available for a z/OS environment. The solution that is best for your environment depends on several factors that are related to your environment and the workload being load balanced, including:

- What type of workload needs to be load balanced, and does a particular load balancing solution support this type of workload? For example, does the workload have affinities to specific servers? Can these affinities be determined only by inspecting data content? If so, an external load balancing solution that supports content inspection and affinities might be the most appropriate solution.
- Is it important that the solution is primarily configured and maintained within the z/OS sysplex, with minimal interactions with network components? In these scenarios, an internal load balancing solution might be the preferred answer.
- Do you already have an external load balancing solution in the network? If so, can it be used to load balance z/OS workloads? Does it support SASP, so that it can perform more optimal load balancing decisions?
- Does the load balancing solution have the needed level of availability? For example, if the primary load balancer fails, can a secondary load balancer take over transparently? Can it do so without disrupting existing connections? What if target applications or systems fail? Does the load balancer recognize these conditions?

While a single load balancing solution might be desirable for all workloads in some environments, you can select multiple solutions based on your specific requirements. For example, you might select an external load balancing solution for a particular workload, while an internal load balancing solution might be enabled for another workload. Table 25 lists some of the key attributes of the various load balancing techniques and specific solutions that were discussed in this information. It can be used as a quick reference for comparing these solutions.

Table 25. Load balancing solution quick reference

Features or considerations	Sysplex distributor	External load balancers with SASP	External load balancers
How is the solution configured and administered?	Initial setup might require some interaction with the network (dynamic routing protocols, DNS updates for dynamic VIPAs, and so on). Ongoing administration (adding and removing target server applications and systems) typically confined within z/OS systems.	Initial setup and configuration on load balancer and on z/OS. Ongoing administration might need to be performed on both the load balancer and the z/OS systems.	Initial setup and configuration on load balancer, some configuration on z/OS might be required. Ongoing administration should be mostly confined to the load balancer, although z/OS configuration might be necessary, such as when adding new target systems.
When is the server instance decision made?	Connection setup (in line Syn segment)	Connection setup (in line Syn segment)	Connection setup (in line Syn segment)
Support for TCP and UDP applications?	TCP only	Depends on the load balancer implementation; SASP supports both TCP and UDP	Depends on the load balancer implementation

Table 25. Load balancing solution quick reference (continued)

Features or considerations	Sysplex distributor	External load balancers with SASP	External load balancers
Extra network flows?	No, for outbound traffic. Yes, for inbound traffic. Inbound traffic must traverse the sysplex distributor node. If sysplex distributor is configured as service manager for CISCO routers, the inbound traffic can flow directly to the target application.	Depends on the load balancer implementation; can be avoided if the load balancer is implemented as part of a router or switch.	Depends on the load balancer implementation; can be avoided if the load balancer is implemented as part of a router or switch.
Support for affinities between TCP connection requests based on data content?	No, but support does exist for timer-based affinities	Depends on implementation; some support affinities for HTTP and HTTPS requests by inspecting data content (correlating cookies, jsessionid)	Depends on implementation; some support affinities for HTTP and HTTPS requests by inspecting data content (correlating cookies, jsessionid)
Network address translation?	Not needed; client and server IP addresses are not modified	Might be required by some implementations; client and server IP addresses might be translated	Might be required by some implementations; client and server IP addresses might be translated
Support for IPv6?	Yes	Depends on the load balancer implementation; SASP supports both IPv4 and IPv6	Depends on the load balancer implementation
z/OS WLM recommendations?	Yes, system level and server level	Yes, system level and server level	Depends on the load balancer implementation
z/OS network QoS recommendations?	Yes, based on z/OS QoS policy	No	No
z/OS TCP/IP server health information?	Yes	Yes	No

Table 25. Load balancing solution quick reference (continued)

Features or considerations	Sysplex distributor	External load balancers with SASP	External load balancers
Detection of target application and target system state changes, active or inactive?	Yes, application and system state changes are detected in near real-time fashion.	Yes, the z/OS Load Balancing Advisor and Agents detect application and system state changes within a configurable time period, 60 seconds by default. How quickly external load balancers become aware of these changes depends on several factors: • If the load balancer is using a push model with SASP, the Load Balancing Advisor sends a notification of a state change as soon as it is detected. • If the load balancer is using a poll model with SASP, it depends on the load balancer's polling interval. • The load balancer might also have additional mechanisms for detecting application and system state changes, which might provide for faster detection of these changes.	Depends on the load balancer implementation.
High availability solution, load balancing continues even if the primary load balancing component becomes unavailable?	Yes, one or more backups can be configured to enable dynamic takeover in cases where the TCP/IP stack, or system that is acting as the distributor, fails.	For failures to the load balancer, it depends on the load balancer implementation. Some solutions provide for backup load balancers that can dynamically take over load balancing responsibilities in cases of failures. The z/OS Load Balancing Advisor and Agents can be configured for high availability to minimize the impact of an Advisor, Agent, or system failure.	For failures to the load balancer, it depends on the load balancer implementation. Some solutions provide for backup load balancers that can dynamically take over load balancing responsibilities in cases of failures.
Caching issues?	No, every new connection request is eligible for load balancing.	No, every new connection request is eligible for load balancing.	No, every new connection request is eligible for load balancing.

Sysplex distributor

Sysplex distributor extends the notion of dynamic VIPA and automatic VIPA takeover to allow for load distribution among target servers within the sysplex. It extends the capabilities of dynamic VIPAs to enable distribution of incoming TCP connections to ensure high availability of a particular service within the sysplex.

Sysplex distributor supports load balancing to non-z/OS targets. For more information, see "Sysplex distribution with DataPower" on page 491.

The functionality of sysplex distributor is that one IP entity advertises ownership of an IP address by which a particular service is known. In this fashion, the single system image of sysplex distributor is that of a special IP address. This IP address is called a distributed DVIPA. Further, in sysplex distributor, the IP entity advertising the distributed DVIPA and dispatching connections destined for it is itself a system image within the sysplex, referred to as the distributing stack.

Sysplex distributor makes use of Workload Manager (WLM) and its ability to gauge server load and provide a WLM recommendation. In this paradigm, WLM provides the distributing stack with a WLM recommendation for each target system (a WLM system weight) , or the target stacks provide the distributing stack with a WLM recommendation for each target server (a WLM server-specific weight). The distributing stack uses this information to optimally distribute incoming connection requests between a set of available servers. Additionally, sysplex distributor has the ability to specify certain policies within the Policy Agent so that it can use QoS information from target stacks to further modify the WLM recommendation. Further, these policies can specify which target stacks are candidates for clients in particular subnetworks.

Sysplex distributor also measures the responsiveness of target servers in accepting new TCP connection setup requests, favoring those servers that are more successfully accepting new requests. For more information, see "Target server connection setup responsiveness monitoring" on page 461.

The Workload Manager weight is a relative value. The WLM system weight is an indication of the target system's capacity for additional work, and the WLM server-specific weight is a more granular indication of the specific target server's capacity for additional work. Higher numbers indicate a target with comparatively greater capacity. The Netstat VDPT/-O display shows these values. WLM system weights are indicated by a `B` beside the weight, and WLM server-specific weights are indicated by an `S` beside the weight.

Distribution using WLM system weights is the default distribution method. This can be specified by using the BASEWLM parameter on the VIPADISTRIBUTE statement. Distribution using WLM server-specific weights can be specified by using the SERVERWLM parameter on the VIPADISTRIBUTE statement. If the SERVERWLM parameter is used and all stacks are able to provide WLM server-specific weights for that VIPA/port, WLM server-specific weights are used. Otherwise, WLM system weights are used.

BASEWLM - Distribution using WLM system weights

When determining a WLM system weight recommendation, WLM assigns a relative weight to each system in the sysplex, with the highest weight going to the system with the most available capacity. The available capacity is based on the system's available general CPU capacity, and optionally (if there are no systems in

the sysplex that are prior to V1R9), available System z Application Assist Processor (zAAP) capacity and available System z Integrated Information Processor (zIIP) capacity. When PROCTYPE for BASEWLM is configured on the VIPADISTRIBUTE statement, a composite WLM weight is determined by the sysplex distributor based on the WLM weight for each processor type and expected utilization of each processor type by an application.

If all systems in the sysplex are running at or near 100%, WLM assigns the highest weights to the systems with the largest amount of lower importance work. In this way, new connection requests are distributed to the systems with the highest *displaceable* capacity. However, this assumes that the new work is of a high enough importance level to displace this work. A system can be so loaded that only higher importance work is running on that system, in which case the new work request is not able to meet the goals specified in the WLM policy for that server. For more information on how displaceable capacity is calculated and using the Sysplex Routing Services, see *z/OS MVS Programming: Workload Management Services*.

Use the Netstat VDPT/-O report option with the DETAIL modifier to determine the WLM system weight recommendations for each processor type, along with the modified weight for each processor based on the expected utilization proportion configured on the VIPADISTRIBUTE statement.

SERVERWLM - Distribution using WLM server-specific weights

When determining a WLM server-specific recommendation, WLM determines the service class of the server's address space, and then assigns a weight based on the following:

- How well that server is actually meeting the goals of its service class.
- The amount of displaceable workload available, given the importance of the service class.
- If the distributor and target systems are not prior to V1R9, the WLM recommendation is a composite weight based on the available and displaceable capacity of each processor type (general, zAAP, and zIIP) and the current utilization of each processor type by this application.

If the distributor and target systems are not running a release prior to V1R11, you can use the PROCXCOST and ILWEIGHTING parameters on the VIPADISTRIBUTE statement to influence the WLM server-specific recommendation.

- PROCXCOST

  For applications that are designed to have a portion of their workload run on a zAAP or zIIP specialty processor, use the PROCXCOST parameter on the VIPADISTRIBUTE statement to influence how aggressively WLM favors servers on systems with available zAAP or zIIP capacity over servers on systems where work targeted for the specialty processors has instead run on the conventional processor. The PROCXCOST parameter specifies a crossover cost in the range 1–100 that is applied to the amount of zAAP-targeted or zIIP-targeted workload that actually ran on the conventional processor. The resulting cost is used to reduce conventional processor use by the application, which in turn reduces the WLM recommendation for that server. A crossover cost of 1 means that zAAP-targeted or zIIP-targeted workload that runs on the conventional processor should not be penalized; the WLM recommendation is not reduced.

  Before specifying a high crossover cost, give careful consideration to the effect this might have on workload distribution, because servers with less zAAP or

zIIP processor capacity might receive a significantly lower percentage of the overall workload. The RMF Workload Activity Report shows the zAAP and zIIP processor use, as well as how much crossover took place. Run this report before and after using the PROCXCOST parameter to better understand how it affects your overall workload performance.

- ILWEIGHTING

  Use the ILWEIGHTING parameter on the VIPADISTRIBUTE statement to influence how aggressively WLM favors servers on systems with displaceable capacity at lower importance levels over servers on systems with displaceable capacity at higher importance levels. Work is categorized into one of seven importance levels (importance levels 0 through 6). The most important work runs at importance level 0 and the least important work runs at importance level 6.

  The ILWEIGHTING parameter value specifies how WLM should consider displaceable capacity when determining a server-specific recommendation. The higher the value specified for ILWEIGHTING, the more a stack with displaceable capacity at lower importance levels is favored. The possible ILWEIGHTING parameter values and examples of their effect are as follows:

  – ILWEIGHTING 0

    Specifies that WLM should ignore importance levels when comparing displaceable capacity. This is the default value. For example, if system A and system B are running at 100 percent capacity and new work will be running at importance level 2, all work at importance level 3 and greater is considered to be available displaceable capacity.

    - If system A has 500 service units of work at importance level 3 that can be displaced as the new work runs on this system, it initially has a raw WLM weight of 500.
    - If system B has 500 service units of work at importance level 6 that can be displaced, it also has an initial raw WLM weight of 500.

    The WLM weights are initially the same for both systems, but might be different after the health and performance of the application are considered. The actual WLM weights returned to the invoker are normalized by WLM so that they are in the range 0–64.

    In this example, as 100 connections are received, 50 connections are distributed to system A and 50 connections are distributed to system B, assuming that the health and performance of each application are optimal.

  – ILWEIGHTING 1

    Specifies that WLM should weigh displaceable capacity at each successively lower importance level slightly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the square root of the importance level difference plus 1. This provides a moderate bias when comparing displaceable capacity at different importance levels. Using the previous example but with ILWEIGHTING 1 specified, system B is preferred over system A even though 500 service units of work are to be displaced on either system.

    - The raw WLM weight of system A is 707:

      ```
        500 × SQUAREROOT ((Importance level of displaced work - Importance level of new work) + 1)
      = 500 × SQUAREROOT ((3 - 2) + 1)
      ```

    - The raw WLM weight of system B is 1118:

      ```
        500 × SQUAREROOT ((Importance level of displaced work - Importance level of new work) + 1)
      = 500 × SQUAREROOT ((6 - 2) + 1)
      ```

In this example, as 100 connections are received, roughly 39 are distributed to system A and 61 are distributed to system B, assuming that the health and performance of each application are optimal.

Guideline: If you are using an ILWEIGHTING value for the first time other than the default value 0, use the value 1 initially.

– ILWEIGHTING 2

Specifies that WLM should weigh displaceable capacity at each successively lower importance level significantly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the importance level difference plus 1. This provides an aggressive bias when comparing displaceable capacity at different importance levels. Using the original example but with ILWEIGHTING 2 specified:

- The raw WLM weight of system A is 1000:

```
  500 × ((Importance level of displaced work - Importance level of new work) + 1)
= 500 × ((3 - 2) + 1)
```

- The raw WLM weight of system B is 2500:

```
  500 × ((Importance level of displaced work - Importance level of new work) + 1)
= 500 × ((6 - 2) + 1)
```

In this example, as 100 connections are received, roughly 28 are distributed to system A and 72 are distributed to system B, assuming that the health and performance of each application are optimal; more than twice as many are routed to system B than system A.

– ILWEIGHTING 3

Specifies that WLM should weigh displaceable capacity at each successively lower importance level significantly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the square of the importance level difference plus 1. This provides an exceptionally aggressive bias when comparing displaceable capacity at different importance levels. Using our original example but with ILWEIGHTING 3 specified:

- The raw WLM weight of system A is 2000:

```
  500 × SQUARE ((Importance level of displaced work - Importance level of new work) + 1)
= 500 × SQUARE ((3 - 2) + 1)
```

- The raw WLM weight of system B is 12500:

```
  500 × SQUARE ((Importance level of displaced work - Importance level of new work) + 1)
= 500 × SQUARE ((6 - 2) + 1)
```

In this example, as 100 connections are received, roughly 14 are distributed to system A and 86 are distributed to system B, assuming that the health and performance of each application are optimal; more than six times as many are routed to system B than system A.

Use the Netstat VDPT/-O report option with the DETAIL modifier to determine the WLM server-specific weight recommendations for each processor type, along with the modified weight for each processor based on the current utilization of each processor type.

Evaluate whether WLM server-specific weight distribution can be used as an alternative to WLM system weight distribution for an application. In addition to the reasons mentioned previously, WLM server-specific weight distribution has the added advantage that processor proportions are automatically determined and dynamically updated by WLM based on the actual CPU usage by the application. If you need to determine the processor proportions necessary for WLM system weight distribution, study the workload usage of assist processors by analyzing SMF records, use performance monitor reports such as RMF, and so on.

While WLM server-specific recommendations can be very effective in helping load balancers optimize their routing decisions, there are some scenarios in which applications that are load balancing targets might experience issues that WLM is not aware of through its normal monitoring functions. For example, consider a scenario in which a specific server application instance is executing on a system with excess CPU capacity, yet it cannot successfully process any transactions routed to it because the back-end database it requires on that system is not currently available. From a WLM perspective, this server application instance appears to be a very good candidate to receive requests, given the current available capacity of the system, and the fact that transactions routed to this server appear to be completing very quickly and consuming very little CPU capacity. WLM would therefore assign a higher server-specific weight to this server instance, causing more work to be routed to the ailing server. This type of problem is sometimes referred to as a storm drain problem.

To help alleviate this problem, WLM also considers the health of the server application in its server-specific recommendations. The health of the server is directly determined by information that the server application provides to WLM through programming interfaces. In this way, the WLM perceived health of the application depends directly on the amount of information that an application provides to WLM, if any. WLM uses this information to potentially reduce the weight recommendations for specific server applications that are experiencing problems. This enables sysplex distributor to direct fewer new TCP connections to these servers, selecting instead servers that are not experiencing these problems. WLM considers the following components when determining a server application's health:

- Rate of abnormal transaction completions reported by the server application

  This is applicable to applications, such as the CICS Transaction Server for z/OS, that act as Subsystem Work Managers, reporting transaction status using Workload Management Services, such as IWMRPT. For example, if an application reports to WLM that 90% of all transactions it processed completed abnormally, this server is probably not a good candidate for receiving many new TCP connection requests, as these requests will likely also complete abnormally. As a result, WLM significantly reduces the weight recommendation that is returned to sysplex distributor for this server.
- General health of the application as reported by the server application

  This health indicator is available only for applications that provide this information to WLM using the IWM4HLTH or IWMSRSRG services. The health indicator provides a general health indication for an application or subsystem. Under normal circumstances, the value of this field is 100, meaning the server is 100% healthy. Any value less than 100 indicates that the server is experiencing problem conditions that are not allowing it to process new work requests successfully. A value of less than 100 also causes the WLM to reduce the recommendation provided to sysplex distributor for this server instance.

Choosing between the BASEWLM and SERVERWLM distribution methods

For most applications, the WLM server-specific recommendations provide a more accurate way to distribute workload to the servers. However, when a server acts as an access point to applications that run in other address spaces (and therefore in a different service class), WLM system weights might be the preferred distribution method. For example:

- The TN3270E Telnet server (Telnet) is a communication gateway function that enables clients to access SNA applications over an IP network. As a result, most

of the actual work associated with a Telnet workload takes place in the SNA application, which is typically classified to a different WLM service class than Telnet and probably at a lower importance level. Therefore, although the WLM server-specific recommendation can provide an accurate assessment of how well an individual TN3270E Telnet server is performing, it does not necessarily provide an accurate assessment of the available capacity required by the back-end SNA applications that the client is accessing. As a result, WLM system weight is probably a more appropriate distribution method for this server.

- The INET daemon also provides access to other applications that are probably associated with service classes of a lower importance level (for example, z/OS UNIX Telnet, REXECD, and RSHD). As a result, similar considerations apply, and WLM system weights are the more appropriate distribution method for this server.
- The FTP daemon address space typically performs very little processing on behalf of new FTP sessions. After accepting a new connection, it performs a fork() for an FTP server process that will service the new FTP session. The FTP server process is classified again by WLM, possibly resulting in a different service class than that of the FTP daemon.
  - If the FTP servers run in a different service class than the FTP daemon, then WLM system weights should be used.
  - If WLM policies are set up so that the FTP servers are classified in the same service class as the FTP daemon, WLM server-specific weights should be the distribution method. Although the WLM recommendation will not take into account how well the actual FTP server is meeting its goal, the recommendation will more accurately reflect the amount of displaceable capacity because it is based on the importance of the service class.

BASEWLM and SERVERWLM display example

In the following Netstat VDPT/-O example, the weights represent normalized weights. That is, the original raw weights received from WLM are proportionally reduced for use by the distribution algorithm. Connections are distributed to these servers in a weighted, round-robin fashion using the normalized weights. In this example, the target server responsiveness (TSR) values are all 100, indicating that all servers are fully responsive to new connection requests. A value of 100 is also displayed for stacks that are at a level prior to z/OS V1R7. In that case, no target server responsiveness calculations are applied to the WLM values.

The SERVERWLM parameter was not coded for DVIPA 201.2.10.11, port 245, so it is using WLM system weights.

```
MVS TCP/IP NETSTAT CS VxRx       TCPIP NAME: TCPCS            12:19:18

201.2.10.12     04011 201.1.10.40     001 0000000000 16   100 S
```

If the BASEWLM parameter or the SERVERWLM parameter is specified and WLM weights are not available, incoming connections are distributed among all available servers using round-robin distribution.

Now consider the same example, as shown in the following Netstat VDPT/-O display, but with TSR values indicating that some of the servers are not accepting new connection setup requests productively. The displayed WLM weights have been modified by the TSR values:

```
MVS TCP/IP NETSTAT CS VxRx       TCPIP NAME: TCPCS            12:19:18
Dynamic VIPA Distribution Port Table:
Dest IPaddr     DPort DestXCF Addr    Rdy TotalConn  WLM  TSR Flg
-----------     ----- ------------    --- ---------  ---  --- ---
201.2.10.11     00245 201.1.10.10     001 0000000000 09   075 DB
201.2.10.11     00245 201.1.10.15     001 0000000000 04   100 B
201.2.10.12     04011 201.1.10.10     001 0000000000 03   090 S
201.2.10.12     04011 201.1.10.15     001 0000000000 06   075 S
201.2.10.12     04011 201.1.10.40     001 0000000000 03   020 S
```

The SERVERWLM parameter was coded for DVIPA 201.2.10.12, port 4011. For the server on destination 201.1.10.10, a TSR value of 90 indicates that the server is 90% responsive in accepting new connection requests. For the server on 201.1.10.15, a TSR value of 75 indicates that this server is 75% responsive in handling new connection requests. Likewise, for the server on 201.1.10.40, a TSR value of 20 indicates that it is only 20% effective in accepting new connection requests. These factors are used to modify the WLM server-specific weights, and the modified weights are normalized. As a result, the server on destination XCF 201.1.10.10 has a normalized WLM value of 3, the server on XCF 201.1.10.40 has a WLM value of 3, and the server on destination XCF 201.1.10.15 has a WLM value of 6. So, the server on destination XCF 201.1.10.15 is now favored over the other servers, and the server at 201.1.10.40 is now equal to the server at 201.1.10.10. Connections are distributed to these servers in a weighted, round-robin fashion using these normalized weights.

The SERVERWLM parameter was not coded for DVIPA 201.2.10.11 port 245, so it is using WLM system weights. The server at 201.1.10.10 has a TSR of 75, so the normalized weight is 9, three-quarters of what it was in the previous example. The server at 201.1.10.15 has a TSR of 100, so the normalized weight is the same as it was in the previous example.

WEIGHTEDACTIVE - Distribution based on active connection load

In some instances, rather than using WLM recommendations, weighted active connections (WEIGHTEDActive) can provide a more appropriate solution to control workload distribution:

- Application scaling concerns

  Target systems vary significantly in terms of capacity (small systems and larger systems). WLM recommendations might favor the larger systems significantly. However, a target application might not scale well to larger systems; because of its design, it might not be able to take full advantage of the additional CPU capacity on the larger systems. This can result in these types of servers getting inflated WLM recommendations when running on larger systems and getting overloaded with work.
- Unequal number of SHAREPORT servers

  SHAREPORT is being used, but not all systems have the same number of SHAREPORT server instances (for example, one system has two instances and the other has three). The current round-robin or WLM recommendations do not change distribution based on the number of server instances on each target. Round-robin distribution distributes one connection per target stack regardless

of the number of SHAREPORT server instances on that stack. WLM server-specific weights from a target stack with multiple server instances reflect the average weight.

- You need to control the amount of capacity that specific workloads can consume on each system.

  For example, you might need to reserve some capacity on certain systems for batch workloads that are added into selected systems during specific time periods and have specific time window completion requirements. If those systems are also a target for long-running distributed DVIPA connections, WLM recommendations allow that available capacity to be consumed. This can potentially impact the completion times of the batch jobs when they begin to run, if they are not able to displace the existing non-batch workloads. Similarly, the existing connections on that system can experience performance problems if the batch jobs displace those workloads.

Weighted active connections provide granular control over workload distribution based on predetermined active connection count proportions for each target (fixed weights). Distribution of incoming TCP connection requests is balanced across the targets so that the number of active connections on each target is proportionally equivalent to a configured active connection weight for each target (specified on the DESTIP parameter for each target). Control is gained at the expense of losing the dynamic benefits of WLM recommendations; however, server-specific abnormal completion information, the general health indicator, and the TSR value are used to reduce the active connection weight when these indicators are not optimal. If weighted active connections are used, study and determine the comparative workload that you want on each system so that you can configure appropriate connection weights.

To enable the distributing stack to use server-specific abnormal completion and health information to affect the active connection weight, specify SYSPLEXROUTING on the IPCONFIG statement for all participating stacks.

You can select this type of distribution for DVIPA and port targets by specifying the WEIGHTEDActive option on the DISTM parameter of the VIPADISTRIBUTE statement, and specifying the proportion of active connections that you want on each target using the WEIGHT option on the DESTIP *dynxcfip* parameter of the VIPADISTRIBUTE statement.

Choosing between RoundRobin and WeightedActive distribution

If weighted active connections are configured with default proportions for each target, connections are evenly distributed across all target servers; the goal is to have an equal number of active connections on each server. This is similar to the round-robin distribution method; the difference is that round-robin distribution distributes connections evenly to all target servers without consideration for the active number of connections on each server.

In certain scenarios, a round-robin distribution might be appropriate for specific server applications. Select this type of distribution for particular targets by specifying the DISTM ROUNDROBIN parameter on the VIPADISTRIBUTE statement.

Although both round-robin and weighted active connection distribution do not consider WLM recommendations in their target selection, weighted active connection distribution does use the server-specific abnormal completion

information, the general health indicator, and the TSR value to reduce the weight when these values are less than optimal. For round-robin distribution, connections are not distributed to a target if its TSR value is 0. Periodically, the distributor sends a new connection request to a target with a TSR of 0 to check whether the responsiveness of that target has improved.

Hot standby distribution

You can use the hot standby distribution method to configure sysplex distributor to have one preferred target server and one or more backup (hot standby) target servers. In this configuration, sysplex distributor does not perform load balancing of new connection requests across multiple targets; rather, a preferred target server with an active listener receives all new incoming connection requests. The hot standby target servers, which typically also have a ready listener application, do not receive any new connections requests; they act as backup target servers should the designated preferred target server become unavailable. A target is considered unavailable if any of the following are true:

- The target is not ready.
- The distributor does not have an active route to the target.
- The target is not healthy.

The hot standby distribution method is useful in situations where there is a trade-off between availability and performance, such as a scenario where data sharing between multiple server applications and LPARs is required for availability, but it is more efficient if the work runs on one LPAR instead of interlocking access to the same data across multiple LPARs. For example, if you prefer that an application instance on one LPAR, if available, always handle the workload, and an application instance on another LPAR that is otherwise performing lower priority work be available for backup, use the hot standby distribution method.

Steps for configuring hot standby distribution

Before you begin: You need to determine which server should initially receive the workload (the preferred server), and which server or servers should be a backup server.

Perform the following steps to configure hot standby distribution on the VIPADISTRIBUTE statement:

1. Configure HOTSTANDBY on the DISTMETHOD parameter.
2. Configure the AUTOSWITCHBACK parameter or the NOAUTOSWITCHBACK parameter.
   - Configure AUTOSWITCHBACK if you want the distributor to automatically switch distribution back to the preferred target when it is available. For example, if the preferred target becomes a standby target because its server is no longer ready, when the server is again in the listening state, the distributor automatically switches back to the preferred target as the active target. This is the default value.
   - Configure NOAUTOSWITCHBACK if you want the distributor to continue to use a backup target when the preferred target is available.

     Rule: If NOAUTOSWITCHBACK is configured, then the active server is initially determined by order of activation; the first ready listener becomes the active server regardless of the configured server type (PREFERRED or BACKUP), and remains the active server unless it becomes unavailable.

3. Configure the HEALTHSWITCH parameter or the NOHEALTHSWITCH parameter.
   - Configure HEALTHSWITCH if you want the distributor to automatically switch from the active target when it is not healthy. This is the default. A target is not healthy when there is a severe problem detected by one of the following health metrics:
     - Target server responsiveness (TSR) value is 0%
     - Rate of abnormal transaction completions is 1000
     - General health of the application is 0%

     For more information, see "Target server connection setup responsiveness monitoring" on page 461, and the WLM health metric information in "SERVERWLM - Distribution using WLM server-specific weights" on page 470.

     Rule: When a switch occurs because a target is no longer healthy, the target is not used as a backup target even if its health recovers, unless all available backup targets have previously had health problems. Health metric indicators typically recover when a server is no longer receiving any work, and although a server can appear healthy, the distributor cannot determine if the server is actually healthy. When the distributor detects that the server is transitioning back to the ready state, it again uses the target as a backup.

     Tip: You can use the VARY TCPIP,,SYSPLEX,QUIESCE command and the VARY TCPIP,,SYSPLEX,RESUME command to manually bring a server back to the ready state. You can also use these commands before and after planned maintenance, or to temporarily divert new workload requests from a particular target. For more information, see "Manually quiescing DVIPA sysplex distributor server applications" on page 375.
   - Configure NOHEALTHSWITCH if you want the distributor to ignore health metrics. The distributor switches from the active target only when it is not ready or when the distributor does not have an active route to the target.
4. Configure the PREFERRED option or the BACKUP option after each XCF address on the DESTIP parameter to designate the preferred server and the backup servers, and configure a rank value for each backup server.
   - Configure PREFERRED to designate the preferred server. This must be configured for one, and only one, XCF address.
   - Configure BACKUP to designate a backup (hot standby) server. This must be configured for at least one XCF address. Also configure a rank value on the BACKUP option for each backup server. The distributor switches to the highest ranked backup if the preferred server becomes unavailable.

Hot standby configuration example

Following is an example of the configuration for the hot standby distribution method:

```
VIPADISTRIBUTE DISTMETHOD HOTSTANDBY AUTOSWITCHBACK HEALTHSWITCH
   9.67.240.02 PORT 10000
   DESTIP
      203.3.10.16   PREFERRED
      203.3.10.17   BACKUP    50
      203.3.10.18   BACKUP   100
```

Because server 203.3.10.16 is the preferred server and AUTOSWITCHBACK is configured, that server becomes the active target when it enters the listening state.

Servers 203.3.10.17 and 203.3.10.18 are the backup servers. The highest ranked backup server (203.3.10.18) becomes the active server if server 203.3.10.16 becomes unavailable.

Use the Netstat VIPADCFG/-F command to display the configuration:

```
Dynamic VIPA Information:
:
  VIPA Distribute:
    Dest:      9.67.240.02..10000
      DestXCF: 203.3.10.16
      DistMethod: HotStandby      SrvType: Preferred
      AutoSwitchBack: Yes         HealthSwitch: Yes
      SysPt:   No   TimAff: No    Flg:
      OptLoc:  No
    Dest:      9.67.240.02..10000
      DestXCF: 203.3.10.17
      DistMethod: HotStandby      SrvType: Backup  Rank: 050
      AutoSwitchBack: Yes         HealthSwitch: Yes
      SysPt:   No   TimAff: No    Flg:
      OptLoc:  No
    Dest:      9.67.240.02..10000
      DestXCF: 203.3.10.18
      DistMethod: HotStandby      SrvType: Backup  Rank: 100
      AutoSwitchBack: Yes         HealthSwitch: Yes
      SysPt:   No   TimAff: No    Flg:
      OptLoc:  No
```

Use the Netstat VDPT/-O command to display the status of the servers:

```
Dest:        201.2.10.15..5000
  DestXCF:   203.3.10.16
  TotalConn: 0000000000  Rdy: 001  WLM: 10 TSR: 100
  DistMethod: HotStandby           SrvType: Preferred
  Flg: Active
Dest:        201.2.10.15..5000
  DestXCF:   203.3.10.17
  TotalConn: 0000000000  Rdy: 001  WLM: 10 TSR: 100
  DistMethod: HotStandby           SrvType: Backup
  Flg: Backup
Dest:        201.2.10.15..5000
  DestXCF:   203.3.10.18
  TotalConn: 0000000000  Rdy: 001  WLM: 10 TSR: 100
  DistMethod: HotStandby           SrvType: Backup
  Flg: Backup
```

The `Active` and `Backup` flags show the current status of each server. For example, the preferred server (203.3.10.16) is displayed with the `Active` flag, indicating that it is the active server. Each server uses a default WLM weight of 10 for displays and health calculations.

If the active server becomes unavailable for some reason, the Netstat VDPT/-O command displays something similar to the following status:

```
Dest:        201.2.10.15..5000
  DestXCF:   203.3.10.16
  TotalConn: 0000000000  Rdy: 001  WLM: 00 TSR: 000
  DistMethod: HotStandby           SrvType: Preferred
  Flg: Backup
Dest:        201.2.10.15..5000
  DestXCF:   203.3.10.17
  TotalConn: 0000000000  Rdy: 001  WLM: 10 TSR: 100
  DistMethod: HotStandby           SrvType: Backup
  Flg: Backup
Dest:        201.2.10.15..5000
```

```
DestXCF:   203.3.10.18
TotalConn: 0000000000  Rdy: 001  WLM: 10 TSR: 100
DistMethod: HotStandby           SrvType: Backup
Flg: Active
```

The target server responsiveness (TSR) value for server 203.3.10.16 dropped to zero, and the distributor switched to use the highest ranked backup, 203.3.10.18 (configured with a Backup rank of 100). The backup target becomes the active target, and the preferred target becomes a backup target. However, because the switch from the preferred target occurred because the TSR value is 0, even when the TSR begins to recover, automatic switchback to this target does not occur. If server 203.3.10.16 is quiesced and resumed, the distributor can switch distribution back to this preferred server.

Timed affinity

The distribution method does not have any effect on incoming connection requests that have an active affinity established to a specific server instance (through the TIMEDAFFINITY parameter). When an affinity exists, it has priority over the distribution method setting.

SHAREPORT

Specifying the SHAREPORT parameter on the PORT statement in the TCP/IP profile enables a group of servers to listen on the same port, and thereby share the incoming workload. As new connections are received, the number of active connections is evenly balanced across the available servers using a weighted, round-robin distribution based on the Servers' accept Efficiency Fractions (SEFs). Specifying the SHAREPORTWLM parameter on the PORT statement enables connections to be distributed in a weighted, round-robin fashion based on the WLM server-specific recommendations modified by the SEFs. For more information on SEFs, see “Target server connection setup responsiveness monitoring” on page 461.

Use the same considerations concerning application type to determine the type of port sharing distribution to use. If the shared port is a sysplex distributed port and WLM server-specific weight is the distribution method that is being used by the distributor, code the SHAREPORTWLM paremeter on each target's PORT statement to take advantage of the WLM server-specific recommendations when connections are received at the target. Otherwise, use the SHAREPORT parameter on the PORT statement.

QDIO Accelerator

You can use QDIO Accelerator to provide accelerated forwarding at the DLC layer for some sysplex distributor packets. For more information, see “QDIO Accelerator” on page 91.

QDIO inbound workload queueing

You can use QDIO inbound workload queueing to improve throughput for inbound sysplex distributor packets. For more information, see “QDIO inbound workload queueing” on page 79.

Optimizing local connections

You can configure sysplex distributor to optimize connections when both connection endpoints potentially reside on the same TCP/IP stack within the sysplex. This feature can be very useful if your environment includes multi-tier

server applications within a single sysplex. In this environment, if communication between the tiers is based on the TCP protocol, sysplex distributor can provide higher server availability. For example, without sysplex distributor or some other form of IP load balancing, when an application in tier 1 tries to connect to a tier 2 application on the local system, if the tier 2 server application is not available, these connections fail and the workload is disrupted. Sysplex distributor dynamically reroutes these connections to another tier 2 application that is running elsewhere in the sysplex, which provides a high availability solution. You can use the OPTLOCAL keyword to further optimize load balancing for this type of configuration; for more information about the OPTLOCAL keyword, see "Sysplex distribution optimizations for multi-tier z/OS workloads" on page 485.

Tip: In networks that have CISCO routers, it might be possible to remove the requirement that all inbound traffic needs to traverse the distributing stack. For more details, see "Optimized connection load balancing using sysplex distributor in a network with CISCO routers (IPv4 only)" on page 483.

Sysplex distributor also enhances the dynamic VIPA and automatic VIPA takeover functions. The enhancements allow a DVIPA to move nondisruptively to another stack. That is, in the past, a DVIPA was only allowed to be active on one single stack in the sysplex. This led to potential disruptions in service when connections existed on one stack, yet the intent was to move the DVIPA to another stack. With sysplex distributor, the movement of DVIPAs can now occur without disrupting existing connections on the original DVIPA owning stack.

See "Configuring distributed DVIPAs — sysplex distributor" on page 371 for more information.

Policy interactions

The Policy Agent interacts with the sysplex distributor to assist with workload balancing. There will be one Policy Agent running on an LPAR regardless of how many stacks are configured. First, the Policy Agent can be configured to collect network performance statistics for applications being distributed on target stacks. These network performance statistics are then used to modify the overall WLM weight assigned to a target server. In this way, processor performance, server performance, and application network performance are taken into account when distributing work. Second, policies established on the distributing stack can be configured to restrict the set of target stacks to be considered for any given inbound connection request. In this way, the total set of target stacks can be partitioned among different groups of users or applications requesting connections to distributed applications.

Previously, the QoS performance data was collected by the Policy Agent on the target for each DVIPA and port or application. After collecting the QoS information, the Policy Agent on the target stack pushed this information down to the stack sysplex function which then forwarded it to the stack sysplex function on the distributing stack. There are two significant additions to Policy Agent and sysplex interaction:

- The Policy Agent at each target will collect information with an additional level of granularity; the QoS performance data will be collected for each service level that a target's DVIPA port or application supports.
- The Policy Agent on the distributing stack drives the collection of this information by pulling it from the Policy Agents on the target stacks:
  - The Policy Agent on the distributor opens up one or two TCP connections to each of the Policy Agents on the target stacks. The distributor can be

configured to distribute connections to IPv4 DVIPAs, IPv6 DVIPAs, or both. The Policy Agent opens an IPv4 connection to a target stack's IPv4 XCF address if it is configured to distribute to an IPv4 DVIPA on that target, and likewise opens an IPv6 connection to a target stack's IPv6 XCF address if it is configured to distribute to an IPv6 DVIPA on that target. As a result, if the routing stack is distributing connections to both IPv4 and IPv6 DVIPAs on a given target, then two connections to that target are opened.

For more information on how the sysplex distributor determines its targets, see "Configuring distributed DVIPAs — sysplex distributor" on page 371.

- The Policy Agent on the distributing stack will send across a list of QoS service level names to the Policy Agent on each target.
- The Policy Agent on each target will send back a QoS Policy Action weight fraction for each requested service level that each target DVIPA port/application supports. A specific Policy Action weight fraction will not be sent unless the distributing stack's Policy Agent requests it. Only weight fractions for IPv4 DVIPA ports and applications flow on the IPv4 Policy Agent connection, and similarly, only IPv6 weight fractions flow on the IPv6 Policy Agent connection.
- Upon receiving the QoS Policy Action weight fraction, the Policy Agent on the distributing stack will pass this information down to the sysplex distribution function on the stack. If two connections to a given target Policy Agent are active, weight fractions for IPv4 DVIPA ports or applications and IPv6 DVIPA ports or applications are passed to the sysplex distribution function separately. The stack sysplex distribution function uses this additional information when it is selecting targets for incoming connections. If it does not have a QoS Policy Action weight fraction, then it uses the existing weight fraction to make the load distribution decision instead.

Steps for enabling Policy Agent load distribution functions

Perform the following steps to enable Policy Agent load distribution functions:

1. Define the PolicyPerfMonitorForSDR statement in the PAGENT configuration file to enable the policy performance monitor function. This function must be active on the target and distributing stacks.

---

2. z/OS Communications Server load distribution needs to be specifically enabled for each service level; a Policy Action with the same service level name needs to be defined on each of the appropriate target stacks and also on the distributing stack for these targets. Note that it is reasonable to have a subset of key service level names defined to the distributing stack. Traffic mapping to those service level names that are defined to the distributing stack will receive z/OS Communications Server load distribution by service level. All other traffic will receive Communications Server V2R10 load distribution.

---

3. A backup distributing stack must have the same Policy Action configuration definitions as the active distributing stack for the corresponding DVIPA targets which it is backing up, if it is desired that the Policy Action behavior stay the same when the backup distributing stack takes ownership of the DVIPA. It will also need to have the Policy Agent performance monitor function active.

---

4. Common PAGENT port numbers will be used by the listener (pagentQosListener) and the collector (pagentQosCollector) They are part of the /etc/services install file. If PAGENT is running on an LPAR containing a

target stack, it will open a listening connection using the pagentQosListener port number. PAGENT running on an LPAR containing a distributing stack will establish a TCP connection with each PAGENT listener using the pagentQosCollector as the source port and the pagentQosListener as the destination port. The listener will fail a connect request if the source/destination port does not match the defined collector/listener port. The /etc/services file on all LPARs in the sysplex must be updated to contain these port numbers.

5. Define these two port numbers as reserved ports for PAGENT using the PORT statement in the PROFILE.TCPIP data set.

6. Define the DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statements in PROFILE.TCPIP. The PAGENT TCP connections use the XCF IP addresses.

For more information on setting up polices, see "Sysplex distributor policy performance monitoring configuration" on page 877, "Sysplex distributor policy example" on page 884, or "Sysplex distributor routing policy example" on page 1539.

Optimized connection load balancing using sysplex distributor in a network with CISCO routers (IPv4 only)

The IBM sysplex distributor function provides a workload balancing function within a parallel sysplex. The sysplex distributor consists of a primary distributor stack (denoted by a dynamic VIPA) and a set of target stacks. An inbound packet destined for that DVIPA flows through the primary distributor stack which then forwards the packet over an internal link (XCF, IUTSAMEH, or HiperSockets) to the selected target stack.

The Cisco Multi-Node Load Balancer (MNLB) provides a workload balancing function which distributes traffic through Cisco routers across multiple destination TCP/IP stacks. The MNLB consists of a service manager (the Cisco local director which is denoted by a cluster IP address) and a set of forwarding agents (Cisco routers). For a TCP connection to the cluster IP address, the forwarding agent sends the SYN packet to the service manager, which then selects a target stack and notifies the forwarding agent of this decision. The forwarding agent then sends all future packets for that TCP connection directly to the target stack.

A solution is available to enable you to use a combination of the sysplex distributor and the MNLB to provide workload balancing.

The scope of a cluster IP address managed by sysplex distributor is still a single sysplex, and integration with Cisco forwarding agents merely allows the sysplex distributor routing stack to be bypassed for inbound traffic. If workload balancing for a single cluster IP address across nodes in multiple clusters (sysplexes) is desired, MNLB using Cisco local director as the service manager will continue to be used. Sysplex distributor will continue to advertise network ownership of the cluster IP address with any attached routing daemon so that sysplex distributor appearance and behavior toward the attached routing network is unchanged except for its new relationship with Cisco forwarding agents.

This solution allows the choice of providing the workload distribution inside the sysplex, outside the sysplex, or a combination of both.

Steps for setting up sysplex distributor to be the service manager for the Cisco MNLB (IPv4 only)

Perform the following steps to set up sysplex distributor to be the service manager for the Cisco MNLB:

1. The Cisco router must be configured as a forwarding agent. The IP CASA control address (which is NOT the interface address to the forwarding agent) must be advertised by the Cisco routing daemons. This is not automatically done by Cisco and must be enabled by a Cisco command. For more information on the commands, see online documentation for Cisco at:

   `http://www.cisco.com/univercd/cc/td/doc/product/software/ios120/120newft/120t/120t5/ipclus.htm`

   _____

2. Specify the SERVICEMGR keyword on the VIPADEFine statement in the TCPIP profile.

   _____

3. Specify the VIPASMparms statement in the TCPIP profile. Specify the same multicast group and UDP port on the VIPASMparms statement in the TCPIP profile as are configured in the MNLB.

   _____

4. Optionally, use MD5 authentication:

   Specify the same password (MD5 key) on the VIPASMparms statement in the TCPIP profile as is configured on the Cisco routers which will communicate with the sysplex distributor. If a password (SMPASSword) is specified, then the sysplex distributor will perform MD5 authentication for all communications with the Cisco forwarding agents. For both the Cisco forwarding agent and the sysplex distributor, the password is treated simply as ASCII characters. No translation or conversion is performed. For more information on MD5 authentication, see RFC 1321.

   _____

5. If you are using V1R7 or later, configure all forwarding agents with IP PIM DENSE-MODE to ensure that MNLB packets are forwarded properly.

6. If using the Cisco MNLB in a configuration where there is an OSA adapter between a Cisco router and the destination TCP/IP stacks such that multiple stacks are sharing the OSA, configure Virtual MAC (VMAC) addressing on each of the destination TCP/IP stacks or configure GRE tunnels on the Cisco routers. The sysplex distributor stack is the only stack that registers the dynamic VIPA to OSA. Therefore, if VMACs or GRE tunnels are not configured, OSA will send all packets destined for the DVIPA to the sysplex distributor stack (or to the default router stack if the OSA is not shared with the sysplex distributor stack).

   When configuring GRE tunnels, you must configure them on the Cisco router such that any packets destined for a DVIPA that are routed by the forwarding agents directly to TCP/IP target stacks are encapsulated to the target stack's dynamic XCF address or, if specified in the distributor, to the VIPAROUTE target IP address. If the primary and backup TCP/IP stacks specify different VIPAROUTE statements for a particular target, you must define GRE tunnels for each target IP address that might be used.

For more detailed information about configuring VMACs, see *z/OS Communications Server: SNA Network Implementation Guide*, or see "OSA-Express virtual MAC routing" on page 68. For more detailed information about configuring GRE tunnels, see the Cisco router publications located at http://www.cisco.com/univercd/cc/td/doc/product/core/index.htm.

---

7. Special consideration must be made for each target stack that will receive data from an OSA that is not shared with the distributor stack. Connection load balanced IP packets routed to target stacks that do not use GRE tunnels will arrive with a destination address of the dynamic VIPA address. Only the OSA associated with the distributor stack is aware of the dynamic VIPA address. If the target stack is not the primary router for this OSA, or does not have Virtual MAC (VMAC) addressing configured for this OSA, the OSA will discard the IP packet. In this case, you must either configure VMAC addressing for the OSA, configure GRE tunnels on the Cisco router, or configure the target stack to be the primary router for the OSA. If configuring GRE tunnels on the Cisco router, ensure that any packets destined for a DVIPA that are routed by the forwarding agents directly to TCP/IP target stacks are encapsulated to the target stack's dynamic XCF address or, if specified in the distributor, to the VIPAROUTE target IP address.

---

8. Verification:

   The Netstat VIPADCFG/-F report may be used to verify the configuration. See *z/OS Communications Server: IP System Administrator's Commands* for more information on this command.

   Cisco's ***show ip casa*** commands may be used to display MNLB information. For more detailed information on these commands, see Cisco's online documentation at:

   `http://www.cisco.com/univercd/cc/td/doc/product/software/ios120/120newft/120t/120t5/ipclus.htm`

Following is a sample VIPADYNAMIC statement:

For more information on the VIPADYNAMIC statement, see *z/OS Communications Server: IP Configuration Reference*.

Sysplex distribution optimizations for multi-tier z/OS workloads

You can configure sysplex distributor to optimize connections when both connection endpoints potentially reside on the same TCP/IP stack within the sysplex. This feature can be very useful in environments in which multi-tier server applications are located within the same z/OS system images in a single sysplex. In this environment, if communication between the tiers is based on the TCP protocol, you can use sysplex distributor to provide higher availability.

For example, without sysplex distributor or some other form of IP load balancing, if an application in tier 1 tries to connect to a tier 2 application on the local system, but the tier 2 server application is not available, then these connections fail and the workload is disrupted. With sysplex distributor, these connections are dynamically rerouted to another tier 2 application that is running elsewhere in the sysplex, which provides a high availability solution.

Examples of tier 1 server applications on z/OS that can be used with tier 2 server applications on the same z/OS logical partition (LPAR) are the IBM HTTP Server, the CICS Transaction Gateway, and the WebSphere Application Server. Examples of applications that can be used as tier 2 servers in the same z/OS system and sysplex as tier 1 servers are the CICS Transaction Server, IMS Connect, and DB2.

Sysplex distributor optimization with the OPTLOCAL keyword

Figure 44 shows a sample configuration that uses the OPTLOCAL keyword.

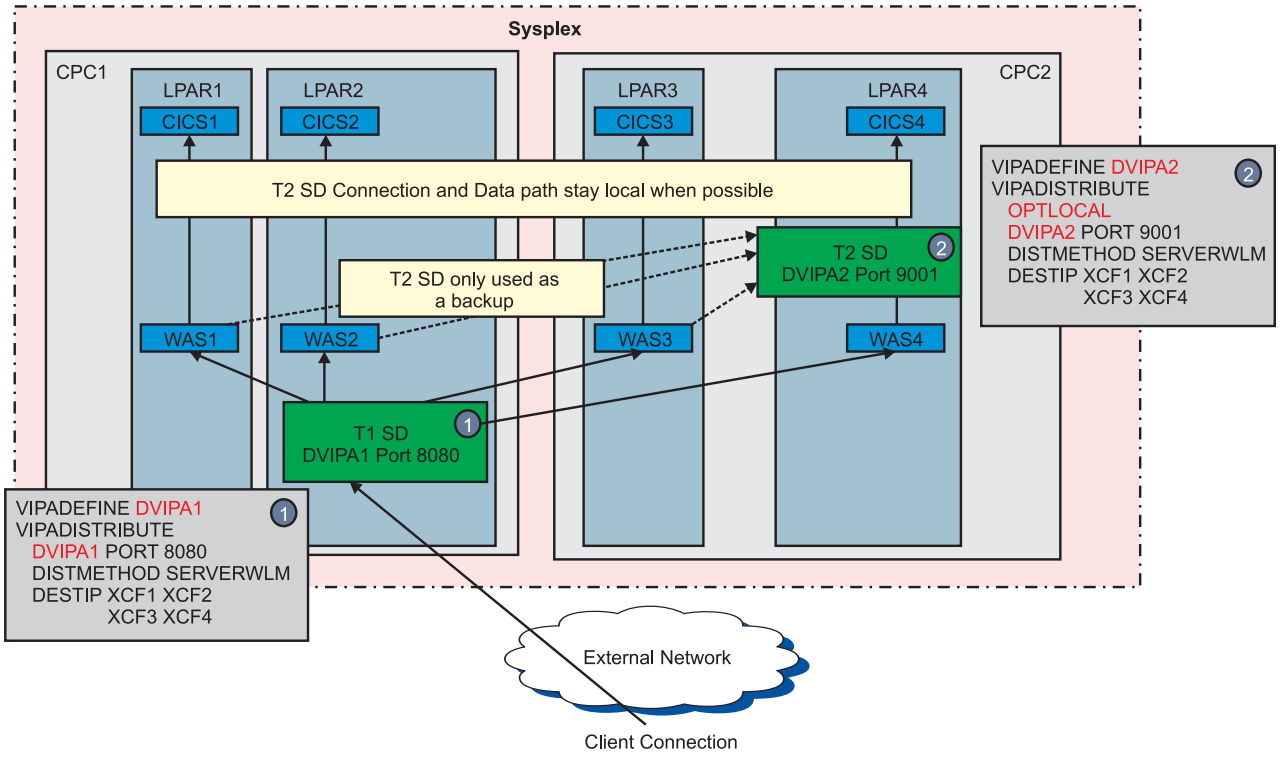

Figure 44. z/OS multi-tier application load balancing using sysplex distributor and the OPTLOCAL keyword

In Figure 44, two tiers of servers are configured across four LPARs that reside on two central processor complexes (CPCs) in a sysplex environment. The tier 1 servers consist of z/OS WebSphere Application Server (WAS) instances that are listening on port 8080 and that are represented by distributed DVIPA1. Sysplex distributor is configured on LPAR2 to receive and distribute any incoming connections for DVIPA1 to any of the active WAS instances in the four LPARs, based on server-specific WLM recommendations for each WAS instance (designated by the dynamic XCF address of each target LPAR). After a request is directed to a tier 1 WAS instance, the request is processed by that server. One or more secondary TCP connections can be established to a back-end tier 2 server, which is a cluster of CICS regions (one CICS region per LPAR).

You can use other sysplex distributor functions to distribute the tier 2 connections in this scenario, but that configuration does add some additional pathlength and processing, because all connection requests and traffic for those connections are forwarded through the sysplex distributor routing stack on LPAR4 so that they can get forwarded to the selected tier 2 server instance. This additional pathlength and processing occurs even in the case where the selected tier 2 server for a given connection resides on the same LPAR as the tier 1 server that originated the connection.

To reduce excess pathlength but still retain high availability, you can specify the OPTLOCAL keyword for DVIPA2 to optimize processing in several ways:

- As long as local target resources are available and are not constrained, extra network flows and overhead through the distributor are avoided, because the local system makes the decision to route the connection to the local instance.
- When the decision is made to make the connection local, TCP/IP enables this connection for fast local sockets processing. This provides a more efficient path through the TCP/IP stack for these communications. All traffic for this connection remains on the local system and is not routed to the distributing stack.
- Optionally, multi-tier applications can also provide their own optimizations by using the Sysplex Sockets API (SO_CLUSTERCONNTYPE) or the trusted TCP connections API (SIOCGPARTNERINFO ioctl). These APIs enable the multi-tier applications to dynamically determine that they both reside on the same system, and as a result, to optimize their processing based on their locality (for example, avoiding encryption of data, sharing memory, and so on). For more information about trusted TCP connections, see *z/OS Communications Server: IP Programmer's Guide and Reference*.
- If local target resources are unavailable or constrained, normal sysplex distributor processing is performed on the connections as a fallback, enabling the sysplex distributor to select another application that is available.

The OPTLOCAL feature provides for optimal performance in the most common scenario in which the local applications and systems are available and healthy, yet the feature also provides a high availability solution when the local applications or systems are not available or are overly constrained.

You can implement the OPTLOCAL feature using the OPTLOCAL keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC block, which enables a target stack to keep outbound connections for local resources on the local stack without having to send the connection request to the distributing stack. The level of preference that is shown to the local stack can be adjusted using the integer value specified on the OPTLOCAL keyword.

Value	Meaning
0	Specifying 0 means that the connections should remain local as long as the server is healthy. The relative capacity of the other systems is not considered in this case.
1	Specifying 1 is the same as specifying 0, except that if the WLM weight for the server on the local stack is 0, the connection request is forwarded to the sysplex distributor to find the best available server.
2 - 16	The values 2 through 16 are used as multipliers against the WLM weight for the server on the local stack, causing its weight to increase and therefore be favored over servers on other stacks. The larger the value specified, the more the local stack is favored.

If the OPTLOCAL keyword is specified with the value 0 or 1, the distribution method is not used for connections originating from the specified target stack, as long as that target application resides on the same stack and is able to handle its current workload. Regardless of the value specified on the OPTLOCAL keyword, connections are sent to the distributing stack if any of the following are true:

- No local server is available.
- The server's accept efficiency fraction (SEF) has fallen below 75.
- The abnormal transaction completions value is greater than 250.
- The health indicator is less than 75.

For more information about the OPTLOCAL keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC block, see *z/OS Communications Server: IP Configuration Reference*.

Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations

In environments in which OPTLOCAL is used to optimize the load balancing between tier 1 and tier 2 server applications, more optimization is possible if sysplex distributor is also used as the load balancer for the tier 1 server applications. This optimization makes both tiers of z/OS server applications on a given system visible to sysplex distributor when making a load balancing decision on an incoming tier 1 connection request. When you are using WLM-based recommendations such as SERVERWLM, this optimization enables sysplex distributor to compute a composite WLM weight for each system, which includes the capacity, performance, and health characteristics of both the tier 1 server applications and the tier 2 server applications. Figure 45 shows an example configuration that enables this enhancement.

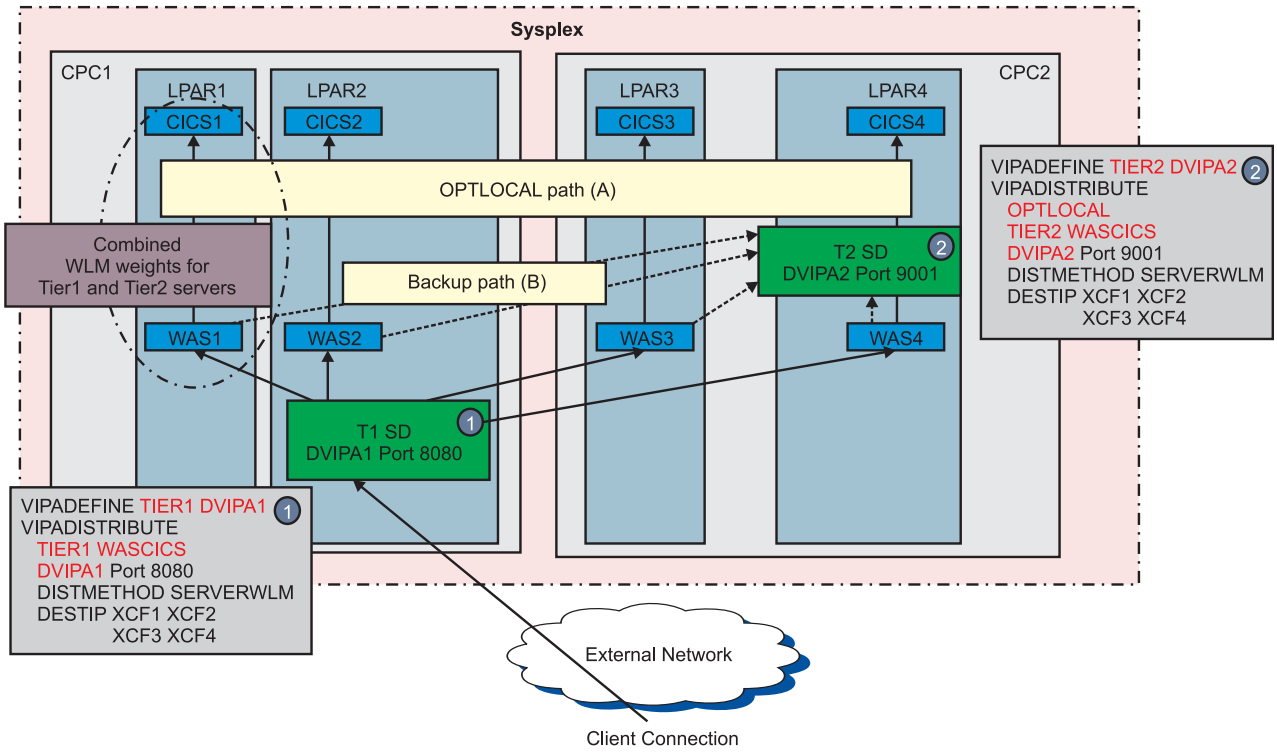

Figure 45. Enhanced z/OS multi-tier application load balancing using sysplex distributor

As shown in Figure 45 on page 488, two VIPADISTRIBUTE statements are required in this configuration. The first statement for DVIPA1 represents the distribution to the tier 1 server applications, a cluster of WebSphere Application Server instances running on each LPAR. The second statement for DVIPA2 represents the tier 2 server applications, a cluster of CICS regions on the same LPARs as the tier 1 servers.

The VIPADISTRIBUTE statement for each DVIPA includes a tier specification that indicates the role of each DVIPA (TIER1 or TIER2). The two DVIPAs are linked by a common group name specification, WASCICS. This association enables sysplex distributor to compute a single weight for each DVIPA1 target system that reflects the combination weight of the tier 1 and tier 2 server applications that are running on that system. Sysplex distributor performs its workload balancing of incoming connection requests to DVIPA1 based on these combined weights, enabling distribution of requests to the target z/OS systems to be based on the aggregate capacity of each system to perform the processing of both server application tiers.

In addition, because the VIPADISTRIBUTE statement for DVIPA2 also includes the OPTLOCAL specification, incoming tier 1 connection requests are typically directed to a system that also enables the subsequent tier 2 connection requests to stay local. This provides an improvement over the base OPTLOCAL configuration, because new workload is directed toward systems that have more capacity to process the work while retaining the local optimizations provided by OPTLOCAL.

Rule: To use this feature, the distribution method for the tier 1 and tier 2 servers must be BASEWLM or SERVERWLM.

Guideline: To take full advantage of this feature, set the distribution method for both tier 1 and tier 2 servers to SERVERWLM. This enables sysplex distributor to obtain server-specific WLM recommendations for each application server tier; the combined weight reflects the composite performance of the servers instead of the capacity of the system.

For more information about the TIER1 and TIER2 keywords on the VIPADISTRIBUTE statement in the VIPADYNAMIC block, see *z/OS Communications Server: IP Configuration Reference*.

Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations with CPC affinity

In addition to multi-tier application awareness and optimizing distribution when these applications are local, you can use the CPCSCOPE keyword to further optimize sysplex distributor load balancing decisions. This configuration option helps to avoid workload distribution to tier 1 servers that cannot perform the tier 2 processing on the same CPC, which requires distribution of those tier 2 connections to systems that reside on a different CPC. Figure 46 on page 490 shows an example configuration in which this option might be useful.

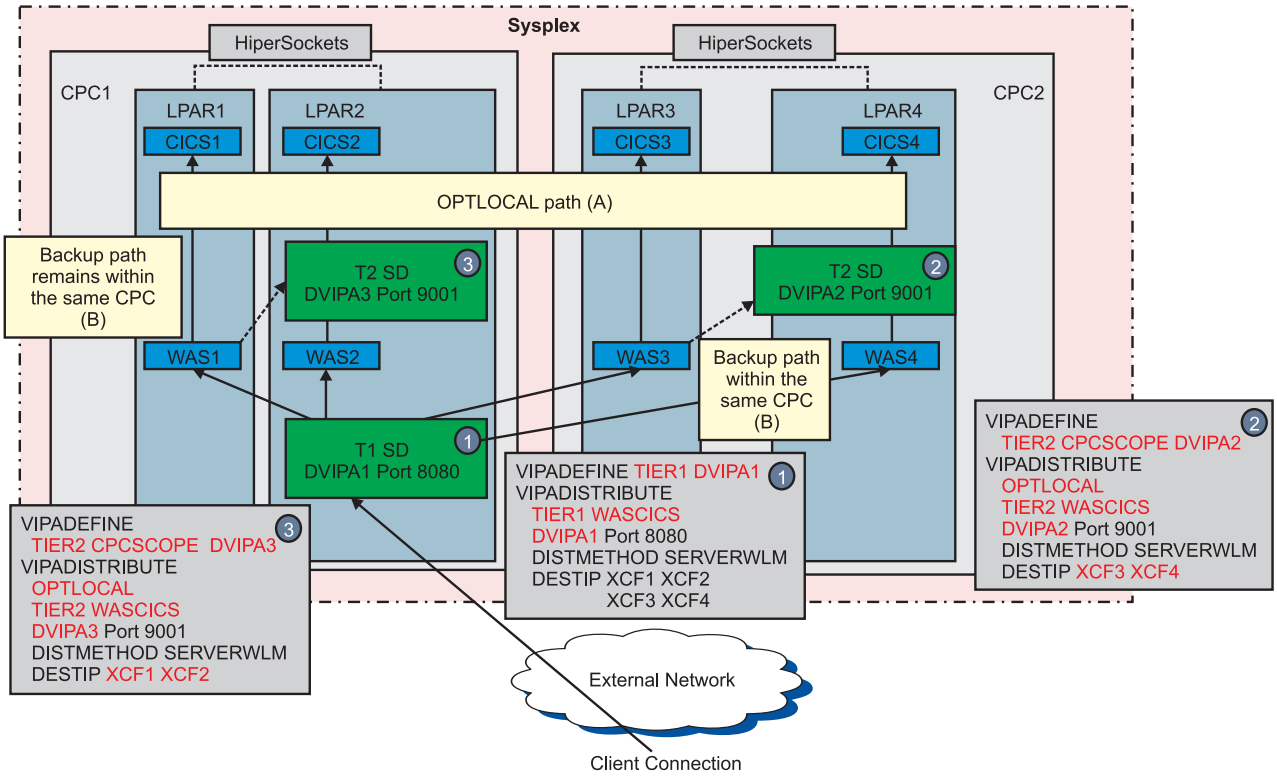

Figure 46. z/OS multi-tier application configuration using CPCSCOPE DVIPAs

In Figure 46, connection requests for tier 1 server applications are distributed to systems based on the aggregate WLM recommendations of the tier 1 and tier 2 server applications running on each system. When connections are directed to a tier 1 server instance, any subsequent tier 2 connections that are originated by that server instance are likely to be directed to the local tier 2 server as a result of the OPTLOCAL keyword, assuming that the tier 2 server application is active on the local system.

If the tier 1 server cannot access a tier 2 server on the same system, the connection requests and their associated data flows are sent to the sysplex distributor for the tier 2 DVIPA; this distributor might be on another system in the sysplex. That system might be on the same CPC as the tier 1 server, or it might be on another CPC at the same site or potentially at a remote site. The sysplex distributor then selects a target tier 2 server instance that resides on the same CPC or in another CPC. In either case, inbound traffic from the tier 1 server to the tier 2 server might need to traverse one or more CPCs or external network links before it reaches the tier 2 server.

You can optimize these flows by using the CPCSCOPE keyword and confining the activation and movement of a DVIPA to a specific CPC, which in turn enables any connection using the backup path to a tier 2 server to also remain within an LPAR on the same CPC. This optimization enables these backup data flows to leverage secure, high speed, virtual network links inside the CPC, such as HiperSockets. This configuration also helps to ensure that these data flows are optimized by avoiding the need to traverse external links, which might result in additional network latency and encryption requirements.

Three DVIPAs are defined in Figure 46:

- DVIPA1 represents the tier 1 servers that reside on LPAR1 - LPAR4. DVIPA1 is defined as a tier 1 DVIPA, and is associated with the group name WASCICS.
- DVIPA2 represents the tier 2 servers that reside on LPAR3 and LPAR4 on CPC2. DVIPA2 is defined as a tier 2 DVIPA, and is associated with the group name WASCICS. DVIPA2 also specifies the CPCSCOPE keyword, which ensures that DVIPA2 remains within LPARs on CPC2, even in recovery scenarios where DVIPA takeover is required.
- DVIPA3 represents the tier 2 servers that reside on LPAR1 and LPAR2 on CPC1. DVIPA3 is similar to DVIPA2; it is also a tier 2 DVIPA, is associated with the same group name (WASCICS), and also specifies the CPCSCOPE keyword. If a takeover is required for this DVIPA, it remains within any backup LPARs residing on CPC1.

Requirement: Configure the tier 1 application servers on each CPC to use a unique, CPC-specific DVIPA for their tier 2 connections. The tier 1 application server configurations need to be unique based on the CPC on which they reside.

Guideline: Before activating this feature, consider the benefits that the feature provides versus the additional configuration requirements that this type of configuration requires. You must carefully define the tier 2 DVIPAs to ensure that the correct VIPADEFINE and VIPBACKUP definitions are maintained on each of the LPARs based on the CPC on which the LPARs are defined. These definitions can have implications on your recovery plans and procedures that might allow z/OS systems or tier 1 server applications to be restarted on LPARs in different CPCs, rather than in the CPC in which they were originally activated.

For more information about the CPCSCOPE keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC block, see *z/OS Communications Server: IP Configuration Reference*.

Sysplex distribution with DataPower

You can use sysplex distributor to balance workload across a cluster of non-z/OS target hosts that are explicitly enabled for sysplex distributor load balancing. An IBM WebSphere DataPower appliance is an example of a non-z/OS target that supports sysplex distributor load balancing.

IBM WebSphere DataPower appliances are often used as a front-end processing tier to z/OS, enabling and enhancing the participation of z/OS applications in a service-oriented architecture (SOA). DataPower can provide for the transparent Web services enablement of z/OS applications, and can enhance distribution of workloads that are already enabled for Web services on z/OS by providing acceleration and more efficient handling of Web services security protocols, XML schema validation, and numerous other functions.

Tips:

- Although a Web services workload is described here, you can apply the concepts in this information to other protocols that DataPower supports, as long as those protocols are TCP-connection oriented.
- Sysplex distribution with DataPower is available for both IPv4 and IPv6. The following examples describe IPv4 distribution with DataPower, but this function applies to IPv6 as well.

In many environments, multiple DataPower instances are placed in a cluster to provide higher availability and scalability. This requires a load balancing

component that distributes incoming Web services connection requests to the DataPower appliance cluster, as shown by the first tier of load balancing in Figure 47. After DataPower has performed its portion of the processing for the incoming request, it typically routes the request to the z/OS application tier, which includes applications such as CICS, IMS, WebSphere, and DB2. In a high availability sysplex configuration, the z/OS application tier probably requires a second tier of load balancing that balances requests across the z/OS application tier.

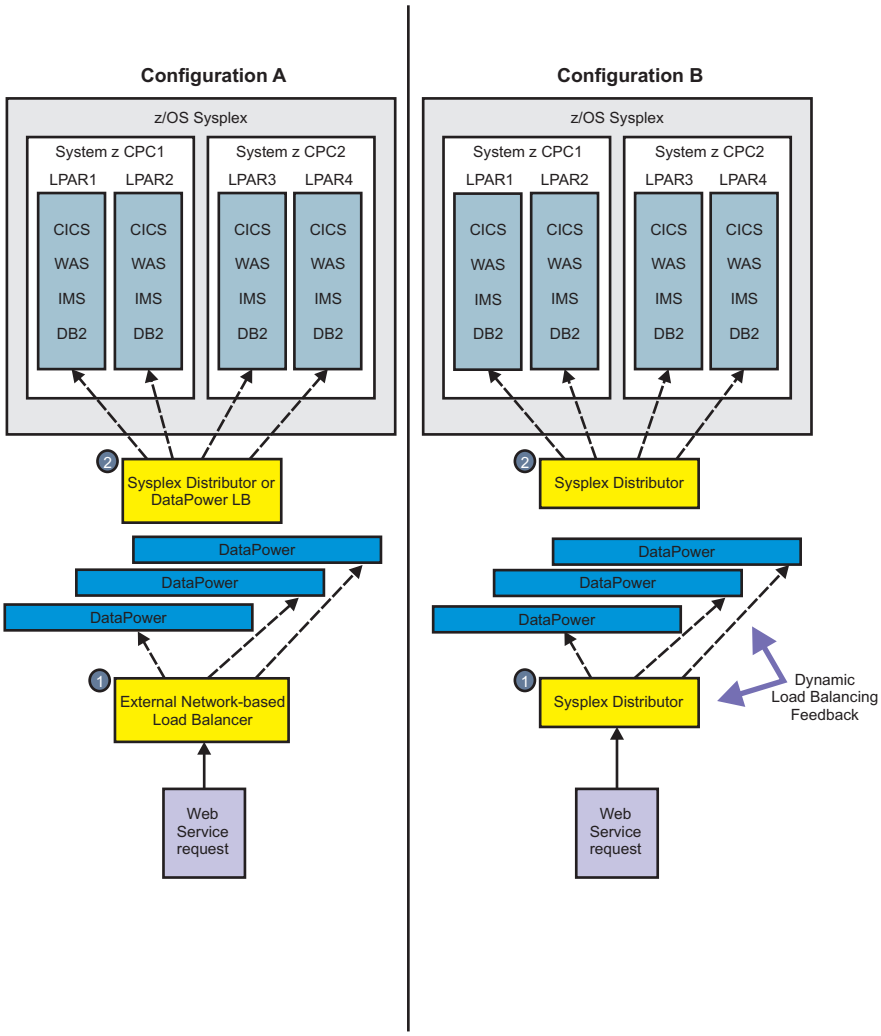

Figure 47. DataPower load balancing overview

Figure 47 shows two options for load balancing of z/OS workloads with DataPower.

In configuration A, an external network-based load balancer is used to balance incoming Web services connection requests to DataPower. The external load balancer is configured to receive TCP connection requests for a specific port and an IP address that represents the cluster of DataPower appliances that can handle the connection request. The external load balancer selects a target DataPower appliance to route the request to based on the distribution method configured for the load balancer (round robin, weighted round-robin, and so on). When the request is processed by the DataPower appliance, a secondary TCP connection might be initiated to route a subsequent request to the z/OS application tier, which requires

a second load balancing tier. You can implement this second load balancing tier using load balancing support that is built into DataPower, which by default uses a round-robin distribution, or you can use the z/OS sysplex distributor for this load balancing tier. Because sysplex distributor is an integral part of the sysplex environment, it has in-depth, real-time knowledge of the z/OS environment, including z/OS Workload Manager recommendations about current capacity and performance of each application and LPAR instance, and in-depth information about the current state and health of the z/OS application tier. This information enables sysplex distributor to make optimal load balancing decisions based on the current state of the z/OS application tier and other sysplex resources.

Configuration B is a variation of configuration A, with the main difference being that sysplex distributor is used as the load balancing component for both distribution tiers. This enables you to use a single load balancing solution for the composite z/OS workload, including both the DataPower and z/OS application processing tiers, which simplifies load balancing administration. Using sysplex distributor as the tier 1 load balancer for DataPower takes advantage of DataPower support to communicate with sysplex distributor over an out-of-band TCP connection to provide dynamic load balancing feedback and enable the following optimizations:

- Routing is optimized so that outbound traffic (from the tier 1 DataPower target server towards the client) does not need to traverse the sysplex distributor.

  Sysplex distributor uses generic routing encapsulation (GRE) to forward inbound distributed packets to DataPower, without performing network address translation (NAT) to map the destination IP address of the connection request to the IP address of the target DataPower appliance. Outbound tier 1 traffic does not need to traverse the sysplex distributor node and can flow directly to the client, because no reverse NAT processing is necessary.
- If a planned or unplanned outage of a primary sysplex distributor instance occurs, connection information provided by the DataPower appliances enables nondisruptive tier 1 takeover of existing connections between clients and DataPower targets.

  If a sysplex distributor takeover occurs, sysplex distributor dynamically discovers the state of any existing tier 1 connections from each DataPower appliance. The connection state information also enables sysplex distributor to maintain its active, distributed connection-routing entries without needing to inspect packets to determine when connections are terminated.
- CPU usage information provided by the DataPower appliance enables sysplex distributor to optimize its load balancing decisions, which avoids overloaded DataPower appliances by directing new requests to DataPower instances with less usage.

For a more detailed explanation of using sysplex distributor to perform load balancing for composite z/OS and DataPower workloads, see the following:

- “Scenario 1 overview - sysplex distributor load balancing to DataPower” on page 494
- “Steps for configuring scenario 1 - sysplex distributor load balancing to DataPower” on page 495
- “Scenario 2 overview - sysplex distributor load balancing to DataPower in a multi-tier and multisite environment” on page 498
- “Steps for configuring scenario 2 - sysplex distributor load balancing to DataPower in a multi-tier and multisite environment” on page 500

Scenario 1 overview - sysplex distributor load balancing to DataPower

In Figure 48, a set of DataPower appliance instances (DATAP) are configured to handle a specific Web service request and to invoke a backend z/OS application (CICS) to complete the processing, prior to sending a response to the Web services client. Sysplex distributor is used for load balancing of both processing tiers, the DataPower tier and the z/OS application tier, both of which are clustered for high availability and scalability.

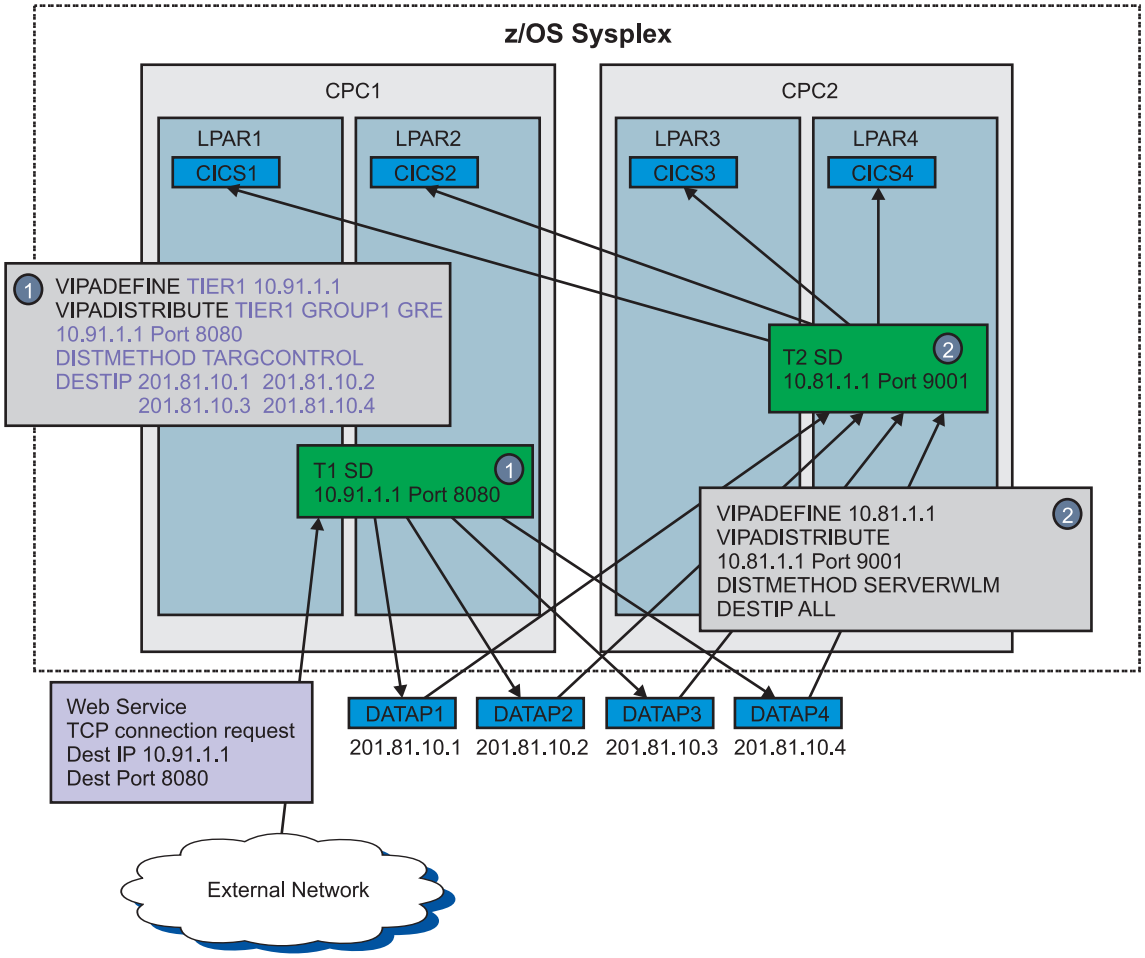

Figure 48. Sysplex distributor load balancing for DataPower

This configuration consists of two main components:

- A tier 1 distributed DVIPA is defined to represent the cluster of DataPower appliances that can process a client Web service request to TCP port 8080.

  For each TCP connection request sent to the tier 1 DVIPA and port, the tier 1 sysplex distributor makes a load-balancing decision and routes the request to one of the eligible DataPower target instances. These targets support a TCP control connection with the tier 1 distributor that enables dynamic load balancing feedback to and from the DataPower appliances and sysplex distributor.

  Periodically, the DataPower appliances send weights that are based on the overall CPU usage of the appliance. The weights enable a type of target-controlled distribution, and the distributor makes optimized

load-balancing decisions based on the target appliance's overall capacity and available capacity as compared to other target DataPower appliances.

Connection state information is passed over the control connection. The connection state information is used to determine whether a target server is available, and also to determine the states of the connections (established or terminated) that are distributed to the target DataPower appliances. The distributor uses GRE to send packets to the targets. Because GRE is used, the packets from the DataPower target back to the client do not need to traverse the tier 1 distributor. The connection state information enables sysplex distributor to maintain its active connection-routing entries and is also used to enable nondisruptive takeover of existing connections by a backup tier 1 distributor.

A DataPower distributed DVIPA can specify any of the following types of distribution methods:

- Target controlled (configured as TARGCONTROLLED)
- Round-robin (configured as ROUNDROBIN)
- Weighted active (configured as WEIGHTEDACTIVE)

Guideline: Target controlled is the preferred tier 1 distribution method, because the distributor can make optimized load-balancing decisions based on the current processing availability of the targets.

- A z/OS application tier completes the processing for the request.

  After the DataPower targets complete their processing of the inbound Web service request, they establish a connection and send the work request to a z/OS application tier.

  You can configure the DataPower targets to use one of their own distribution methods and to establish connections directly to the z/OS servers, or to use sysplex distributor for a more optimized load-balancing decision. In Figure 48 on page 494, sysplex distributor is shown. The distributed DVIPA that represents the z/OS application tier does not require any special configuration, and you can select any distribution method that is supported for z/OS distributed DVIPAs; however, SERVERWLM provides the most granular WLM recommendations, along with visibility into the health of the z/OS application tier.

  After sysplex distributor routes the request to the target CICS application, it is processed and the results of the request are sent to the DataPower instance that originated the request. DataPower can then perform any necessary outbound processing and send a response back to the client that originated the Web service request.

Steps for configuring scenario 1 - sysplex distributor load balancing to DataPower

Before you begin:

- All z/OS systems within the sysplex that can act as the tier 1 sysplex distributor for DataPower (active or backup) must be z/OS V1R11 or later.
- Evaluate workloads to be routed to DataPower, and understand the distribution tiers and routing options. See "Scenario 1 overview - sysplex distributor load balancing to DataPower" on page 494.

Perform the following steps to configure sysplex distributor and the DataPower appliances:

1. "Configure sysplex distributor tier 1 distributed DVIPAs and ports" on page 496.

2. "Configure the DataPower appliances to work with a tier 1 sysplex distributor and act as targets of the tier 1 DVIPAs and ports" on page 497.
3. "Configure a distributed DVIPA for the target z/OS application servers used by the group of DataPower appliances (optional)" on page 498.

Configure sysplex distributor tier 1 distributed DVIPAs and ports

To define the characteristics of tier 1 DVIPAs for use with target DataPower appliances, code the VIPADEFINE, VIPABACKUP, and VIPADISTRIBUTE statements with the following parameters in the VIPADYNAMIC block of the TCP/IP profile:

Parameter	Description
TIER1	Appears on the VIPADEFINE or VIPABACKUP statement, and on the VIPADISTRIBUTE statement, and indicates that the DVIPA specified as an IP address on this statement is to be used in a multi-tiered distribution configuration.
groupname	Appears on the VIPADISTRIBUTE statement, and specifies the name of a cluster of equivalent server applications in the sysplex. This name is a required value on the TIER1 parameter of the VIPADISTRIBUTE statement; however, the name is used only when there is a corresponding VIPADISTRIBUTE statement with the TIER2 parameter. The name correlates a VIPADISTRIBUTE TIER1 statement with the corresponding VIPADISTRIBUTE TIER2 statements with the same name.
GRE	Appears on the VIPADISTRIBUTE statement. GRE indicates that the tier 1 target is a non-z/OS target (a DataPower target), and that GRE is used in distributing requests to the DataPower appliances. GRE is the only routing type supported for DataPower load balancing.
CONTROLPORT *port_number*	Optionally appears on the VIPADISTRIBUTE statement, and enables configuration of a control port other than the default for the DataPower sysplex distributor agent. The control port must be the same on all VIPADISTRIBUTE TIER1 statements. If a control port is not specified, the default control port is 1702.
DISTMETHOD TARGCONTROLLED	Appears on the VIPADISTRIBUTE statement. TARGCONTROLLED indicates that connection requests are distributed using weights provided by the DataPower sysplex distributor agent, and by availability and capacity of the z/OS server applications in the application group.
DESTIP *target_IP_list*	Appears on the VIPADISTRIBUTE statement; the target IP address list includes the IP addresses of the DataPower appliances.

For more information about these statements and parameters, see *z/OS Communications Server: IP Configuration Reference*.

In the following example, clients in the network send requests to IP address 10.91.1.1, port 8080, and the DESTIP list consists of the IP addresses of the DataPower appliances:

```
VIPADEFINE  TIER1 255.255.255.0 10.91.1.1
VIPADISTRIBUTE
   TIER1
   GRE CONTROLPORT 5601
   10.91.1.1 Port 8080
   DISTM TARGCONTROLLED
   DESTIP 201.81.10.1  201.81.10.2
          201.81.10.3  201.81.10.4
```

The DataPower appliances have been configured with control port 5601. If the CONTROLPORT parameter is not specified on the VIPADISTRIBUTE statement, then the control port is 1702 by default.

DISTMETHOD TARGCONTROLLED indicates that sysplex distributor and the DataPower appliances exchange information about the availability and capacity of the DataPower appliances, and sysplex distributor uses this information to make load-balancing decisions.

These VIPADEFINE and VIPADISTRIBUTE statements are placed in the TCP/IP profile of one sysplex stack, and another sysplex stack on any LPAR in the sysplex might have the following VIPABACKUP statement to enable nondisruptive VIPA takeover:

```
VIPABACKUP 10 TIER1 10.91.1.1
```

Configure the DataPower appliances to work with a tier 1 sysplex distributor and act as targets of the tier 1 DVIPAs and ports

From the DataPower control panel, under **Objects** and then **ZOS Configurations**, start the **Sysplex Distributor Agent services**. The port number should match the control port that is configured on the tier 1 VIPADISTRIBUTE statement, as shown in the following example:

```
Admin State enabled
Local IP Address 0.0.0.0
Port Number 5601
SSL Proxy (none)
```

As with the sysplex distributor, the default port is 1702.

Requirement: The control port must be the same for all participating DataPower appliances, because a tier 1 distributor must use the same control port on all of its VIPADISTRIBUTE statements.

Sysplex distributor automatically registers the tier 1 DVIPA ports to the DataPower appliance over this connection, and DataPower starts servers listening on those ports.

During initial registration, the DataPower appliance sends the current availability of each DVIPA port listener to the distributor, along with all connections that are currently using each listener. This enables a backup distributor to take over a tier 1 DVIPA and its connections without disruption.

After initial registration, DataPower sends connection state information to the distributor whenever the state of a listener or of a connection using a DVIPA port changes.

DataPower sends its weight to the distributor during each polling interval. A new weight is sent by the DataPower appliance during each interval based on its available CPU service appliances.

Sysplex distributor provides updates to DataPower if an operator makes any changes to the tier 1 DVIPA configuration.

For more information about configuring DataPower appliances as tier 1 targets, see the DataPower documentation.

Configure a distributed DVIPA for the target z/OS application servers used by the group of DataPower appliances (optional)

The configuration of this distributed DVIPA has no special requirements; it is a normal distributed DVIPA that represents a cluster of z/OS applications in the sysplex environment. Code VIPADEFINE, VIPABACKUP, and VIPADISTRIBUTE statements within the VIPADYNAMIC block of the TCP/IP profile using the normal options for z/OS applications.

Rule: Do not specify the CPCSCOPE, TIER2, and *groupname* parameters on these statements. These parameters are supported for DataPower workloads; however, they have very specific configuration requirements and do not apply in this scenario.

In the following example, the DataPower appliances are all configured to send requests to IP address 10.81.1.1 and port 9001:

```
VIPADEFINE 10.81.1.1
VIPADISTRIBUTE
    10.81.1.1 Port 9001
    DISTMETHOD  SERVERWLM
    DESTIP ALL
```

These VIPADEFINE and VIPADISTRIBUTE statements are placed in the TCP/IP profile of one sysplex stack.

To configure the DataPower appliances to use the tier 2 distributed DVIPA and port when connecting to the z/OS application tier, see the DataPower documentation.

Scenario 2 overview - sysplex distributor load balancing to DataPower in a multi-tier and multisite environment

When you use sysplex distributor to provide load balancing of tier 1 work requests to DataPower, and DataPower connects to tier 2 servers on z/OS in a multisite environment, you can enhance the load balancing configuration by using the multi-tier support of sysplex distributor in combination with load balancing to DataPower.

In figure Figure 49 on page 499, DataPower is the tier 1 server layer and z/OS applications are the tier 2 servers.

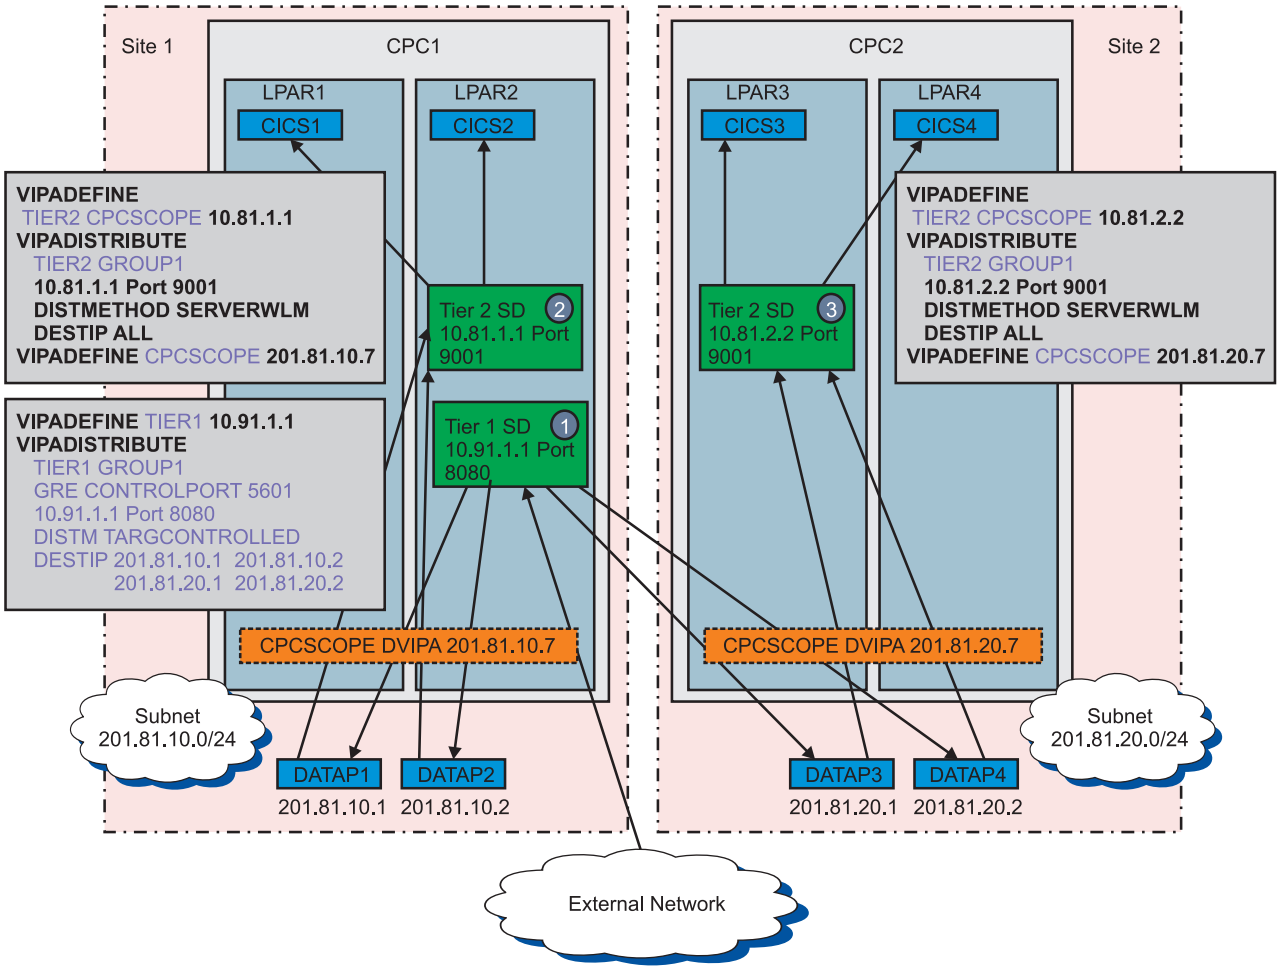

Figure 49. Sysplex distributor load balancing to DataPower in a multi-tier and multisite environment

In a multisite environment, each tier 2 sysplex distributor is configured to balance and route service requests to z/OS server application instances in its CPC. The tier 2 distributors send the combined WLM weight of the group of target application instances in their CPC to the tier 1 distributor. The tier 1 distributor makes its load balancing decision using composite weights that are based on the weight received from each tier 1 DataPower target along with the combined WLM weights of the corresponding tier 2 distribution targets.

For example, in figure Figure 49, for DataPower DATAP1 and DATAP2, the weights of CICS1 and CICS2 are included in the tier 1 sysplex distributor decision. For DataPower DATAP3 and DATAP4, the weights of CICS3 and CICS4 are included in the tier 1 sysplex distributor decision.

The tier 1 distribution method that is being used is target controlled (DISTMETHOD TARGCONTROLLED), so each DataPower target sends a weight to the tier 1 distributor that represents its overall health. Because the tier 2 DVIPAs are configured with the CPCSCOPE keyword, their targets must reside in the same CPC; the tier 2 distributors aggregate the WLM weights for their GROUP1 target application instances and send the result to the tier 1 distributor. The tier 1 distributor then determines a composite weight for each target based on the DataPower weight and the corresponding tier 2 combined weight.

A CPC is associated with a specific set of DataPower appliances through the use of a shared IPv4 subnet. In figure Figure 49 on page 499, the DataPower appliances in site 1 are attached to subnet 201.81.10.0/24, and the DataPower appliances in site 2 are attached to subnet 201.81.20.0/24. The CPC in site 1 (CPC1) uses a CPCSCOPE DVIPA that belongs to the site 1 DataPower subnet, 201.81.10.7, and the CPC in site 2 (CPC2) uses another CPCSCOPE DVIPA that belongs to the site 2 DataPower subnet, 201.81.20.7. When the tier 1 sysplex distributor matches DataPower destination IP addresses to tier 2 targets, it uses these CPCSCOPE DVIPAs to determine which z/OS LPARs are associated with which DataPower appliances. OMPROUTE should be set up to advertise host routes for only these CPCSCOPE DVIPA addresses.

The main connection flows in this scenario are the following:

- The remote client sends a connection request to the tier 1 sysplex distributor. The tier 1 sysplex distributor collects weights from the available tier 1 DataPower appliances and WLM weights from the available tier 2 servers, creates a composite weight, and determines which DataPower appliance is the best choice for this connection. Sysplex distributor connection routing forwards the inbound packets using GRE to the chosen DataPower appliance.
- DataPower processes the requests and initiates a tier 2 connection. DataPower appliances in site 1 are set up to connect to address 10.81.1.1, while DataPower appliances in site 2 are set up to connect to address 10.81.2.2. The connection request arrives at the appropriate site-local tier 2 sysplex distributor, and a suitable tier 2 server instance is chosen. Responses from the chosen CICS server instance are routed directly back to the initiating DataPower appliance. When DataPower has finished processing the response from CICS, its response back to the remote client is routed directly back to that client.

Steps for configuring scenario 2 - sysplex distributor load balancing to DataPower in a multi-tier and multisite environment

Before you begin:

- All z/OS systems within the sysplex that participate in workload distribution processing must be z/OS V1R11 or later.
- Evaluate workloads to be routed to DataPower, and understand the distribution tiers and routing options. See “Scenario 2 overview - sysplex distributor load balancing to DataPower in a multi-tier and multisite environment” on page 498.
- The tier 1 and tier 2 sysplex distributor instances must reside within the same z/OS sysplex environment.
- Each tier 2 sysplex distributor instance and its targets must reside within the same CPC.

Perform the following steps to configure sysplex distributor and the DataPower appliances:

1. “Configure sysplex distributor tier 1 distributed DVIPAs and ports” on page 501.
2. “Configure the DataPower appliances to work with a tier 1 sysplex distributor and act as targets of the tier 1 DVIPAs and ports” on page 501.
3. “Configure tier 2 distributed DVIPAs for each CPC containing target servers used by a group of DataPower appliances” on page 501.

4. "Configure a CPCSCOPE dynamic VIPA for each CPC for use by a group of DataPower target applications" on page 502.

Configure sysplex distributor tier 1 distributed DVIPAs and ports

Configuring sysplex distributor tier 1 distributed DVIPAs and ports in this scenario is similar to scenario 1. To review that information, see "Configure sysplex distributor tier 1 distributed DVIPAs and ports" on page 496.

In scenario 2, the group name GROUP1 is added, and the IP addresses of the DataPower appliances in the DESTIP list are at two sites instead of one, as shown in the following example:

```
VIPADEFINE  TIER1 255.255.255.0 10.91.1.1
VIPADISTRIBUTE
   TIER1
   GROUP1
   GRE CONTROLPORT 5601
   10.91.1.1 Port 8080
   DISTM TARGCONTROLLED
   DESTIP 201.81.10.1  201.81.10.2
          201.81.20.1  201.81.20.2
```

DISTMETHOD TARGCONTROLLED indicates that sysplex distributor and the DataPower appliances exchange information about the availability and capacity of the DataPower appliances. Sysplex distributor makes a load-balancing decision based on this information and, in this scenario, on the availability and capacity of the z/OS server applications in application group GROUP1 on the CPC of each DataPower appliance. The group name is used when the tier 1 sysplex distributor gathers information from the tier 2 distributors about availability and capacity of z/OS server applications for a specific server group on that CPC.

Configure the DataPower appliances to work with a tier 1 sysplex distributor and act as targets of the tier 1 DVIPAs and ports

Configuring the DataPower appliances to work with a tier 1 sysplex distributor and act as targets of the tier 1 DVIPAs and ports in this scenario is similar to scenario 1. See "Configure sysplex distributor tier 1 distributed DVIPAs and ports" on page 496.

Configure tier 2 distributed DVIPAs for each CPC containing target servers used by a group of DataPower appliances

Code VIPADEFINE, VIPABACKUP, and VIPADISTRIBUTE statements within the VIPADYNAMIC block of the TCP/IP profile, using the following parameters to define the characteristics of the tier 2 DVIPAs that are to receive connections from DataPower appliances:

Parameter	Description
CPCSCOPE	Appears on the VIPADEFINE or VIPABACKUP statement, and indicates that distribution targets must be on the same CPC as the distributor.
TIER2	Appears on the VIPADEFINE or VIPABACKUP statement, and the VIPADISTRIBUTE statement, and indicates that this dynamic VIPA is used to distribute incoming requests from a TIER1 target to a named group of server instances.
groupname	Appears on the VIPADISTRIBUTE statement, and specifies the name of a cluster of equivalent server applications in the sysplex. The group name correlates VIPADISTRIBUTE TIER2 statements with a corresponding VIPADISTRIBUTE TIER1 statement.

In the following example, the DataPower appliances in site 2 are configured to send requests to IP address 10.81.2.2 and port 9001:

```
VIPADEFINE TIER2 CPCSCOPE 255.255.255.0 10.81.2.2
VIPADISTRIBUTE
    TIER2 GROUP1
    10.81.2.2 Port 9001
    DISTMETHOD  SERVERWLM
    DESTIP ALL
```

The TIER2 parameter, in conjunction with the group name (GROUP1), indicates that the tier 2 sysplex distributor gathers information about availability and capacity of the target servers of that group. This information is forwarded to the corresponding tier 1 distributor for that group as a combined CPC weight for use in making the tier 1 load-balancing decision.

The tier 2 weight information cannot be used until the next step in the configuration process (configure a CPCSCOPE DVIPA for each CPC for use by a group of DataPower target appliances) is completed and the tier 1 distributor is able to determine which CPC is used by a DataPower appliance.

Similar to the tier 2 configuration for site 2, the DataPower appliances using site 1 send requests to IP address 10.81.1.1 and port 9001:

```
VIPADEFINE TIER2 CPCSCOPE 255.255.255.0 10.81.1.1
VIPADISTRIBUTE
    TIER2 GROUP1
    10.81.1.1 Port 9001
    DISTMETHOD SERVERWLM
    DESTIP  ALL
```

Configure a CPCSCOPE dynamic VIPA for each CPC for use by a group of DataPower target applications

A CPCSCOPE DVIPA is specific to the CPC on which it is defined, and cannot be moved to or taken over by another TCP/IP stack that is in a different CPC.

Code a VIPADEFINE or VIPABACKUP statement within the VIPADYNAMIC block of the TCP/IP profile, and include the CPCSCOPE parameter to indicate that the DVIPA specified by an IP address on this statement is specific to the CPC on which it is defined.

Requirements:

- The CPCSCOPE DVIPA must be in the same subnet as the DataPower appliances that are using that site.
- The address and subnet mask combination must define a unique subnet for each CPC.
- The CPCSCOPE DVIPA and the tier 2 DVIPA must be on stacks that are in the same CPC.

Using the CPCSCOPE subnet mask, the tier 1 distributor determines the DataPower appliances that are in its subnet. The distributor associates these DataPower appliances with a tier 2 distributor in the CPC of the stack where the CPCSCOPE DVIPA was defined. When determining the composite weights for these DataPower appliances, the distributor uses the tier 2 combined CPC weights received from the tier 2 distributor on that CPC.

The following example shows the definition on an LPAR on site 1:

```
VIPADEFINE CPCSCOPE 255.255.255.0 201.81.10.7
```

As shown in Figure 49 on page 499, the tier 1 distributor uses the CPCSCOPE subnet mask (201.81.10.0/24) to determine that DATAP1 and DATAP2 are in that subnet. The distributor associates these DataPower appliances with the tier 2 distributor for address 10.81.1.1, because it is defined on a stack in CPC1 and this CPCSCOPE DVIPA is also defined on a stack in CPC1. As the distributor receives a tier 2 weight for GROUP1 (combined CPC weights for CICS1 and CICS2) from this distributor, it finds the matching tier 1 GROUP1 DataPower targets and uses this weight when determining the composite weights for DATAP1 and DATAP2.

LPAR3 in CPC2 contains the tier 2 distributor for that site, so a CPCSCOPE DVIPA for CPC2 is defined on one of the LPARs in CPC2:

```
VIPADEFINE CPCSCOPE 255.255.255.240 201.81.20.7
```

The VIPABACKUP statements for the tier 2 DVIPA and CPCSCOPE DVIPA defined in CPC1 are defined in one or more other stacks in that CPC:

```
VIPABACKUP TIER2 CPCSCOPE 201.81.1.1
VIPABACKUP CPCSCOPE 255.255.255.240 201.81.10.7
```

Similarly, the VIPABACKUP statements for the tier 2 DVIPA and CPCSCOPE DVIPA defined in CPC2 are defined in one or more other stacks in that CPC:

```
VIPABACKUP TIER2 CPCSCOPE 201.81.2.2
VIPABACKUP CPCSCOPE 255.255.255.240 201.81.20.7
```

Chapter 9. TCP/IP in an ensemble

OSA-Express Ethernet features in QDIO mode can access the external data network when configured with the OSD channel path ID (CHPID) type. This is the default CHPID type on the IPAQENET and IPAQENET6 INTERFACE statements in the TCP/IP profile.

IBM zEnterprise System (zEnterprise) provides communications access to two internal networks through OSA-Express3 adapters that are configured with the OSM or OSX CHPID types. Communications Server supports OSA-Express3 adapters configured with these CHPID types, thus allowing TCP/IP connectivity to the following internal networks.

- Intraensemble data network (CHPID type OSX)

  The intraensemble data network provides access to other images connected to the intraensemble data network, and to applications and appliances running in an IBM zEnterprise BladeCenter® Extension (zBX). The intraensemble data network can be accessed through 10 gigabit OSA-Express3 adapters configured with CHPID type OSX. OSX interfaces can be IPv4 or IPv6, and must be on a VLAN. To configure OSX interfaces, see "Steps for configuring an interface for the intraensemble data network (CHPID type OSX)" on page 506.
- Intranode management network (CHPID type OSM)

  The intranode management network is an IPv6 network that provides connectivity between network management applications within a zEnterprise node, and can be accessed through 1000BASE-T Ethernet OSA-Express3 adapters configured with CHPID type OSM. OSM interfaces are not configured in the TCP/IP profile, but are generated by the stack and have only link-local IP addresses. The stack does not report OSM interfaces to OMPROUTE, and OMPROUTE is unaware of these interfaces; there are no OMPROUTE configuration considerations for OSM interfaces. To use the intranode management network, see "Steps for using the intranode management network (CHPID type OSM)" on page 507.

Requirement: For access to the intraensemble data network or the intranode management network, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the LPAR must be configured as members of an ensemble. For information about using the ENSEMBLE start option to specify that an LPAR is a member of an ensemble, see *z/OS Communications Server: SNA Resource Definition Reference*.

For more information about zEnterprise and ensembles, see the following:

- *zEnterprise BladeCenter Extension Installation Manual*
- *zEnterprise System Introduction to Ensembles*
- *zEnterprise System Ensemble Planning and Configuring Guide*
- *zEnterprise System Ensemble Performance Management Guide*
- *zEnterprise System Hardware Management Console and Support Element Operations Guide for Ensembles*

Steps for configuring an interface for the intraensemble data network (CHPID type OSX)

Before you begin:

- For access to the intraensemble data network, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the LPAR must be configured as members of an ensemble.

  For information about using the ENSEMBLE start option to specify that an LPAR is a member of an ensemble (ENSEMBLE=YES), see *z/OS Communications Server: SNA Resource Definition Reference*.
- Before the OSX device can become active, the Hardware Management Console (HMC) must be configured in the following way:
  - The VLAN ID specified at the HMC must match the ID specified on the VLANID parameter of the IPAQENET or IPAQENET6 statement.
  - The HMC must have added the LPAR and CHPID combination to the definition for that VLAN.

  See the information about creating and managing virtual server networks in *zEnterprise System Ensemble Planning and Configuring Guide*.
- To use an IBM zEnterprise BladeCenter Extension (zBX) with OSX, you must configure the zBX from the HMC to use addresses on the same network specified on the IPAQENET or IPAQENET6 statements.

  See the information about obtaining the pairing code for accelerator authentication in the *IBM Smart Analytics Optimizer for DB2 for z/OS*.

Perform the following steps to configure an interface for the intraensemble data network:

1. Specify CHPIDTYPE OSX on the INTERFACE statement for the IPAQENET or IPAQENET6 interface.
2. Include the CHPID parameter to have VTAM dynamically create the associated TRLE definition, and include the VLANID parameter.

   Unlike OSD interfaces, OSX interfaces must be associated with a specific VLAN, and can communicate only with other applications and images that have access to the same VLAN on the intraensemble data network.

   The following example is a sample INTERFACE definition; adjust values as needed:

   ```
   INTERFACE QDIOOSX1 DEFINE IPAQENET
   CHPIDTYPE OSX   CHPID F1    VLANID 10
     MTU 8992     IPADDR 172.16.1.1/24
   ```
3. For IPv6, if you connect an external router on this network, then you can use stateless address autoconfiguration. Otherwise, you need to configure IPv6 addresses and prefixes manually.

Guideline: For more information about configuring CHPID type OSX for IPAQENET and IPAQENET6 interfaces, see *z/OS Communications Server: IP Configuration Reference*. Some INTERFACE statement defaults are different for OSX interfaces than for OSD interfaces, and some INTERFACE statement parameters that apply to OSD interfaces do not apply to OSX interfaces.

Steps for enabling IPv6 on a stack for access to the intranode management network

Perform the following steps to enable IPv6 on a stack so that the stack can access the intranode management network:

1. Test and migrate any scripts that you use to format Netstat output in long format.

   After you enable a z/OS TCP/IP stack for IPv6, Netstat output for the stack is available in the long format only. While you are still using IPv4 for your data networks, you can test the Netstat reports in the long format using one of the following methods:

   - Use the FORMAT/-M LONG option on the Netstat command.
   - Specify the FORMAT LONG parameter on the IPCONFIG statement in your TCP/IP profile.

   For more information about the Netstat command, see *z/OS Communications Server: IP System Administrator's Commands*. For more information about the IPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

2. Update the BPXPRM*xx* parmlib member to include an additional NETWORK statement for IPv6.

```
FILESYSTYPE TYPE(INET) ENTRYPOINT(EZBPFINI)

NETWORK DOMAINNAME(AF_INET)
        DOMAINNUMBER(2)
        MAXSOCKETS(nnnnn)
        TYPE(INET)

NETWORK DOMAINNAME(AF_INET6)
        DOMAINNUMBER(19)
        MAXSOCKETS(nnnnn)
        TYPE(INET)
```

   For more information about updating BPXPRM*xx*, see "Defining TCP/IP as a UNIX System Services physical file system" on page 45.

Steps for using the intranode management network (CHPID type OSM)

Before you begin: The stack must be enabled for IPv6. For information about enabling a stack for IPv6, see "Steps for enabling IPv6 on a stack for access to the intranode management network".

For access to the intranode management network, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the LPAR must be configured as members of an ensemble. For information about using the ENSEMBLE start option to specify that an LPAR is a member of an ensemble, see *z/OS Communications Server: SNA Resource Definition Reference*.

If the stack is enabled for IPv6 and the LPAR is configured as a member of an ensemble, Communications Server automatically configures, locates, and activates up to two interfaces (named EZ6OSM01 and EZ6OSM02) onto the intranode management network. Each of these interfaces is an IPv6 interface that has only a link-local IP address. You cannot configure static or dynamic routes over OSM interfaces.

The intranode management network is intended for only authorized applications, such as those performing platform performance management functions. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*..

Perform the following steps to use the intranode management network:

1. Authorize the application to the EZB.OSM.*sysname*.*tcpname* resource.

   To send or receive data over an OSM interface, an application must have READ authorization to the EZB.OSM.*sysname*.*tcpname* resource. If used on this image, authorize the application to this resource.
2. Reserve the UDP port that the platform management application is to use to listen for multicast traffic over the intranode management network.
3. Authorize any user IDs to this resource that might issue diagnostic commands, such as Ping and Traceroute, over OSM interfaces to verify connectivity.
4. If you enable IP security for IPv6, you can configure a security class for IP filtering that applies to all OSM interfaces.

   Use the OSMSECCLASS parameter on the IPCONFIG6 statement. This enables you to configure filter rules for traffic over the EZ6OSM01 and EZ6OSM02 interfaces.
5. If the multicast address that is used by the platform management application is configured into a network access zone, then give the user ID for this application read permission to the resource profile for that zone.

Routing considerations for the intraensemble data network

If there is an external router attached to the intraensemble data network, dynamic and static routing considerations for OSX interfaces are the same as those for OSD interfaces connected to an external router. However, if no external router is present on that network, see the following guidelines.

Guidelines:

- Implement the intraensemble data network as a flat network, meaning that all addresses that are reachable through the intraensemble data network are in the same subnet (or IPv6 prefix) as that of the intraensemble data network. In this configuration, a single route (static or dynamic) to this subnet enables all addresses on the intraensemble data network to be reached.
- Static routing might be appropriate in the following cases:
  - The intraensemble data network is implemented as a flat network, in which case a single static route over the OSX interface to the subnet of the intraensemble data network can reach all destinations in the intraensemble data network.
  - A z/OS host will not be routing traffic between external networks and the intraensemble data network, so you do not want to advertise the intraensemble subnet addresses to the external network.

    Tip: If you are using static routing over the intraensemble data network and there are destination IP addresses on the IBM zEnterprise BladeCenter Extension (zBX) that are not part of the intraensemble subnet, you need to define static routes to those destination IP addresses on the intraensemble network using OSX interfaces.
- Dynamic routing might be appropriate in the following cases:

- You want destinations on the intraensemble subnet to be reachable from outside the ensemble, and therefore want to advertise the intraensemble data network addresses to the external network.
- There are destination IP addresses on the zBX that are not part of the intraensemble subnet, and you do not want to have to code individual static routes to reach them (for example, if other hosts on the intraensemble data network have VIPA addresses that are not in the intraensemble subnet).

OMPROUTE considerations for the intraensemble data network

In an ensemble environment with dynamic routing where a z/OS stack is the router for the ensemble, you can control whether the subnet of the intraensemble data network is advertised.

- If you want to prevent external traffic from being routed to this VLAN, then do one of the following so that OMPROUTE does not advertise the intraensemble subnet:
  - Define the OSX interface to OMPROUTE using an INTERFACE statement or IPV6_INTERFACE statement, and do not enable the IMPORT_DIRECT_ROUTES function of AS boundary routing. This function is disabled by default, so ensure that the IMPORT_DIRECT_ROUTES parameter of the AS_BOUNDARY_ROUTING statement or the IPV6_AS_BOUNDARY_ROUTING statement is not set to YES.
  - Do not define the OSX interface to OMPROUTE, and ensure that GLOBAL_OPTIONS IGNORE_UNDEFINED_INTERFACES is configured to OMPROUTE.

  You might also want to install IPSec filter rules to restrict which traffic can flow on this network.
- If you want to allow external traffic to be routed to this VLAN, then define the OSX interface to OMPROUTE as an OSPF_INTERFACE or IPV6_OSPF_INTERFACE, and code a nonzero value for the ROUTER_PRIORITY parameter on the interface. As long as no other hosts on that OSX VLAN have coded their interfaces as OSPF interfaces, then OMPROUTE advertises the subnet (or IPv6 prefixes) of the intraensemble data network into the OSPF network. This advertisement makes all addresses that fall into the intraensemble subnet (or IPv6 prefixes) reachable using OSPF. In addition, if you have a subset of hosts on the intraensemble data network with VIPAs that are not in the intraensemble subnet, which you want to be able to reach over the intraensemble data network, you can define the OSX interfaces on those hosts as OSPF interfaces; OMPROUTE communicates with them (and only them) and can route to their VIPAs, while still preserving the ability to route to the other hosts by subnet only.

Tip: These definitions apply per interface, so you could implement advertising on one VLAN while not advertising on a different VLAN attached to the same z/OS router.

Sysplex distributor considerations for the intraensemble data network

In a sysplex distributor configuration, if the client, sysplex distributor, and at least one sysplex distributor target are all connected over the intraensemble data network, then the client, sysplex distributor, and all potential sysplex distributor targets must be connected to the same VLAN on the intraensemble data network.

Multilevel security and network access control considerations

In a multilevel secure environment, you should treat the intraensemble data network and the OSX interfaces as any other data network with OSA-Express access. However, the intranode management network and the OSM interfaces require special considerations. For information about these additional considerations, see Chapter 4, “Preparing for TCP/IP networking in a multilevel secure environment,” on page 153.

If you are using network access control, the intraensemble data network and the OSX interfaces are subject to the same network access control as any other data network with OSA-Express access. However, all traffic to and from the intranode management network over OSM interfaces is exempt from network access control, and is instead subject to OSM access control. Only multicast addresses to which a platform management application binds are subject to network access control.

Part 2. Server applications

Chapter 10. Network connectivity with an SNA network

The objective of this topic is to guide you through the steps required to implement:

- SNALINK LU0
- SNALINK LU6.2
- X.25 NPSI
- NCPROUTE

Before you configure:

Read and understand Chapter 2, "IP configuration overview," on page 11. It covers important information about data set naming and search sequences.

SNALINK LU0 environment

SNALINK allows TCP/IP to send and receive packets using SNA sessions instead of dedicating physical network hardware (such as a channel-to-channel adapter or channel connection to a 3745/46 Communication Controller).

Prior to NCP V7R3, NCP did not support cross-channel native IP transmission of the transport PDUs associated with RIP traffic. NCP expects these PDUs to be carried in SNA frames. SNALINK is therefore still required for installations where dynamic routing is performed with the NCP (via NCPROUTE). See *z/OS Communications Server: IP Configuration Reference* for more information.

SNALINK allows an installation to multiplex SNA and IP traffic over the same I/O subchannels, rather than requiring separate subchannels dedicated to VTAM and TCP/IP. While such multiplexing capability may be desirable at some installations, the native TCP/IP CTC and 3745/46 device drivers will likely outperform SNALINK connections. Interaction with the SNALINK address space is very CPU-intensive, and is not required with the native TCP/IP CTC and 3745/46 device drivers. (See the *z/OS Communications Server: IP Configuration Reference* for configuration information.) It is therefore important to weigh the multiplexing capability that SNALINK provides against its performance cost, in determining whether to use SNALINK or the native TCP/IP CTC or 3745/46 device drivers.

Understanding the SNALINK environment

The SNALINK environment interfaces between the TCP/IP environment's SNAIUCV driver and the customer's SNA network. SNALINK communicates with one or more instances of SNALINK at remote nodes, using the SNA LU type 0 protocol. See Figure 50 on page 514 for a description of the SNALINK environment interfaces.

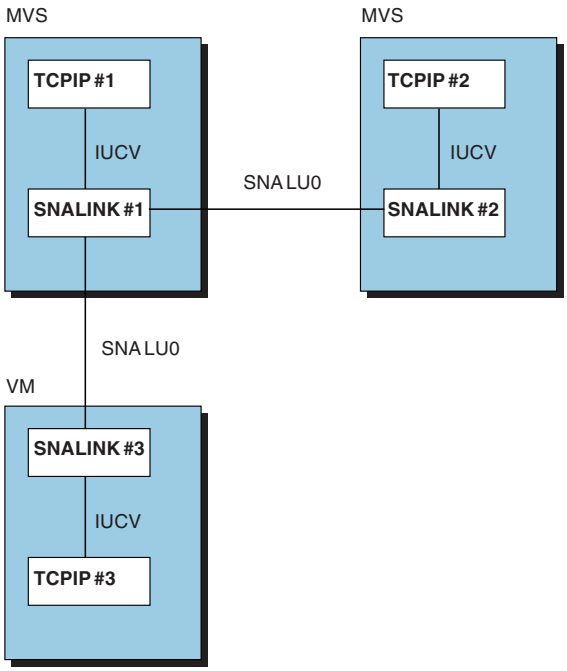

Figure 50. SNALINK environment interfaces

Each SNALINK environment can communicate with up to 9999 SNALINKs simultaneously. The number of connections is determined by the parameters you pass to the SNALINK cataloged procedure. The default is 6 sessions running in dual mode for a total of 3 SNALINKs.

- When operating in single mode, SNALINK opens one full duplex session.
- When operating in dual mode, SNALINK opens two System Network Architecture (SNA) sessions for each remote logical unit (LU) with which it communicates, one for sending and one for receiving.

Configuring SNALINK LU0

Steps to configure SNALINK LU0:

1. Specify configuration statements in *hlq*.PROFILE.TCPIP.
2. Update the SNALINK cataloged procedure.
3. Define the SNALINK application to VTAM.
4. Configure the program properties table (PPT) for SNALINK LU0.

Step 1: Specify configuration statements in *hlq*.PROFILE.TCPIP

The following topics describe the changes you must make to your TCPIP address space configuration data set (*hlq*.PROFILE.TCPIP).

Defining SNA DLC links: SNA DLC links are point-to-point and require DEVICE and LINK statements in the configuration data set. The DLC link constitutes a separate network, even though it includes only two hosts. To define a link, each host to which the DLC link is attached requires:

- A pair of SNA LU0 DEVICE and LINK statements
- A HOME statement
- A BSDROUTINGPARMS or GATEWAY or BEGINROUTES statement

SNA DLC links are defined in one of two ways:

- By unique network or subnetwork numbers, if the hosts to which they connect are not attached to other networks.
- By the IP address of the hosts to which they connect, if the hosts are attached to other networks.

You usually have to assign a unique network or subnetwork number to the SNALINK. If the link connects 2 hosts that also have other networks attached to them, the DLC link does not need its own subnetwork number. Figure 51 illustrates how to define an SNA DLC link if the 2 hosts are connected to other networks in the following way:
- Host A and Host B are connected by SNA DLC
- Host A is also connected to a token ring, 193.1.1
- Host B is also connected to a token ring, 193.1.2
- Host A's home address on its token ring is 193.1.1.1
- Host B's home address on its token ring is 193.1.2.1

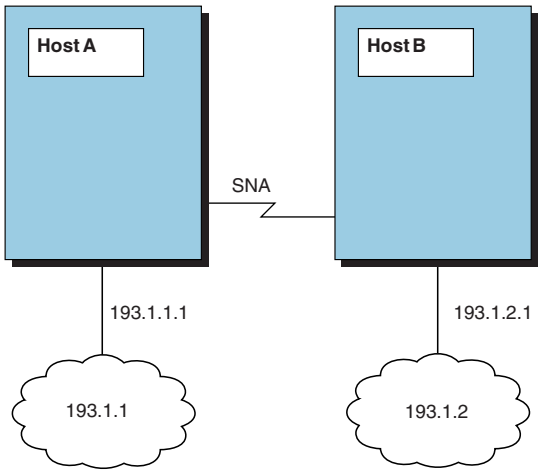

Figure 51. SNA DLC link

Host A's *hlq*.PROFILE.TCPIP could contain:

```
DEVICE  LCS1 LCS BA0
LINK  TR1  IBMTR 0 LCS1
DEVICE SNALU0 SNAIUCV SNALINK LU000000 SNALINKA
LINK SNAIUCV1 SAMEHOST  1 SNALU0
HOME
    193.1.1.1  TR1
    193.1.1.2  SNAIUCV1

GATEWAY
;  Network         First hop  Link    Packet size    Subnet mask
    193.1.1.0      =          TR1         2000        0
    193.1.2.0      =          SNAIUCV1    2000        0
```

Host B's *hlq*.PROFILE.TCPIP could contain:

```
DEVICE LCS2 LCS BE0
LINK  TR1 IBMTR 0 LCS2
DEVICE SNALU0 SNAIUCV SNALINK LU000001 SNALINKA
LINK SNAIUCV1 SAMEHOST  1 SNALU0
HOME
    193.1.2.1  TR1
    193.1.2.2  SNAIUCV1

GATEWAY
```

```
;  Network         First hop  Link    Packet size    Subnet mask
    193.1.2.0      =          TR1         2000        0
    193.1.1.0      =          SNAIUCV1    2000        0
```

Notes:

1. The *lu_name* must be different on each host. In the example, the *lu_name* for Host A is LU000000. The *lu_name* for Host B is LU000001.
2. In the example, the *lu_name* is the remote or partner LU.

Hosts A and B are addressed by their token-ring home addresses, even if the packets reach them through the SNA DLC link.

If Host B had no other network attached to it, you would have to assign a separate subnetwork number to the SNA DLC link. Even in this case, Host A does not need a separate home address for its SNA link, because it can be addressed by its token-ring home address. Host B's only home address is the home address for the SNA link.

Note: If you plan to run a network-monitoring protocol that requires each subnet to have its own subnet number, you can assign a separate subnet network number to the DLC link.

Defining NCPROUTE and 3745 LAN attachments: If your TCP/IP configuration supports NCPROUTE or 3745 Communications Controller Ethernet or token-ring links, you must do the following:

- Match the *lu_name* on the DEVICE statement to the LU statement in NCST section of your NCP generation.

  The following example shows the LU name A04TOLU1 defined in the *hlq*.PROFILE.TCPIP DEVICE statements and in the NCP generation.

```
DEVICE  SNA1LINK SNAIUCV SNALINK A04TOLU1 SNAL1STC
LINK  SNALINK SAMEHOST 1 SNA1LINK

HOME
    9.67.116.66  SNALINK

GATEWAY
;  Network         First hop  Link    Packet size    Subnet mask
    9.67.116.65   =          SNALINK     2000        HOST

START SNA1LINK
```

```
*************************************************************************
*               NCST IP INTERFACES**
*************************************************************************
A04NCSTG GROUP NCST=IP,LNCTL=SDLC,VIRTUAL=YES
A04NCSTL LINE LINEFVT=CXSXFVT,PUFVT=CXSXFVT,LUFVT=(CXSXFVT,CXSXFVT),LIN*
              ECB=CXSXLNK
A04NCSTP PU VPACING=0,PUTYPE=2,PUCB=CXSP0000S
*
A04TOLU1 LU INTFACE=(NCSTALU1,1492),REMLU=SNALKLU1,LUCB=(CXSXL0000,CXSS0*
              000),LOCADDR=1
*************************************************************************
```

- Match the remote LU name SNALKLU1 in the NCP generation to the APPLID in the SNALINK cataloged procedure parameters and in the VTAM APPL definition.

```
//SNALINK  PROC MODULE=SNALINK,TCPID='TCPV3',APPLID='SNALKLU1'
//SNALINK  EXEC PGM=&MODULE<REGION=$4096K,TIME=1440,
           PARM='&TCPID &APPLID C7 6 0003 SINGLE'
```

For additional information on configuring these links, see *z/OS Communications Server: IP Configuration Reference*.

Step 2: Update the SNALINK cataloged procedure

Update the SNALINK cataloged procedure by copying the sample in SEZAINST(SNALPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Specify SNALINK parameters and change the DD statements, as required. See *z/OS Communications Server: IP Configuration Reference* for more information about the SNALINK cataloged procedure.

Step 3: Define the SNALINK application to VTAM

In dual mode, SNALINK opens 2 SNA sessions for each remote logical unit with which it communicates: one for sending and one for receiving. In single mode, SNALINK opens one full-duplex session.

Figure 52 is an example of a typical VTAM APPL statement for SNALINK. The application identifier (SNALKB03 in this example) must match the APPLID specified in the SNALINK cataloged procedure parameters.

```
SNALKB03  APPL ACBNAME=SNALKB03,                                    X
               AUTH=(ACQ,VPACE),                                    X
               SRBEXIT=YES,                                         X
               EAS=12,                                              X
               PARSESS=YES,                                         X
               SONSCIP=YES,                                         X
               VPACING=0
```

Figure 52. APPL statement for SNALINK

Note: ***SRBEXIT must be YES.***

See *z/OS Communications Server: SNA Resource Definition Reference* more information about defining VTAM applications.

VTAM considerations:

- Each connection requires 100KB of virtual storage.
- SNALINK provides its own BIND parameters, so it does not assume or require any particular LOGMODE entries.
- The EAS value should be two times the number of maximum sessions passed to the SNALINK cataloged procedure.
- SRBEXIT=YES.
- You might have to specify pacing values (VPACING). Consult your VTAM network administrator for further details.
- For *max_ru_size*, be sure to consider the size of the TH, RH, and RU portions. If the maximum size PIU exceeds MAXRU, the NCP issues a negative response with sense 800A0000 (PIU too long). The definition used in NCP and SNALINK must be such that MAXRU is at least 29 bytes less than MAXDATA. See *z/OS Communications Server: SNA Network Implementation Guide* for more information on defining the MAXDATA, MAXBFRU, and UNITSZ operands.

Step 4: Configure PPT for SNALINK LU0

To avoid startup problems, ensure that the PPT entry for SNALINK LU0 (PGM=SNALINK) is configured with the required program properties. For more information, see *z/OS MVS Initialization and Tuning Reference*.

Stopping and starting SNALINK

If necessary, you can immediately retry a session that is waiting for the retry delay to expire by stopping and starting the SNALINK LU0 interface.

To stop SNALINK and close all connections, use the STOP command on the operator's console. For example, if SNALPROC was the name of the cataloged procedure used to start SNALINK, you enter:

```
STOP SNALPROC
```

You can also stop SNALINK with the HALT parameter on the MODIFY command. See "Controlling the SNALINK LU0 interface with the MODIFY command" on page 520.

SNALINK can be started by:

- Restarting the TCPIP address space if you have included the SNALINK procedure in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP data set.
- Issuing START *procname* at the command console (where *procname* is the name of the cataloged procedure used to start the SNALINK LU0 interface).

For example, to restart SNALPROC, enter

```
START SNALPROC
```

Sample console

The example in Figure 53 on page 519 and the accompanying information illustrate SNALINK operation.

The line number notations in the example have been added for clarity. They do not appear in the console output.

```
Line 1              | Init complete, APPLID SNALKB03, TCPIP id TCPIPB

Line 29    STOP SNALINK
Line 30             | Received STOP command, shutting down
```

Figure 53. SNALINK console example

Line number	Description
Lines 1 and 2	SNALINK displays its startup information from its command line parameters, which are customized as described in *z/OS Communications Server: IP Configuration Reference*. The maximum RU size and all other values are displayed in hexadecimal.
Lines 3 and 4	The TCPIP address space, TCPIPB, issues a DLC CONNECT to establish a session with the remote LU SNALKC04. SNALKC04 is higher in the collating sequence than the local LU name SNALKB03. Consequently, SNALKB03 takes the passive role in connecting to SNALKC04, and waits for SNALKC04 to establish a session.
Lines 5 and 6	TCP/IP issues another DLC CONNECT to establish a session with SNALKA04. In this case, SNALKA04 is lower in the collating sequence. Consequently, SNALKB03 takes an active role in connecting to SNALKA04.
Lines 7 and 8	The session establishment attempt to SNALKA04 has failed, as indicated by the (nonzero) return code and the sense information printed.
Lines 9 through 12	Thirty seconds later, TCP/IP again tries to connect to SNALKA04.
Lines 13 and 14	SNALINK receives a BIND request from SNALKC04. SNALINK calls the resulting session

	the receive session, because it is used only to send data from SNALKC04. Now that the active end has initiated communication, SNALKB03 as the passive end, sends a BIND request to establish a send session.
Lines 15 through 17	The send and receive sessions are fully established. Establishment of the send session causes SNALINK to accept the corresponding DLC path.
Lines 18 through 23	TCP/IP again tries to connect to SNALKA04. This time it is successful (success is indicated by no nonzero return codes).
Lines 24 through 26	SNALKC04 terminates its sessions, and various error messages result.
Lines 27 and 28	Thirty seconds later, TCP/IP again tries to establish communication with SNALKC04. As in lines 13 and 14, SNALKB03 is the passive partner.
Lines 29 and 30	The operator issues a STOP SNALINK command, which causes SNALINK to stop. All DLC paths and SNA sessions are ended.

Verifying connection status using Netstat DEVLINKS/-d

The DLC connect protocol between TCP/IP and SNALINK causes the status of the SNAIUCV device, reported by Netstat DEVLINKS/-d, to reflect the status of the SNA sessions to the remote LU. See *z/OS Communications Server: IP System Administrator's Commands* for more information on the Netstat command.

Controlling the SNALINK LU0 interface with the MODIFY command

The following command would pass parameters to a SNALINK LU0 address space started with a procedure named SNLK12.TCPSETUP.

```
MODIFY SNLK12.TCPSETUP,HALT
```

SNALINK LU6.2

The SNALINK LU6.2 cataloged procedure runs a VTAM application program called SNALNK62, which is an interface between the TCPIP address space and the SNA network. SNALNK62 uses SNA LU type 6.2 sessions to pass the TCP/IP data to or from SNALNK62 devices running on other hosts. Examples of SNALNK62 devices include an OS/2 workstation running TCP/IP for OS/2 or a host running TCP/IP for MVS.

Configuring SNALINK LU6.2

Steps to configure SNALINK LU6.2:

1. Specify DEVICE and LINK statements in *hlq*.PROFILE.TCPIP.
2. Update the SNALINK LU6.2 cataloged procedure.
3. Define the SNALINK LU6.2 application to VTAM.
4. Update the SNALINK LU6.2 configuration data set.

Step 1: Specify DEVICE and LINK statements in *hlq*.PROFILE.TCPIP

You must update the *hlq*.PROFILE.TCPIP data set to include a DEVICE and LINK statement for each DLC connection to be established between the main TCPIP address space and the SNALINK LU6.2 address space.

Step 2: Update the SNALINK LU6.2 cataloged procedure

Update the SNALINK LU6.2 cataloged procedure by copying the sample in SEZAINST(LU62PROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. No system parameters are required for the SNALINK LU6.2 address space.

The DD statements in the cataloged procedure should be defined as follows:

DD Name	Description
SYSTCPD	TCPIP.DATA configuration data set
LU62CFG	SNALINK LU6.2 configuration data set
SYSPRINT	Runtime diagnostic or trace output
SYSUDUMP	User abend dump output (optional)

See "Resolver configuration files" on page 759 for information on data set search sequences.

Step 3: Define the SNALINK LU6.2 application to VTAM

SNALINK LU6.2 opens two SNA LU type 6.2 sessions with each destination node; one for sending and one for receiving. If a destination node supports parallel SNA LU type 6.2 sessions (PARSESS=YES), the two sessions use the same remote logical unit; otherwise, two remote logical units are used. In either case, SNALINK LU6.2 uses a single local logical unit that must support parallel sessions.

The SNALINK LU6.2 address space must be defined to VTAM as an SNA LU type 6.2 application program. The following APPL statement defines a SNALINK LU6.2 application to VTAM.

```
LU62APPL  APPL ACBNAME=LU62APPL,                                *
               PRTCT=QWERTY,                                    *
               AUTH=(ACQ,VPACE),                                *
               SRBEXIT=NO,                                      *
               EAS=12,                                          *
               PARSESS=YES,                                     *
               SONSCIP=YES,                                     *
               APPC=YES,                                        *
               DLOGMOD=LU62MODE,                                *
               VPACING=0
```

Figure 54. APPL statement for SNALINK LU6.2

Note: ***SRBEXIT must be NO.***

See *z/OS Communications Server: SNA Resource Definition Reference* for further information about defining VTAM applications.

The LOGMODE table entry specified by the APPL DLOGMOD parameter should have the following form:

```
LU62MODE MODEENT LOGMODE=LU62MODE,FMPROF=X'13',TSPROF=X'07',          *
               PRIPROT=X'B0',SECPROT=X'B0',COMPROT=X'D0B1',           *
               RUSIZES=X'8585',ENCR=B'0000',                          *
               PSERVIC=X'060200000000000000000300'
```

See *z/OS Communications Server: SNA Customization* for more information about defining log mode tables and *z/OS Communications Server: SNA Programming* for information on PSERVIC values.

Step 4: Update the SNALINK LU6.2 configuration data set

Customize the SNALINK LU6.2 configuration data set by copying the sample provided in SEZAINST(LU62CFG) to your system or recognized PROCLIB and modifying it to suit your local conditions. Add or change the configuration statements as required. Be sure the //LU62CFG statement in the cataloged procedure points to this data set. See *z/OS Communications Server: IP Configuration Reference* for more information about parameters.

Sample console

The example in Figure 55 shows the messages that are expected when the SNALINK LU6.2 address space is started and a network connection is established.

```
S SNAL621A
$HASP100 SNAL621A ON STCINRDR
$HASP373 SNAL621A STARTED
 1 IEF403I SNAL621A - STARTED - TIME=15.26.03
 2 EZA5927I LU62CFG : NO ERRORS DETECTED - INITIALIZATION WILL CONTINUE
 3 EZA5932I INITIALIZATION COMPLETE - APPLID: SNAL621A  TCP/IP: TCPCS
 4 EZA5935I SEND CONVERSATION ALLOCATED FOR 9.67.22.2
 5 EZA5933I LINK SNALU62L OPENED
EZZ4313I INITIALIZATION COMPLETE FOR DEVICE SNALU621
 4 EZA5936I RECEIVE CONVERSATION ALLOCATED FOR 9.67.22.2
```

Figure 55. Sample MVS system console messages on SNALINK LU6.2 address space startup

The following list explains the MVS system console messages on SNALINK LU6.2 address space startup as shown in Figure 55.

1 The SNAL621A address space has been started.

2 The SNALINK LU6.2 configuration data set for the SNAL621A address space has been successfully parsed.

3 The SNAL621A address space displays its local VTAM application LU and the TCP/IP address space name to which it will connect.

4 The SNAL621A address space establishes a network connection through the VTAM API.

5 The SNAL621A address space establishes a DLC connection with its TCP/IP address space.

X.25 NCP Packet Switching Interface

The X.25 NCP Packet Switching Interface (NPSI) server runs a VTAM application program called XNX25IPI, which is the interface between the TCPIP address space's DLC driver and your X.25 network. XNX25IPI communicates with the X.25 NCP Packet Switching Interface in a front-end IBM 37xx Communications Controller.

Large scale X.25 network applications often require multiple physical lines to the network switch for increased capacity and reliability. You can configure the X.25 NPSI server to support multiple lines as a group, rather than individually. In this configuration, the collection of lines is assigned a single address called a *hunt group*

address. Incoming X.25 calls are distributed among the lines in either rotary or traffic balancing fashion, depending on the services offered by the X.25 network provider.

For information about improving the performance of the X.25 NPSI network, see the options on the PORT statement and GATEWAY statement in the *hlq*.PROFILE.TCPIP and the explanation provided in the *TCP/IP: Performance Tuning Guide*.

Configuring X.25 NPSI

This topic describes how to configure the X.25 NPSI server.

Steps to configure the X.25 NPSI server:

1. Specify X.25 configuration statements in *hlq*.PROFILE.TCPIP.
2. Update the X.25 NPSI cataloged procedure.
3. Update the X.25 NPSI server configuration data set.
4. Define the X.25 NPSI configuration.
5. Define the X.25 NPSI application to VTAM.
6. Define VTAM Switched Circuits.

If you want to run the X.25 NPSI cataloged procedure in a different domain than the X.25 NPSI communication controller, see *z/OS Communications Server: IP Configuration Reference*.

For information about operating the X.25 NPSI server with the MODIFY command, see *z/OS Communications Server: IP Configuration Reference*.

Step 1: Specify X.25 configuration statements in *hlq*.PROFILE.TCPIP

To configure the *hlq*.PROFILE.TCPIP data set for X.25 NPSI, include appropriate DEVICE, LINK, HOME, GATEWAY, and START statements. The following example shows the statements that would correspond with the other X.25 samples.

```
;
DEVICE X25DEV X25NPSI TCPIPX25
LINK X25LINK SAMEHOST 1 X25DEV
;
HOME
   199.005.058.23     X25LINK
;
GATEWAY
;
; Network  First hop   Link name Packet size  Subnet mask  Subnet value
  192.005      =        X25LINK     2000       0.0.255.0    0.0.58.0
;
START X25DEV
;
```

Note: Only one DEVICE and LINK statement per TCPIPX25 address space is allowed.

Step 2: Update the X.25 NPSI cataloged procedure

Update the X.25 NPSI cataloged procedure by copying the sample provided in SEZAINST(X25PROC) to your system or recognized PROCLIB and modifying it to suit your local conditions.

Change the data set names as needed:

- See "Resolver configuration files" on page 759 for data set search sequence information.
- Modify the //X25IPI DD statement to point to your X.25 configuration data set.

Step 3: Update the X.25 NPSI server configuration data set

A sample configuration data set provided in SEZAINST(X25CONF) gives examples of how to define a public network connection, a Defense Data Network connection, and private point-to-point connection to a router. Copy this sample to the data set pointed to by the //X25IPI DD statement in your X.25 NPSI cataloged procedure. Update this sample to define your X.25 connections using the statements listed in the *z/OS Communications Server: IP Configuration Reference*.

Each connection must have a LINK and at least one DEST statement. You can optionally define hunt groups, fast connects, and call handling options for each link, and global options such as trace levels, when to clear inactive connections, and the buffer size to use for IP datagrams. You can find complete syntax for each of these statements in *z/OS Communications Server: IP Configuration Reference*.

Step 4: Define the X.25 NPSI configuration

Define the X.25 NPSI configuration according to the information in *X.25 NPSI Planning and Installation*. The X.25 NPSI server supports use of the LOGAPPL operand on the X25.MCH definition in the X.25 NPSI configuration to allow automatic recovery. You can use either the Generalized Access to X.25 Transport Extension (GATE) or Dedicated Access to X.25 Transport Extension (DATE).

IBM recommends using the X.25 NPSI GATE configuration which allows sharing of an X.25 physical link and provides better error recovery. A sample is provided in SEZAINST(NPSIGATE). NPSI GATE requires that you include the OPTIONS GATE statement in the X.25 NPSI configuration data set after the LINK statement, as shown in this portion of the X25CONF sample:

```
*
*        NPSI MCH       DTE             Window Packet Logical
*        LU Name   DNIC Address         Size   Size   Channels
*        --------  ---- --------------- -      ----   ---
Link     XU024     PRIV 1               2      1024   2
Options  GATE
*
*        IP address      X.25 DTE addr       C.U.D.
*        --------------- ---------------     --------
Dest     192.5.57.2      2
```

Sites that need to use the X.25 NPSI DATE configuration can find a sample in PV SEZAINST(NPSIDATE). See *X.25 NPSI Host Programming* for information about the definitions and parameters used in these configurations.

The following example shows portions of the sample NPSI GATE configuration (NPSIGATE). Ellipses (....) indicate code that has been omitted.

```
************************************************************************
         OPTIONS NEWDEFN=YES,USERGEN=X25NPSI
************************************************************************
....
....
NPSIV32  BUILD ADDSESS=400,                                            +
               AUXADDR=800,                                            +
               ERLIMIT=16,                                             +
               NAMTAB=120,                                             +
               MAXSESS=250,                                            +
               USGTIER=5,                                              +
               BRANCH=8000,                                            +
```

```
               BFRS=104,           BUFFER SIZE TO BE GENED             +

 ********************************************************************
 ....
 ....
 GENEND   GENEND
```

Step 5: Define the X.25 NPSI application to VTAM

Define the X.25 NPSI VTAM application with an APPL statement in VTAMLST. Following is an example of a VTAM APPL statement for X.25 NPSI.

```
         VBUILD TYPE=APPL                                           +
TCPIPX25 APPL  ACBNAME=TCPIPX25,                                    +
               PRTCT=TCPX25,                                        +
               AUTH=(ACQ),                                          +
               PARSESS=YES,                                         +
               EAS=20
```

Step 6: Define VTAM switched circuits

X.25 NPSI switched virtual circuits (SVCs) appear to VTAM as switched links, [1] requiring a switched circuit definition of a physical unit (PU) and logical unit (LU) for each SVC. The sample provided in SEZAINST(X25VSVC) shows the definitions of a VTAM switched circuit corresponding to the sample X.25 NPSI GATE configuration.

The definitions are associated with the SVCs by identifying numbers (IDNUMs) created automatically during X.25 NPSI generation. The entries, in hexadecimal, run in steps of 2, by default, in the opposite order of the MCH and SVC definitions in the X.25 NPSI configuration.

Notes:

1. Permanent virtual circuits (PVCs) are not supported.
2. If you specify a local version of the z/OS UNIX table with the SSCPFM operand, the table must not have an entry for message 10 (the welcome message); otherwise, the X.25 NPSI server does not operate correctly.

Following is a sample SVC configuration data set (X25VSVC):

NCPROUTE

NCPROUTE is a server that provides an alternative to using the Network Control Program (NCP) as a static host-independent IP router. NCPROUTE has the following effects:

- NCP becomes an active RIP router on a TCP/IP network.
- NCP becomes responsive to SNMP route table queries.

Notes:

1. NCPROUTE requires NCP V7R1, or later.
2. NCPROUTE requires SNALINK LU0 when using NCP V7R3 or previous.
3. SNALINK and IP over CDLC is supported for ESCON, BCCA, and CADS channels.
4. IP over CDLC can be used instead of SNALINK when using NCP V7R4, or later.
5. If using RIP Version 2, NCPROUTE requires NCP V7R6, or later. Also, the NCP generation definition must have VSUBNETS=YES specified on the BUILD statement.
6. NCP versions V6R1 and V6R2 support static IP routing only. NCP uses these static route tables to deliver datagrams over connected TCP/IP networks. NCP V7R1 can be specified only as a host-dependent router and it requires the NCPROUTE server to function as a RIP router.
7. If using NCPROUTE with SNALINK, IP over CDLC channels, and OMPROUTE, you should customize the NCST interface metric on the NCP client side for the SNALINK NCST connection so the routes will be less preferred. This causes OMPROUTE to prefer routes from the IP over CDLC interface over the ones from the SNALINK interface. To customize the interface metric, see the *interface metric* option in "Step 8: Configure the NCPROUTE gateways data set (Optional)" on page 544. Do the same for the SNALINK interface on the MVS host side by customizing the metric in the BSDROUTINGPARMS statement. RIP traffic will be carried over the IP over CDLC interface, while transport PDUs (for example, Hello, Add Route Request, Delete Route Request) will be carried over the SNALINK interface.
8. NCPROUTE does not support zero subnets.

NCPROUTE provides dynamic route table updates for one or more NCP clients that have been generated as IP routers and have NCPROUTE specified as the NCPROUTE server. NCPROUTE tables are updated periodically in the NCP client based on updates sent by the NCPROUTE server. These updates reflect dynamic changes in route states.

An NCPROUTE server at the host uses the Routing Information Protocol (RIP), described in RFC 1058 (RIP version 1) and in RFC 1723 (RIP version 2). The same routing protocols are used by OMPROUTE. NCPROUTE is implemented as a RIP server operating on an MVS host connected to a RIP client in the NCP. Together they provide the appearance to the TCP/IP network of an IP router using the RIP protocol. The same client/server pair also provides SNMP agent support for network management route table queries. RIP Versions 1 and 2 are currently supported by NCPROUTE. For a brief description of RIP (Versions 1 and 2), see Chapter 6, “Routing,” on page 255.

Understanding the NCPROUTE environment

The NCPROUTE server:

- Supports multiple host-attached, link-attached, and remote link-attached NCP clients as illustrated in Figure 56
- Generates RIP datagrams for the NCP to send
- Maintains separate routing tables for each NCP client
- Generates SNMP route table responses for each NCP SNMP agent

The client NCP unit appears as an active router to other RIP routers on the network. Multiple NCP clients can connect to the same NCPROUTE server. Each NCP appears as an IP router to the rest of the network. Each NCP client must have one or more LU0 sessions established with SNALINK. One LU0 session per client is used as the primary session, with the remaining sessions serving as backups.

Figure 56 illustrates the different ways the NCPROUTE server can support NCP clients. NCP3 and NCP4 are host-attached NCP clients, NCP5 and NCP6 are link-attached NCP clients, and NCP1 and NCP2 are remote link-attached NCP clients.

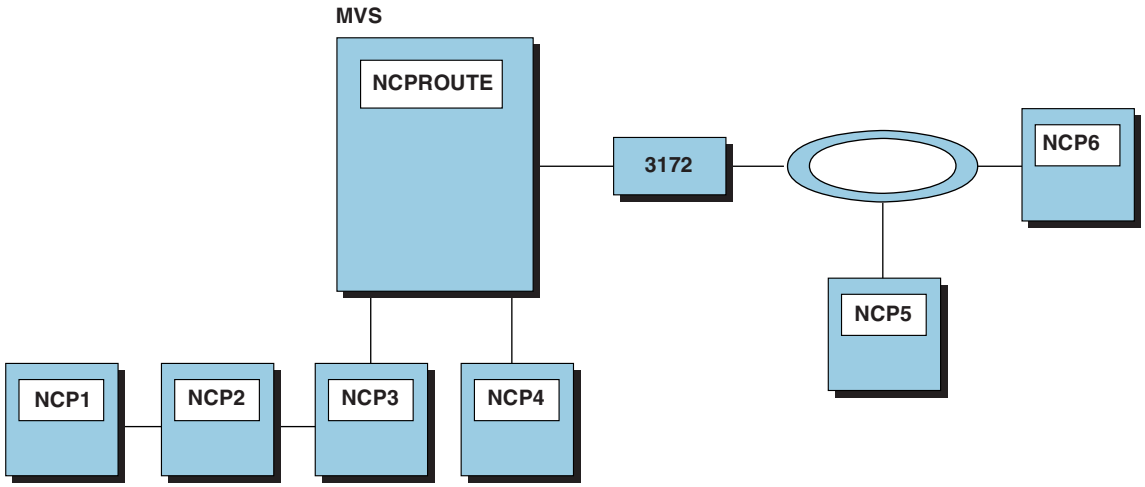

Figure 56. NCPROUTE environment

Server requirements

NCPROUTE processes RIP and SNMP datagrams addressed to all attached NCP units, generates datagrams for the NCP units, and maintains the state of each NCP unit's routing tables.

SNMP support is limited to route table queries. Queries are made to the NCP, which sends the request to the NCPROUTE server for processing.

NCPROUTE operation

An NCP's IPOWNER statement defines the controlling host and the interface this NCP client must use to reach the host. The NCP client initiates contact with NCPROUTE by sending a datagram, known as a "Hello" message, to the controlling host. It transmits this datagram on UDP port 580.

Note: The port number is generated in the NCP (using the UDPPORT keyword on the IPOWNER statement) and configured in NCPROUTE.

The "Hello" message identifies the client NCP and determines which member from the *hlq*.NCPROUTE.GATEWAYS partitioned data set to use for this NCP's route table. Any valid MVS data set name can be used for the gateways data set.

The NCP client then sends a list of its inactive links to NCPROUTE. NCPROUTE uses additional routes defined for this NCP in the NCPROUTE gateways data set, as defined in the NCPROUTE profile. It also uses the inactive links provided dynamically by the NCP to build the current route table for this NCP. The following process is repeated for each NCP that has been generated to act as a RIP router:

1. A RIP packet arrives at the NCP client from a foreign router.
2. The NCP client sends this datagram to the NCPROUTE server.
3. The NCPROUTE server processes the RIP packet.
4. The NCPROUTE server creates a RIP update for an NCP client.
5. This update is sent to the NCP client.
6. The NCP client transmits the datagram to the network.

NCPROUTE sends route table updates to each NCP client every 30 seconds. After a client has been activated, updates must be supplied over each of its interfaces every 30 seconds. The NCPROUTE server creates these updates and sends them to the NCP client along with the IP addresses of other RIP routers that the NCP client should send them to.

At the same time, adjacent RIP routers are providing periodic updates every 30 seconds to NCPROUTE. These updates are sent by the NCP client to the NCPROUTE server, where they are processed, and the results are reflected in future updates back to the NCP client.

The NCP client sends all SNMP and RIP datagrams to the NCPROUTE server for processing. The NCPROUTE server provides RIP packets and SNMP replies to the NCP client to send to their final destination.

NCPROUTE gateways:

Passive RIP route: Information about passive routes is put in NCP's and NCPROUTE's routing tables. A passive entry in NCPROUTE's routing table is used as a placeholder to prevent a route from being propagated and from being

overwritten by a competing RIP route. With the exception of directly-connected passive routes, passive routes are not propagated; they are known only by this router.

Using passive routes can create routing loops, so care must be taken when creating them.

Do not define passive routes such as these:
- A to C is via B.
- B to C is via A.

Passive routes should be used when adding routes where the host or network is not running RIP. Passive routes should also be used when adding a default route, because this is the only way to prevent a route from timing out.

External RIP route: External routes are managed by other protocols, for example, the External Gateway Protocol (EGP). NCPROUTE needs to know not to interfere with these routes and not to delete them.

An external entry exists in the NCPROUTE routing table as a place holder to prevent a route from being overwritten by a competing RIP route. External routes are not propagated. NCPROUTE does not manage an external route. Therefore, NCPROUTE only knows that there is an existing route to the host or network and that is the route known by NCP.

External routes should be used when the local machine is running a non-RIP routing protocol that dynamically changes the TCP/IP routing tables. The remote machine does not need to run any routing protocol, since the only concerns are how to route traffic from the local machine to the remote machine, and how to prevent multiple routing protocols from interfering with each other.

RIP route advertising rules:

Note: RIPv1 and RIPv2 protocols are mutually exclusive; you cannot run RIPv1 and RIPv2 simultaneously.

Table 26 illustrates the differences between routing rules on the basis of RIP version.

Table 26. RIP route advertising rules

Version[2]	**Advertised destination route**[1]	**Same subnet as interface**	**Different network from interface with same subnet mask**	**Same network as interface regardless of subnet mask**	**Different network from interface**	**Same supernet as interface**	**Different supernet from interface**
RIPv1	Host	Yes[3]	Yes[3]	Yes[3]	Yes[3]		
	Subnet	No	Yes	No	No		
	Network			No	Yes		
	Supernet						
	Default				Yes[3]		

Table 26. RIP route advertising rules (continued)

Version[2]	Advertised destination route[1]	Same subnet as interface	Different network from interface with same subnet mask	Same network as interface regardless of subnet mask	Different network from interface	Same supernet as interface	Different supernet from interface
RIPv2	Host	Yes[3]	Yes[3]	Yes[3]	Yes[3]	Yes[3]	Yes[3]
	Subnet	No	Yes	Yes	Yes	Yes	Yes
	Network			No	Yes	No	Yes
	Supernet			No	Yes	No	Yes
	Default				Yes[5]		

Notes:

1. According to RIP design, route advertising relies on network-specific routes because they are the lowest common denominator. The network-specific routes consist of supernet, network, and subnet routes. The advertising of host specific routes is optional.
2. RIPv1 is the default setting for the RIP version. To set to RIPv2, specify the RIP2 parameter in NCPROUTE Profile and/or on interface options in the NCPROUTE Gateways data set.
3. The optional host specific routes are allowed to be advertised outside networks, and they are advertised in addition to the network specific routes. The option is enabled when the system -h parameter (or SUPPLY HOSTS option in NCPROUTE Gateways data set) is specified.
4. Although it is possible to advertise only the host specific routes using the RIP filters, doing so creates network unreachable problems when some routers in the network do not support the host specific routes. These routers rely on network-specific routes.
5. A default route has a network number of zero and is usually advertised over all network interfaces.
6. It does not matter whether the advertised route is VIPA or not. VIPA routes follow the same advertising rules as the non-VIPA routes.
7. Routes that are subjected to RIP filters may not be advertised at all over certain network interfaces.

NCPROUTE active gateways: Active gateways are treated as remote network interfaces. Active gateways are routers that are running RIP, but are reached through a medium that does not allow broadcasting or multicasting and is not point-to-point, for example, Hyperchannel. NCPROUTE normally requires that routers be reachable by broadcast or multicast for non-point-to-point links or by unicast addresses for point-to-point links. If the interface is neither, then an active gateway entry can add the gateway to NCPROUTE's interface list. NCPROUTE will treat the active gateway as a remote network interface. Note that the active gateway must be directly connected.

Active gateways should be used when the foreign router is reachable over a non-broadcast-capable, non-multicast-capable, and non-point-to-point network, and is directly connected to the local host.

NCPROUTE communicates with active routes by unicast transmissions to the gateway address. Routes are not added immediately to either NCPROUTE or the NCP routing table. They are added and propagated normally when route advertisements arrive from an active gateway. The sole effect of an active gateway statement is to bypass the requirement for broadcast communication on non-point-to-point links. Interfaces that are not broadcast, non-point-to-point, and are not active gateways are assumed to be loopback interfaces to the local machine. Also, while a route to an active gateway might timeout, the interface entry is never removed. If transmissions resume, then the new routes will still be available to the active gateways.

NCPROUTE gateways summary

Table 27 provides a list of NCPROUTE gateways and their characteristics.

Table 27. NCPROUTE gateways summary

	Propagate	Kernel	NCPROUTE	Timeout
Dynamic (1)	Yes	Yes	Yes	Yes
Passive	No (2)	Yes	Yes	No
External	No	No	Yes	No
Active	Yes	Yes	Yes	Yes
1 Dynamic routing is provided by NCPROUTE.				
2 Except directly-connected passive routes. Directly-connected passive routes are propagated to other network interfaces for network reachability. A directly-connected passive route is one where the gateway address is one of the local interfaces in an NCP client.				

RIP input/output filters

The RIP input/output filters provide routing table manipulation and routing control. The filters are provided by NCPROUTE and consist of:

- Route receiving (unconditional and conditional)
- Route noreceiving
- Route forwarding (unconditional and conditional)
- Route noforwarding
- Interface Supply switch
- Interface RIP On/Off switch
- Gateway noreceiving

For more information on these filters, see "Step 8: Configure the NCPROUTE gateways data set (Optional)" on page 544.

Configuring NCPROUTE

Steps to configure NCPROUTE:

1. Specify configuration statements in *hlq*.PROFILE.TCPIP.
2. If using SNALINK, configure VTAM and SNALINK applications.
3. If using IP over CDLC, configure IP over CDLC DEVICE and LINK statements.
4. Update the NCPROUTE cataloged procedure.
5. Update *hlq*.ETC.SERVICES.
6. Configure the host-dependent NCP clients.
7. Configure the NCPROUTE profile data set for SNMP support and specification of an NCPROUTE gateways data set (optional).

8. Configure the NCPROUTE gateways data set for each NCP client (optional).
9. If OMPROUTE is not used, define a directly connected host route to each NCP client.

Figure 57 shows the network addresses used in the configuration examples:

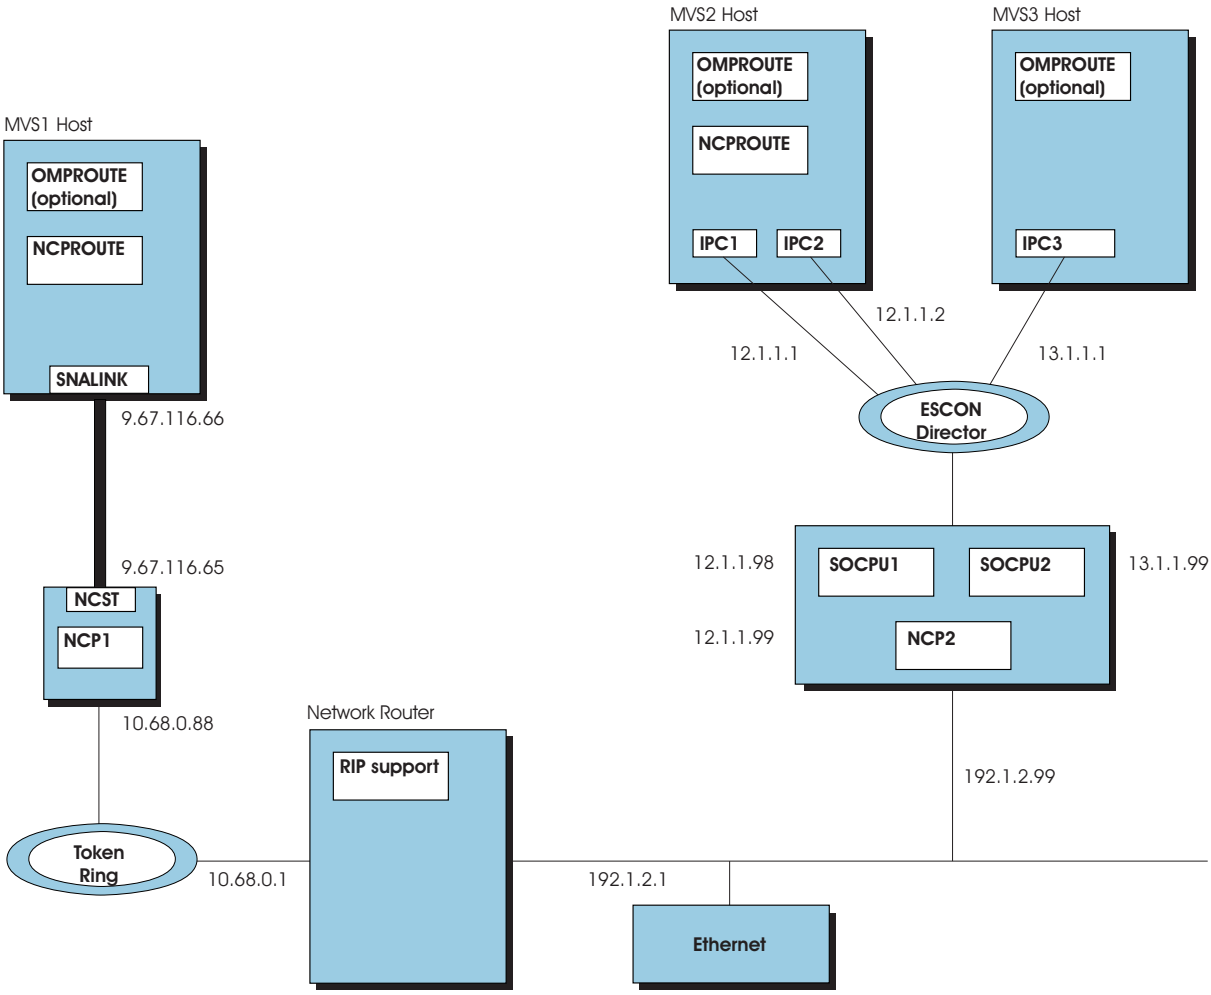

Figure 57. NCPROUTE example configuration

Step 1: Specify configuration statements in *hlq*.PROFILE.TCPIP

1. To have the NCPROUTE server started automatically when the TCPIP address space is started, include the name of the member containing the NCPROUTE cataloged procedure in the AUTOLOG statement in *hlq*.PROFILE.TCPIP:

```
AUTOLOG
   NCPROUT
ENDAUTOLOG
```

2. To ensure that UDP port 580 is reserved for the NCPROUTE server, also add the name of the member containing the NCPROUTE cataloged procedure to the PORT statement in *hlq*.PROFILE.TCPIP:

```
PORT
   580 UDP NCPROUT
```

Note: This port number must match the one defined in the NCP generation definition (using the UDPPORT keyword on the IPOWNER statement) and assigned in *hlq*.ETC.SERVICES.

3. NCPROUTE also requires HOME and BSDROUTINGPARMS statements for the SNALINK type LU0 and IP over CDLC connections. For example, you would use this HOME and BSDROUTINGPARMS statement and, optionally, the BEGINROUTES or GATEWAY statement for the configuration shown in Figure 57 on page 535:

```
MVS1:   HOME
           9.67.116.66  SNALINK
           BSDROUTINGPARMS false
             SNALINK 2000     0    255.255.240.0    9.67.116.65
           ENDBSDROUTINGPARMS
MVS2:   HOME
           12.1.1.1   IPC1
           12.1.1.2   IPC2
           BSDROUTINGPARMS false
             IPC1    1000     0    255.255.255.0   12.1.1.98
             IPC2    1000     0    255.255.255.0   12.1.1.99
           ENDBSDROUTINGPARMS
MVS3:   HOME
           13.1.1.1   IPC3
           BSDROUTINGPARMS false
             IPC3    1000     0    255.255.255.128   13.1.1.99
           ENDBSDROUTINGPARMS
```

Notes:

a. If you are not using OMPROUTE to manage the host routes, configure static routes to the NCP client or clients in the BEGINROUTES or GATEWAY statement in *hlq*.PROFILE.TCPIP. The BSDROUTINGPARMS statement is required to route transport PDUs over static routes. See "Step 9: Define a directly connected host route for the NCST session" on page 548 for sample definition. For more information on the BEGINROUTES or GATEWAY statement, see *z/OS Communications Server: IP Configuration Reference* for each NCP client.

b. If using NCPROUTE with OMPROUTE, the BSDROUTINGPARMS statement is required to route transport PDUs prior to OMPROUTE activation. Because the BSDROUTINGPARMS parameters are overridden by the interface parameters defined in the OMPROUTE configuration, ensure that the interface parameters for the SNALINK or IP/CDLC channel connections are identical in both the BSDROUTINGPARMS statement and the OMPROUTE configuration file.

You can find a complete explanation of these configuration statements in *z/OS Communications Server: IP Configuration Reference*.

Step 2: Configure VTAM and SNALINK applications

If you are using NCP V7R3 or previous, NCPROUTE requires SNALINK type LU0 to run. To use SNALINK LU0, verify that you have configured the SNALINK LU0 interface, defined it to VTAM with a VTAM APPL definition, and included the correct DEVICE and LINK statements in *hlq*.PROFILE.TCPIP. For NCP V7R4, or later, IP over CDLC can be used instead of SNALINK.

If you are using the Cross Domain Resource (CDRSC), verify that the cross-domain resource managers are configured in VTAM.

Following is an example of an appropriate VTAM APPL definition:

```
*********************************************************************
*       SNALINK VTAM APPL DEFINITION                                *
*********************************************************************
SNALKLU1 APPL AUTH=(ACQ,VPACE),ACBNAME=SNALKLU1,EAS=12,PARSESS=YES,   *
               SONSCIP=YES,VPACING=0,SRBEXIT=YES
```

Note: The application name (the ACBNAME value, SNALKLU1, in this example) must match the REMLU interface definition in the NCP clients generation program. See the example in "Step 6: Configure the host-dependent NCP clients" on page 538 for more information.

Following is an example of corresponding DEVICE and LINK statements:

```
;
;  DEVICE AND LINK DEFINITIONS FOR SNALINK LU0
;
DEVICE SNA1LINK SNAIUCV SNALINK A04TOLU1 SNALPROC
LINK SNALINK SAMEHOST 1 SNA1LINK
;
```

Note: The LU name on the DEVICE statement (A04TOLU1 in this example) must match the LU name of the NCST interface definition in the NCP clients generation program. See the example in "Step 6: Configure the host-dependent NCP clients" on page 538 for more information.

If you want the SNALINK device to start automatically, verify that you have a START statement for this device in *hlq*.PROFILE.TCPIP. For example, `START SNA1LINK`. Otherwise, you will have to start the device manually.

Step 3: Configure the IP over CDLC DEVICE and LINK statements

For NCPROUTE, IP over CDLC can be configured along with SNALINK for NCP V7R3, or later, or it can be used to replace SNALINK for NCP V7R4, or later.

Following is an example of corresponding DEVICE and LINK statements for the configuration shown in Figure 57 on page 535 for the MVS2 host:

```
;
;  DEVICE AND LINK DEFINITIONS FOR IP OVER CDLC
;
DEVICE IPC1NCP CDLC 013 40 40 1024 1024
LINK IPC1 CDLC 0 IPC1NCP
;
DEVICE IPC2NCP CDLC 014 40 40 1024 1024
LINK IPC2 CDLC 0 IPC2NCP
```

Note: If you want a CDLC device to start automatically, verify that you have a START statement for this device in *hlq*.PROFILE.TCPIP, for example, START IPC1NCP. Otherwise, you will have to start the device manually.

Step 4: Update the NCPROUTE cataloged procedure

Update the NCPROUTE cataloged procedure by copying the sample in SEZAINST(NCPROUT) to your system or recognized PROCLIB. Specify NCPROUTE parameters and change the data set names to suit your local configuration. See Figure 58 on page 544 for an illustration of NCPROUTE data set relationships.

Step 5: Update *hlq*.ETC.SERVICES

NCPROUTE uses the *hlq*.ETC.SERVICES data set to determine the port number on which to run. This data set can be used to define a port number other than the reserved well-known port for NCPROUTE. This data set must exist for NCPROUTE to run.

The ETC.SERVICES data set is dynamically allocated using the standard search sequence for data set names. This data set also can be explicitly allocated in the NCPROUTE cataloged procedure using the //SERVICES DD statement.

The entries in *hlq*.ETC.SERVICES are case and column sensitive. They must be in lowercase and begin in column 1.

Add the following lines to the *hlq*.ETC.SERVICES data set:

```
ncproute  580/udp
router    520/udp
```

Note: Verify that the NCPROUTE service port number is the port being used by the NCP clients. This number should match the port number defined in the NCP generation definition using the UDPPORT keyword on the IPOWNER statement. This port number does not necessarily have to match the reserved port number for NCPROUTE on the PORT statement in *hlq*.PROFILE.TCPIP.

The reserved router service port number is 520. It is required for the NCPROUTE transport of RIP packets to NCP clients which are responsible for broadcasting the packets to other RIP routers. It cannot be overridden.

If you want to use name aliases, see INFO APAR II08205 for information.

Step 6: Configure the host-dependent NCP clients

You should see the appropriate NCP documentation for more information about defining and generating the NCP and creating route information tables.

- For more information about defining IP, see *NCP, SSP, and EP Resource Definition Guide*.
- For more information about the IP Dynamics function, see *NCP and EP Reference*.
- For more information about NCP generation definitions for IP, see *NCP, SSP, and EP Resource Definition Reference*.
- For more information about generating NCP as an IP router, see *NCP, SSP, and EP Generation and Loading Guide*.

Note: See NCPROUTE notes in on page 529.

Generating the routing information tables: To support IP dynamics, NCP's Network Definition Facility (NDF) builds a routing information table (RIT) for networks and subnetworks for use by TCP/IP at NCP generation time.

The RIT consists of routing tables that are generated from the NCP IPROUTE and IPLOCAL statements. During NCP generation, the RIT is added as a member of the NCP load library partitioned data set ncp.v7r1.ncpload. You identify the member name of ncp.v7r1.ncpload that NCPROUTE uses at execution time with the NEWNAME parameter of the BUILD statement for each NCP client generation.

Determining the gateway route table name: There is one RIT in the ncp.v7r1.ncpload data set for each NCP client this server supports. The NCPROUTE server receives the NCP name from an NCP client in the “Hello”

message. This name is used as the base to determine the member name in the ncp.v7r1.ncpload partitioned data set to use for the initial RIT for this NCP client. The RIT member name in the ncp.v7r1.ncpload data set is the NEWNAME parameter of the BUILD statement for the NCP generation with a suffix of **P** added. Specify a unique name on the NEWNAME parameter of the BUILD statement for each NCP client. This name is also used as the member name if the optional gateways data set (GATEWAYS_PDS) is specified in the NCPROUTE profile. The RIT is accessed by NCPROUTE from a //STEPLIB DD statement in the NCPROUTE cataloged procedure, LINKLST, or authorized library.

NCST session interface definition: The NCP Connectionless SNA Transport (NCST) interface is used to establish a session that can provide a connection to another IP node (NCP or z/OS) over a SNA network. Use this definition when using NCST PU interfaces to communicate with NCPROUTE using SNALINK devices with the MVS host. The NCST interface must be defined to match the SNALINK LU0 interface in VTAM so that an NCP client can establish a connection with NCPROUTE. The LU statement in the NCST interface definition tells VTAM which interface to use for the SNALINK application. The following are important keywords in this definition:

NCST
Specifies the protocol type. Must be coded as IP for internet protocol.

INTFACE
Specifies the name of the interface and the maximum transfer unit (MTU) size for the NCST session to the VTAM owner (IPOWNER).

REMLU
Specifies the name of the remote LU for the SNALINK LU0 VTAM connection. This name must match:
- The APPLID in the PROC statement of the SNALINK cataloged procedure
- The application name in the VTAM APPL definition

Note: If you define a backup NCST SNALINK session, the REMLU can specify the primary logical name for the remote LU or a different remote LU. Ensure that the MTU sizes are the same for the backup NCST sessions.

Following is an example of an NCST session interface definition:

```
*************************************************************************
*     NCST IP INTERFACES                                                *
*************************************************************************
A04NCSTG GROUP NCST=IP,LNCTL=SDLC,VIRTUAL=YES
A04NCSTL LINE LINEFVT=CXSXFVT,PUFVT=CXSXFVT,LUFVT=(CXSXFVT,CXSXFVT),   *
               LINECB=CXSXLNK
A04NCSTP PU VPACING=0,PUTYPE=2,PUCB=CXSP0000
*
A04TOLU1 LU INTFACE=(NCSTALU1,1492),REMLU=SNALKLU1,LUCB=(CXSL0000,CXSS0*
               000),LOCADDR=1
*
```

Note: The NCST LU name (A04TOLU1 in this example) must match the LU name on the SNALINK LU0 DEVICE statement in *hlq*.PROFILE.TCPIP. See the example in "Step 2: Configure VTAM and SNALINK applications" on page 536 for more information.

Channel PU interface definition: Use this definition with channel PU interfaces (ESCON, BCCA, or CADS) to communicate with NCPROUTE using IP over CDLC devices with the MVS host.

Following is an example of channel PU interface definition using the ESCON channel type:

```
*********************************************************************
*   PHYSICAL ESCON CHANNEL DEFINITIONS                              *
*********************************************************************
*
A04PSOC1 GROUP LNCTL=CA,MONLINK=NO,NPACOLL=NO,XMONLNK=YES
               SPEED=144000000,SRT=(32768,32768)
*
A04S2240 LINE  ADDRESS=2240
A04P2240 PU    ANS=CONTINUE,PUTYPE=1
*
*********************************************************************
*    LOGICAL ESCON CHANNEL DEFINITIONS                              *
*********************************************************************
*
A04PSOCB GROUP LNCTL=CA,PHYSRSC=A04P2240,NPACOLL=NO,
               DELAY=0.2,MAXPU=16,MODETAB=AMODETAB,
               DLOGMOD=INTERACT,SPEED=144000000,
               SRT=(21000,20000),PUDR=YES,
               TIMEOUT=150.0,CASDL=0.0
*
A04LSOC2 LINE  ADDRESS=NONE,HOSTLINK=1
A04L2S1  PU    ADDR=01,PUTYPE=1,ARPTAB=(10,,NOTCANON),
               INTFACE=SOCPU1
A04L2S2  PU    ADDR=02,PUTYPE=1,ARPTAB=(10,,NOTCANON),
               INTFACE=SOCPU2
```

NCP host interface definition: The IPOWNER statement in the NCP generation definition contains the TCP/IP host information and tells NCP which interface to use for NCPROUTE. The following are important keywords on the IPOWNER statement:

INTFACE
Specifies the name of the interface to the owning TCP/IP host that is running NCPROUTE.

HOSTADDR
Specifies the IP address of the owning TCP/IP. This address must match the IP address in the HOME statement in *hlq*.PROFILE.TCPIP data set for a SNALINK or IP over CDLC interface.

UDPPORT
Specifies the UDP port number for NCPROUTE. The default is 580. This port number must match the NCPROUTE service port number defined in the *hlq*.ETC.SERVICES data set. See "Step 5: Update ***hlq***.ETC.SERVICES" on page 538 for more information.

The IPLOCAL statement in the NCP generation definition contains the NCP routing information for the local attached routes. During NCP generation, this information gets included in the Routing Information Table (RIT) which NCPROUTE uses to build the interface and routing tables. IPLOCAL routes are predefined as permanent or static to prevent modification by NCPROUTE. The following are important keywords on the IPLOCAL:

INTFACE
Specifies the name of the locally attached interface.

LADDR
Specifies the IP address of the locally attached interface.

P2PDEST
For point-to-point interfaces only. Specifies the IP address of the remote end of the point-to-point link.

PROTOCOL
Specifies the type of protocol to be used for the interface. The default is RIP which indicates that the interface is RIP-managed by NCPROUTE.

SNETMASK
Specifies the subnetwork mask for a route to a network that is subnetted. Because RIP does not support variable subnetwork masking, this value must be equal to the subnetwork mask of the route's destination.

The IPROUTE statement in the NCP generation definition contains the NCP routing information for optional predefined routes. During NCP generation, this information gets included in RIT which NCPROUTE uses to add the routes to its routing tables. IPROUTE routes can be predefined as permanent or non-permanent for route management control by NCPROUTE. The following are important keywords on the IPROUTE statement:

INTFACE
Specifies the name of the locally attached interface for the route.

DESTADDR
Specifies the route's destination IP address.

DISP
Specifies the disposition for the route. A disposition of PERM indicates that this route is a permanent route and will not be modified by NCPROUTE. The default is NONPERM.

HOSTRT
Indicates whether this is a host route. The default is NO.

NEXTADDR
Specifies the IP address of the gateway through which the route can reach its destination. A value of 0 indicates that there is no gateway.

The following example shows typical NCP RIP router generation source statements.

```
*************************************************************************
*       IP ROUTING DEFINITIONS                                          *
*************************************************************************
*
        IPOWNER INTFACE=NCSTALU1,HOSTADDR=9.67.116.66,                  *
                NUMROUTE=(100,100,100),MAXHELLO=25,UDPPORT=580
*
        IPLOCAL LADDR=9.67.116.65,INTFACE=NCSTALU1,METRIC=1,            *
                P2PDEST=9.67.116.66,PROTOCOL=RIP,SNETMASK=FFFFF000
        IPLOCAL LADDR=10.68.0.88,INTFACE=TR88,METRIC=1,                 *
                SNETMASK=FFFFF000
        IPLOCAL LADDR=10.68.0.92,INTFACE=TR92,METRIC=1,                 *
                SNETMASK=FFFFF000
*
        IPROUTE DESTADDR=11.0.0.1,NEXTADDR=0,INTFACE=TR88,METRIC=2,     *
                DISP=PERM,HOSTRT=YES
        IPROUTE DESTADDR=12.0.0.0,NEXTADDR=13.0.0.1,INTFACE=TR92,       *
                METRIC=2,DISP=NONPERM
```

The following example shows IPOWNER and IPLOCAL statements for the ESCON channel PU interfaces in the configuration for NCP2 as shown in Figure 57 on page 535.

```
************************************************************
*   IP ROUTING DEFINITIONS USING ESCON CHANNEL INTERFACES   *
************************************************************
*
IPOWNER INTFACE=SOCPU1,UDPPORT=580,NUMROUTE=(110,120,130),
        HOSTADDR=12.1.1.1
*
IPLOCAL LADDR=12.1.1.98,INTFACE=SOCPU1,METRIC=1,
        P2PDEST=12.1.1.1,PROTOCOL=RIP,SUBNETMASK=FFFFFF00
*
IPLOCAL LADDR=12.1.1.99,INTFACE=SOCPU1,METRIC=1,
        P2PDEST=12.1.1.2,PROTOCOL=RIP,SUBNETMASK=FFFFFF00
*
IPLOCAL LADDR=13.1.1.99,INTFACE=SOCPU2,METRIC=1,
        P2PDEST=13.1.1.1,PROTOCOL=RIP,SUBNETMASK=FFFFFF80
```

Step 7: Configure the NCPROUTE profile data set (Optional)

To build the NCPROUTE profile, create a data set and specify its name in the //NCPRPROF DD statement in the NCPROUTE cataloged procedure. You can find a sample in SEZAINST(EZBNRPRF). Include configuration statements in this data set to define SNMP functions and to identify the NCPROUTE gateways data set. For more information, see *z/OS Communications Server: IP Configuration Reference*.

RIP_SUPPLY_CONTROL *supply_control*

Specifies one of the following options on a server-wide basis:

- RIP1—Unicast/Broadcast RIP Version 1 packets (Default)
- RIP2B—Unicast/Broadcast RIP Version 2 packets (Not Recommended)
- RIP2M—Unicast/Multicast/Broadcast RIP packets (Migration)
- RIP2—Unicast/Multicast RIP Version 2 packets
- NONE—Disables sending RIP packets

Note: If RIP2 is specified, the RIP Version 2 packets are multicast over multicast-capable interfaces only. No RIP packets are sent over multicast-incapable interfaces. For RIP2M, the RIP Version 2 packets are multicast over multicast-capable interfaces and RIP Version 1 packets over multicast-incapable interfaces. For RIP2B, the RIP Version 2 packets are unicast or broadcast; this option is not recommended since host route misinterpretations by adjacent routers running RIP Version 1 can occur. For this reason, RIP2B may become obsolete in a future release. For point-to-point interfaces that are non-broadcast and multicast-incapable, the RIP Version 2 packets are unicast.

RIP_RECEIVE_CONTROL *receive_control*

Specifies one of the following options on a server-wide basis:

- RIP1—Receive RIP Version 1 packets only
- RIP2—Receive RIP Version 2 packets only
- ANY—Receive any RIP Version 1 and 2 packets (Default)
- NONE—Disables receiving RIP packets

Note: If the client NCP does not support variable subnetting, the default of ANY is changed to RIP1.

RIP2_AUTHENTICATION_KEY *authentication_key*

Specifies a plain text password *authentication_key* containing up to 16 characters. The key is used on a router-wide basis and can contain mixed case and blank characters. Single quotes (') can be included as delimiters to include leading and trailing blanks. The key will be used to authenticate RIP Version 2 packets and be included in the RIP updates for authentication by adjacent

routers running RIP Version 2. For maximum security, set RIP_SUPPLY_CONTROL and RIP_RECEIVE_CONTROL to RIP2. This will discard RIP1 and unauthenticated RIP2 packets. A blank key indicates that authentication is disabled. Following are examples of authentication passwords:

```
my password        (no leading or trailing blanks)
' my password '    (leading and trailing blanks)
''abc''            (single quotes part of password)
'     '            (5-character blanks)
```

SNMP_AGENT *host_name*
Specifies the host name or IP address of the host running an SNMP daemon. Only one NCPROUTE server can use a particular SNMP agent at a time.

SNMP_COMMUNITY *community_name*
Specifies a community name that SNMP applications must use to access data that the agent manages. Protect this information accordingly.

GATEWAY_PDS *dsname*
Specifies the optional partitioned data set that contains GATEWAY information for each client NCP. Quotation marks are not needed when specifying *dsname*. One member for each NCP client of this data set must be configured to match the NCP NEWNAME parameter with the **P** suffix which is the same as the NCP's RIT member name. See "Step 8: Configure the NCPROUTE gateways data set (Optional)" on page 544 for information on defining the statements necessary for the members of this data set.

Note: You can use a semicolon in column 1 to permit comments in the profile. Blank lines are also permitted.

Figure 58 on page 544 shows the relationship between the data set names specified in the NCPROUTE cataloged procedure and the NCPROUTE profile, as well as the relationship between the members of the gateways PDS and the ncpload PDS.

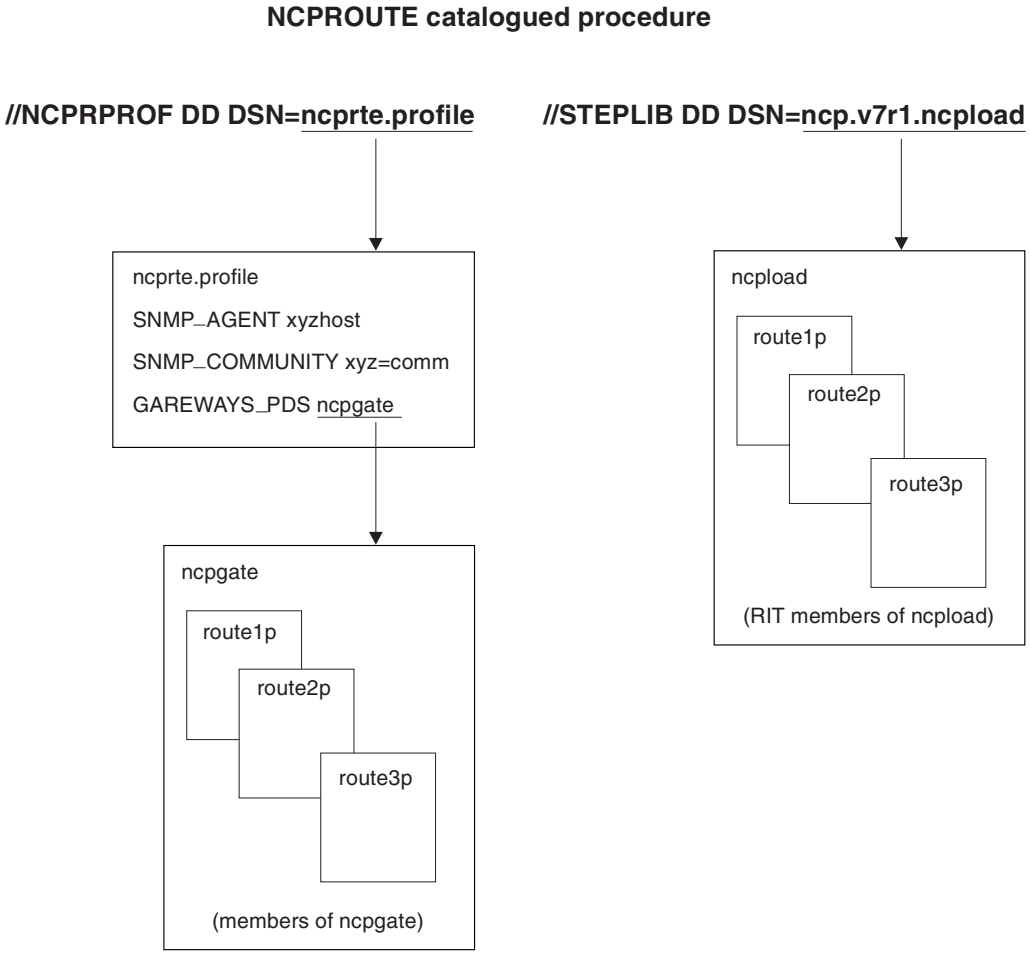

Figure 58. NCPROUTE data sets relationship

Step 8: Configure the NCPROUTE gateways data set (Optional)

The gateways data set is used to identify routes not defined in the NCP routing information table.

The NCPROUTE gateways data set is optional. However, if you use it, you must include the GATEWAY_PDS statement in the NCPROUTE profile to specify the gateway data set name. The NCPROUTE server queries the gateways data set for static routing information. It also dynamically receives routing information from the NCP client portion of this RIP router.

Allocate the gateways data set with partitioned organization (PO), a fixed block format (FB), a logical record length of 80 (LRECL), and any valid block size value for a fixed block, such as 3120.

A `passive` entry in the gateways data set is used to add a route to a part of the network that does not support RIP. An `external` entry in the gateways data set indicates a route that should never be added to the routing tables. If another RIP server offers this route to your host, the route is discarded and not added to the routing tables. An `active` entry indicates a gateway that can only be reached through a network that does not allow or support link-level broadcasting or multicasting.

Note: The gateways data set is not related to the GATEWAY statement used in *hlq*.PROFILE.TCPIP data set.

To configure NCPROUTE, add an entry to the gateways data set for each route not defined in the NCP RIT. Use the options statement to define the characteristics of the routes in this member of the PDS.

Configuring a passive route: Figure 59 illustrates an NCPROUTE configuration using NCP as the destination hosts. In other configurations, destination hosts might not necessarily be NCPs.

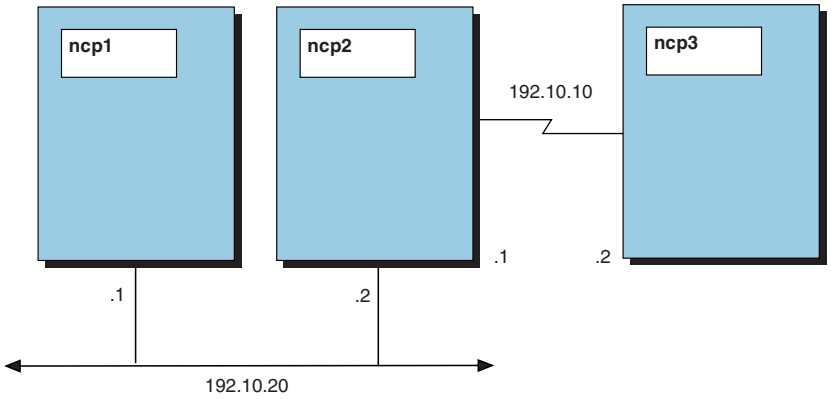

Figure 59. NCPROUTE configuration example of a passive route

Using Figure 59, assume that your NCP client `ncp1` is channel-attached to an MVS host running an NCPROUTE server. The other two NCP clients, `ncp2` and `ncp3`, are not running a RIP server. Also assume that permanent routes to `ncp2` and `ncp3` are not defined with the IPROUTE definitions in the NCP generation definition for `ncp1`. Your NCPROUTE server cannot learn a route to `ncp3`, because `ncp2` is not running a RIP server. Your NCPROUTE server sends routing updates to `ncp3` over the link to `ncp2`, but never receives a routing update from `ncp2`. After 180 seconds, your NCPROUTE server deletes the route to `ncp2`. This problem is inherent to the RIP protocol and cannot be prevented. Therefore, you need to add a `passive` route to `ncp3` in the NCPROUTE gateways data set for the NCP client `ncp1`. This is the data set defined by the GATEWAYS_PDS statement in the NCPROUTE profile.

You can use either of the following gateway statements:

```
host  ncp3         gateway  ncp2         metric 2  passive

host  192.10.10.2  gateway  192.10.20.2  metric 2  passive
```

Similarly, because `ncp2` is not running an RIP server supported by NCPROUTE, you need to add a directly-connected `passive` route as follows:

```
host  ncp2         gateway  ncp1         metric 1  passive
```

A directly-connected passive route is one where the gateway address or name is one of the local interfaces in the NCP generation.

Assume that your NCP client is now `ncp2` and is running an NCPROUTE server. `ncp1` is also running a RIP server, but `ncp3` is not. Your NCPROUTE server sends routing information updates to `ncp3` over the link to `ncp3` but never receives a routing update from `ncp3`. After 180 seconds, your NCPROUTE server deletes the route to `ncp3`.

You should add a passive route to ncp3 as follows:

```
host  ncp3        gateway  ncp2        metric 1  passive
```

ncp1 cannot reach ncp3 unless a passive routing entry is added to ncp1. For example:

```
host   ncp3    gateway  ncp2  metric  2  passive
```

or

```
host  192.10.10.2  gateway  192.10.20.2  metric  2  passive
```

Configuring an external route: Using Figure 59, assume that your NCP client ncp1 is channel-attached to an MVS host running an NCPROUTE server. The other two NCP clients, ncp2 and ncp3, are also running a RIP server. Your NCPROUTE server normally learns a route to ncp3 from ncp2, because ncp2 is running a RIP server. You might not want ncp1 to route to ncp3 for security reasons. For example, a university might want to prevent student hosts from routing to administrative hosts.

To prevent your NCPROUTE server from adding a route to ncp3, add an external route to the NCPROUTE gateways data set. This is the data set defined by the GATEWAYS_PDS statement in the NCPROUTE profile. You can use either of the following gateway statements:

```
host  ncp3         gateway   ncp2        metric 2  external

host  192.10.10.2  gateway  192.10.20.2  metric 2  external
```

Configuring an active gateway:

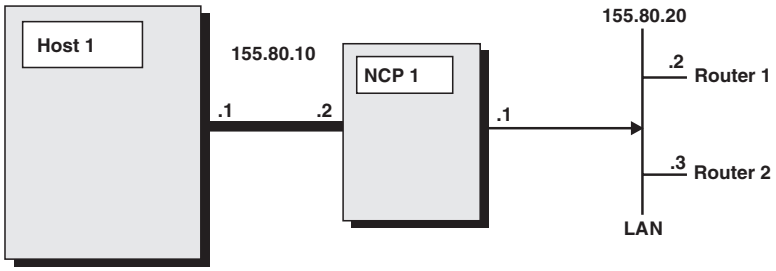

Figure 60. Configuring an active gateway

As shown in Figure 60, assume that your NCP client is ncp1, which is channel-attached to an MVS host running an NCPROUTE server and that it has a network attachment adapter that does not support link-level broadcasting or one that does not support ARP processing. Also, assume that there are routers Router1 and Router2 on the local area network. Because the IP addresses Router1 and Router2 are unknown by ncp1, they have to be manually configured in NCPROUTE for NCPROUTE to communicate with them. Configuring active gateways for Router1 and Router2 as remote network interfaces enables NCPROUTE to send RIP responses to the target addresses.

1. Specify IP addresses for each network adapter (without link-level broadcasting or ARP support) attached to the local network in the NCP client according to the NCP generation definition. For example, 155.80.20.1 is the IP address for the local network adapter attachment in ncp1.

2. Define active gateways for the remote routers in the NCPROUTE gateways data set specified on the GATEWAYS_PDS statement in the NCPROUTE profile:

```
active active gateway 155.80.20.2 metric 1 active
active active gateway 155.80.20.3 metric 1 active
```

NCPROUTE will use these active gateway addresses as the destination addresses to send RIP responses to the remote routers. In addition, NCPROUTE will continue to receive RIP responses from the active gateways over the NCP client.

Configuring a default route: A default route is typically used on a gateway or router to an internet, or on a gateway or router that uses another routing protocol, whose routes are not reported to other local gateways or routers.

To configure a route to a default destination, add a default route using the IPROUTE statement in the NCP generation definition. For example, if the default destination router has a gateway address 9.67.112.1, an IPROUTE statement might look like:

```
IPROUTE  DESTADDR=0.0.0.0,NEXTADDR=9.67.112.1,INTFACE=TR88,
         METRIC=1,DISP=PERM
```

An easier way would be to use the passive route definition specified in the NCPROUTE gateways data set for the NCP client. For example, the gateways entry would look like:

```
net 0.0.0.0 gateway 9.67.112.1 metric 1 passive
```

Only one default route to a destination gateway or router can be specified. For an NCP client, NCPROUTE currently does not support multiple default routes.

Configuration examples: The following example shows the contents of an NCPROUTE gateways data set containing multiple entries:

```
options default.router no trace.level 4 supply on
net testnet gateway 9.0.0.100 metric 1 passive
net 2.0.0.2 gateway 9.0.0.101 metric 2 external
host 2.0.0.3 gateway 9.0.0.102 metric 3 passive
host 2.0.0.4 gateway 9.0.0.103 metric 2 external
active active gateway 2.0.1.1 metric 1 active
```

In the second entry, the route indicates that NCPROUTE can reach network `testnet` through the gateway `9.0.0.100`, and that it is one hop away. This passive route is not broadcast to other RIP routers.

In the third entry, the route indicates that NCPROUTE can reach network `2.0.0.2` through the gateway `9.0.0.101`, and that it is two hops away. Because this route is external, NCPROUTE should not add routes for this network to the routing tables and routes received from other RIP routers for this network should not be accepted.

In the fourth entry, the route indicates that NCPROUTE can reach host `2.0.0.3` through gateway `9.0.0.102`, and that it is one hop away. This passive route is not broadcast to other RIP routers.

In the fifth entry, the route indicates that NCPROUTE can reach host `2.0.0.4` through gateway `9.0.0.103`, and that it is two hops away. Because this route is external, NCPROUTE should not add routes for this network to the routing tables, and routes received from other RIP routers for this network should not be accepted.

The sixth entry shows an active gateway. Note that it is specified as the last entry in the data set.

Note: If a default route is to be defined to a destination gateway or router, configure a default route in this gateways data set (if the default route is not defined in a NCP client's generation definition).

Step 9: Define a directly connected host route for the NCST session

If you are not using OMPROUTE, you need to configure a directly connected static host route using the BEGINROUTES or GATEWAY statement in *hlq*.PROFILE.TCPIP. For example, if you are using SNALINK as the host route and have the IP addresses shown in Figure 57 on page 535, the GATEWAY statement might look like this:

```
GATEWAY
; net_number first_hop link_name packet_size     subnet_mask  subnet_value
  9.67.116.65     =    SNALINK     32758           HOST
```

See *z/OS Communications Server: IP Configuration Reference* and the GATEWAY syntax information in "Step 8: Configure the NCPROUTE gateways data set (Optional)" on page 544 for more information about configuring GATEWAYS statements.

Note: The host routes on the MVS host are managed by TCP/IP, as defined on the BEGINROUTES or GATEWAY statement or as added dynamically by OMPROUTE. NCPROUTE does not manage the host routes on the MVS host. It only manages the routes on the NCP clients.

Controlling the NCPROUTE address space with the MODIFY command

You can control most of the functions of the NCPROUTE address space from the operator's console using the MODIFY command.

For information about modifying the NCPROUTE address space with the MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

Chapter 11. Accessing remote hosts using Telnet

Telnet is a terminal emulation protocol. With Telnet, end users can log on to remote host applications as though they were directly attached to that host. Telnet protocol requires that the end user have a Telnet client that emulates a type of terminal that the host application can understand. The client connects to a Telnet server, which communicates with the host application. The Telnet server acts as an interface between the client and host application. A PC can support several clients simultaneously, each with its own connection to any Telnet server. This topic describes how to set up and use the following kinds of Telnet servers:

- TN3270E Telnet server

  Provides access to z/OS VTAM SNA applications on the MVS host using Telnet TN3270E, TN3270, or linemode protocol
- z/OS UNIX Telnet server

  Provides access to z/OS UNIX shell applications on the MVS host using Telnet linemode protocol

You can use the same port for both Telnet servers. For an overview of port management, see "Port management overview" on page 50. For more specific information about the PORT BIND statement, see "Setting up reserved port number definitions in PROFILE.TCPIP" on page 234.

The TN3270E Telnet server

The TN3270E Telnet server (Telnet) provides access to z/OS VTAM SNA applications on the MVS host using Telnet TN3270E, TN3270, or linemode protocol. Telnet acts as an interface between IP and SNA networks. End users in an IP network connect to Telnet, which is also a VTAM application. Telnet activates one SNA application minor node logical unit (LU) to represent each Telnet IP client. The Telnet application LU establishes a session with a VTAM host application (for example, CICS or TSO), simulating a terminal (LU0 or LU2) or a printer (LU1 or LU3). To enable connections, you must modify the VTAM and Telnet configuration data sets with Telnet statements. These statements describe Telnet server characteristics, the Telnet LUs, a listening port, and the characteristics of that port. After Telnet is started, you can use VARY and DISPLAY commands that are specifically related to Telnet to alter the state of Telnet or to display information about Telnet. For more information about these command sets, see *z/OS Communications Server: IP System Administrator's Commands*.

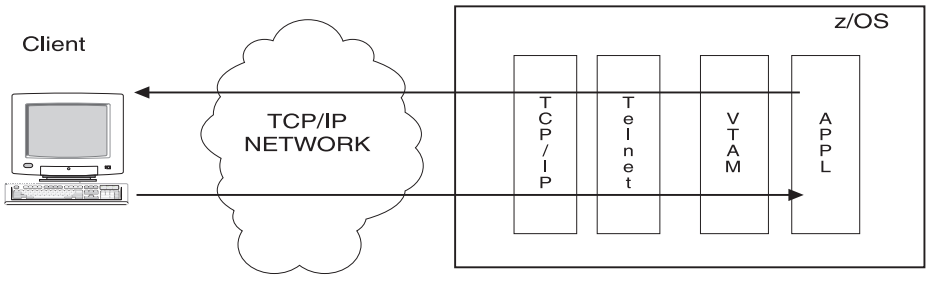

Figure 61. Telnet connectivity

Steps for starting the TN3270E Telnet server

This topic provides the minimum information that you need to start the TN3270E Telnet server, and refers to more specific information about customizing your server.

Before you begin: You need to know how to create VTAM definition data sets; specifically, you need to know how to define VTAM application LUs. You need to set up and know how to use a TN3270E client emulator.

Perform the following steps to start the TN3270E Telnet server:

1. Create a new data set member in your procedure library for the TN3270E Telnet server JCL.

   A sample procedure is in SEZAINST(EZBTNPRC). The only valid parameter that can be passed in from the JCL (using the PARM= keyword on the EXEC JCL statement) is the component trace options parmlib member name.

2. Define security for a user ID and associate the user ID with the Telnet procedure name; see "Steps for defining security for a user ID and associating the user ID with the Telnet procedure name" on page 551.

3. Customize the VTAM configuration data set to define VTAM application LUs for Telnet to use; see "Steps for customizing the VTAM configuration data set for Telnet" on page 553.

4. Customize the TCP/IP configuration data set.

   Reserve your Telnet ports by using the PORT *num tnproc* statement in the TCP/IP startup profile. If you do not code the PORT *num tnproc* statement, another application might use the port before the Telnet application can claim it.

5. Customize the TN3270E Telnet server configuration data set; see "The TN3270E Telnet server configuration data set" on page 554 and "Steps for customizing the TN3270E Telnet server configuration data set" on page 556.

6. Set the component trace options (CTRACE).

   Component trace options are set in a separate parmlib data set member. The sample procedure JCL points to a sample parmlib member, CTIEZBTN, in SYS1.PARMLIB, which starts a minimum trace. Use this member unless you need to turn on other options to debug a Telnet problem.

   To change the component trace options, specify a new parmlib member in the JCL. The member has the form CTIEZB*xx*. For more information about setting up trace options, see "Telnet CTRACE" on page 557.

7. Set up the resolver input file.

   Use the default search order unless there are special circumstances that require you to use unique parameters. For example, if there are parameters that are to be used only when the resolver is called by Telnet, you need to define those unique parameters. Define the unique parameters in a data set that is specified on the SYSTCPD DD statement in the Telnet procedure JCL. For more information about resolvers and resolver configuration files, see Chapter 14, "The resolver," on page 731.

8. Start Telnet by issuing START *tnproc*, where *tnproc* is the Telnet procedure member name.

You should now see message `EZZ6003I` *`tnproc`* `LISTENING ON PORT` *`nnnnn`*. To verify your configuration, connect to the Telnet port from your Telnet client emulator;

Telnet uses the first Telnet LU that is available. A solicitor panel or USSMSG10 screen prompts you to enter an application. Enter the name of any valid SNA application to log on to that SNA application. If an error occurs during session initiation, the MSG07 statement causes an error message to be sent to the client. If you do not code the MSG07 statement, then the connection is dropped.

Tips:

- To help avoid any unnecessary IPL, specify REUSASID=YES on the START command to ensure that the address space identifier (ASID) associated with the Telnet address space can be reused. The Telnet address space provides PC-entered services that must be accessible to all address spaces, so a system linkage index (LX) is obtained. Unless you specify REUSASID=YES on the START command, the ASID associated with the Telnet address space will be nonreusable when the address space is stopped or restarted. If the Telnet address space is stopped enough times and REUSASID=YES is not specified when started, all available ASIDs could be exhausted, preventing the creation of a new address space on the system. In this case, an IPL is required. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in *z/OS MVS Initialization and Tuning Reference*.
- The default MVS program properties table (PPT) entry sets Telnet to be a non-cancelable application. As a non-cancelable application, a TCP/IP stack should not automatically start Telnet using the AUTOLOG function. If the TCP/IP stack is recycled, the stack tries to cancel and restart all AUTOLOG applications. A non-cancelable application does not end and the following messages are issued repeatedly:

  ```
  N 0140000 SA6I     2005147 04:59:27.69 STC07087 00000084  EZZ0621I AUTOLOG FORCING IBMTNSI0, REASON: TCP/IP HAS BEEN RESTARTED
  NR0000000 SA6I     2005147 04:59:27.71 STC07087 00000080  IEE838I IBMTNSI0          NON-CANCELABLE - ISSUE FORCE ARM
  ```

  If you want to set the priority for Telnet in the PPT, change the priorities by assigning the job name to another service class in the STC subsystem.

  The default settings are: Privileged, non-swappable, non-cancelable, running in key 6, and system task. With these settings, Telnet and the TCP/IP stack have the same priority. The privileged or system task setting causes the started job to be assigned to the SYSSTC service class.
- To change the IPv6 or INET environments, you must recycle the Telnet procedure. Telnet checks for changes in the environment each time a port is activated. If Telnet detects a change in the environment, then the port is not activated. If you change from an IPv4 environment to an IPv6 environment, from an IPv6 environment to an IPv4 environment, from an INET environment to a CINET environment, or from a CINET environment to an INET environment, then results are unpredictable on existing ports.

Steps for defining security for a user ID and associating the user ID with the Telnet procedure name

Before you can start Telnet, you must define security for a user ID and associate it with the Telnet procedure name. The following steps use RACF as the example security subsystem. If you are using another security product, see the documentation for that product to determine the procedure that you should use.

Before you begin:

- You need to know the name of the Telnet procedure that you are using.
- Ensure that the MAXSOCKETS value is large enough to support the anticipated number of sockets that will be used by the system. If your system is IPv6 enabled, Telnet listening sockets are IPv6; set the IPv6 MAXSOCKETS value appropriately.

- If the user ID is permitted to the BPX.SUPERUSER resource or is a superuser ID, Telnet issues setrlimit() on each port to automatically set the maximum number of connections allowed to the maximum allowed by z/OS UNIX System Services, currently 524 287. Each Telnet port will support that number of connections if the system total does not exceed the MAXSOCKETS value.

Perform the following steps to define security for a user ID and to associate it with the procedure name.

1. Use an existing user ID or create a new user ID:
   - Permit a user ID with a nonzero UID value to the BPX.SUPERUSER resource in the FACILITY class:
     a. Add the user to RACF:

        ```
        ADDUSER TN3270E
        ```

     b. Permit the user ID:
        1) Create a BPX.SUPERUSER FACILITY class profile:

           ```
           RDEFINE FACILITY BPX.SUPERUSER
           ```

        2) If this is the first class profile, activate the FACILITY class:

           ```
           SETROPTS CLASSACT(FACILITY)
           SETROPTS RACLIST(FACILITY)
           ```

        3) Permit the user to the class:

           ```
           ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(23) HOME('/'))
           PERMIT BPX.SUPERUSER CLASS(FACILITY) ID(TN3270E) ACCESS(READ)
           ```

           In this example, the user ID is TN3270E and the UID is 23. The UID can be any nonzero number. UID 23 was used to match the well-known Telnet port number.

        4) Refresh the FACILITY class:

           ```
           SETROPTS RACLIST(FACILITY) REFRESH
           ```

     This example uses TN3270E for the user ID, but you can use any name.

     Tip: You can combine the ADDUSER and ALTUSER commands into one command by putting the OMVS parameter on the ADDUSER command line. The ADDUSER and ALTUSER commands are performed separately in case the user ID already exists. Even if the ADDUSER command fails, the ALTUSER command is successful.
   - Define a user ID with a nonzero UID value and do not permit it to the BPX.SUPERUSER resource. You will see message `EZZ6049I tnproc NON-ZERO OMVS UID IN EFFECT`, indicating that you associated Telnet to a user ID that does not have superuser authority. The number of connections allowed on a single port will be the MAXFILEPROC value. The number of connections can be overridden on the ALTUSER command with the FILEPROCMAX option. For example, you can allow 150 000 connections using the following command:

     ```
     ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(23) FILEPROCMAX(150000) HOME('/'))
     ```

     If connection failures occur (`EZZ6012I tnproc BPX1AIO ACCEPT FAILED, RC = 0000007C RSN = 050B0146`) followed by a port quiesce (`EZZ6003I tnproc QUIESCED ON PORT 23`), the MAXFILEPROC value has been reached.

     Tip: If your MAXFILEPROC value is less than your expected number of Telnet connections on a single port, you should use superuser authority or the FILEPROCMAX option on the RACF ALTUSER command. The FILEPROCMAX value will override the MAXFILEPROC value for processes associated with the user ID. If you do not use the FILEPROCMAX option and you do not give the associated user ID superuser authority by

permitting the user ID to the BPX.SUPERUSER resource, Telnet is not able to increase the MAXFILEPROC value on the listener socket and will support the number of connections specified by the MAXFILEPROC value instead of the OMVS maximum.

- Use an existing superuser ID to associate with the job name.
- Define a superuser ID to associate with the job name.

  To define a superuser ID, add a user ID to RACF and alter it to superuser status:

  ```
  ADDUSER TN3270E
  ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
  ```

  Sample statements for defining a superuser ID are in SEZAINST(EZARACF). For more information, see *z/OS UNIX System Services Planning*, *z/OS Security Server RACF Security Administrator's Guide*, and *z/OS Security Server RACF Command Language Reference*.

2. Add the procedure name to the RACF STARTED class and associate the user ID from step 1 with the name.

   For example, code the following:

   ```
   RDEFINE STARTED TELNET*.*  STDATA(USER(TN3270E))
   SETROPTS RACLIST(STARTED) REFRESH
   ```

   Sample statements for adding the procedure to the STARTED class are in SEZAINST(EZARACF). For more information, see *z/OS UNIX System Services Planning*, *z/OS Security Server RACF Security Administrator's Guide*, and *z/OS Security Server RACF Command Language Reference*.

3. If you are using secure Telnet connections, make sure that the user ID that runs Telnet has access to the SSL key ring and certificates.

   Do one of the following:

   - Create a new key ring and certificate that is owned by the user ID that runs Telnet.
   - Share the existing key ring and certificates with Telnet. For more information about implementation scenarios, see *z/OS Security Server RACF Security Administrator's Guide*.

4. If you are using hardware encryption, ensure that the Telnet user ID has read access to the RACF CSFSERV class resources. For details, see "Encryption algorithms" on page 1464.

You know you are done when you can start Telnet without receiving errors.

If your job ends abnormally with system completion code EC6 and a register 15 value of 0F01C008, you did not associate a valid user ID with the started job name.

Steps for customizing the VTAM configuration data set for Telnet

Telnet uses application LUs that are defined in VTAM application (APPL) major nodes to represent clients. You can code these definitions in the data set members of your choice. You must include the data set that contains your member updates in the list of data sets that is specified on the VTAMLST DD statement in the procedure that is used to start VTAM. Including this data set in the list ensures that the LUs are available for activation after VTAM is started.

Perform the following steps to customize the VTAM configuration data set:

1. Automatically activate the application definition deck by including it in ATCCONxx.

2. Define the LUs in a VTAM data set member.

   A sample VTAM configuration data set is in SEZAINST(IVPLU).

   Tip: In the VTAM configuration data set, you can define Telnet LUs that represent either terminal or printer emulators with a wildcard character instead of coding individual Telnet application LU statements. The Model Application Names function enables you to code a model APPL name with an asterisk (*) or a question mark (?) (see *z/OS Communications Server: SNA Resource Definition Reference* for more information). Use * as a wildcard character to replace a character string. For example, if you need Telnet LUs in the range TCPABC01 - TCPABC99, then you can add a single VTAM application definition statement to the sample configuration data set. The definition statement has the Telnet application minor node (Telnet LU) name TCPABC*, which supports all 99 LUs.

3. Use the default value YES for the SESSLIM parameter.

   Telnet server LUs do not support multiple concurrent sessions.

4. Code LOSTERM=IMMED on all target (PLU) applications that will have a SNA session with Telnet.

   If you do not code this value, CLOSEACB might stop while it is waiting for UNBIND RESPONSE if the target (PLU) application does not issue CLSDST when the LOSTERM exit is processed.

5. Code EAS=1 to minimize Common Service Area (CSA) storage use.

   If you use the default value for EAS, excessive CSA storage will be used.

6. Use the default VTAM value NO for PARSESS.

   You should not use parallel sessions with Telnet LUs.

When you are done, start VTAM. Put the LUs in a connectable state by activating the APPL major node that represents the Telnet LUs. Issue the D NET,MAJNODES command or the D NET,ID=*appl_major_node_name* command to verify that your APPL major node is active.

The TN3270E Telnet server configuration data set

Telnet configuration statements are processed during the initialization of the TN3270E Telnet server or when you issue the VARY TCPIP,*tnproc*,OBEYFILE command to update the Telnet configuration data set. (For information about using the VARY TCPIP,*tnproc*,OBEYFILE command to update the Telnet configuration data set, see "Using the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration" on page 559). The Telnet configuration statements do the following:

- Define Telnet server characteristics
- Define connection characteristics
- Define LU names to represent Telnet clients
- Facilitate session setup with MVS host VTAM applications

Requirement: When configuration data sets are processed, the TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify.

You use the following statement blocks to configure Telnet:

TELNETGLOBALS and ENDTELNETGLOBALS
: An *optional* statement block that contains Telnet parameter statements. The parameters define connection characteristics for all ports.

TELNETPARMS and ENDTELNETPARMS

A *required* statement block that contains Telnet parameter statements. You must create a unique TELNETPARMS block for each port and for each qualified port. The parameters define connection characteristics for the specified port. A TELNETPARMS block is required for each port that you start or modify using the VARY TCPIP,*tnproc*,OBEYFILE command.

BEGINVTAM and ENDVTAM

A *required* statement block that contains Telnet mapping statements. The mapping statements define how applications and LU names are mapped (assigned) to clients. Each port that you start or modify using the VARY TCPIP,*tnproc*,OBEYFILE command must have a BEGINVTAM block. You can use one BEGINVTAM block for all ports, you can use one BEGINVTAM block for some of your ports and another BEGINVTAM block for the remaining ports, or you can use a unique BEGINVTAM block for each of your ports.

PARMSGROUP and ENDPARMSGROUP

An *optional* parameter group statement in the BEGINVTAM block that contains Telnet parameter statements. The parameters define connection characteristics for the mapped clients.

See *z/OS Communications Server: IP Configuration Reference* for the exact syntax rules for these statement blocks. See "Using the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration" on page 559 for information about profile processing.

Telnet initially sets all connection parameters to default values. These connection parameter values are arranged hierarchically, as shown in Figure 62.

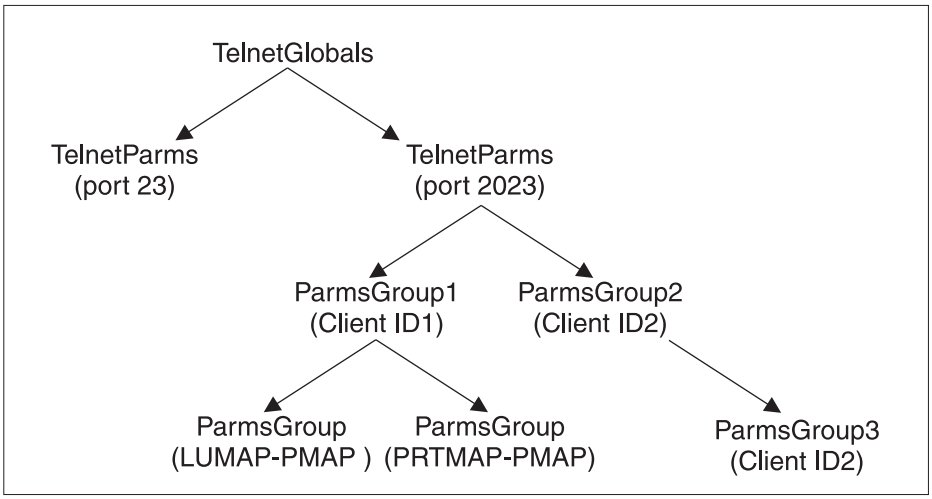

Figure 62. Telnet parameter placement

You can change these parameter values at any of the levels in the hierarchy, depending on how you want the changes to be applied to successive connection levels. Parameters that you code in the TELNETGLOBALS block are applied to all connections on all ports, unless these values are overridden by parameters in either the TELNETPARMS block or the PARMSGROUP block. Parameters that you code in the TELNETPARMS block are applied to all connections on the specified port, unless these values are overridden by parameters in the PARMSGROUP block. Parameters that you code in the PARMSGROUP block are applied to connections

with clients that are mapped to that PARMSGROUP block. For a complete list of Telnet parameters, see *z/OS Communications Server: IP Configuration Reference*.

Eleven mapping statements are available in the BEGINVTAM block. These mapping statements map objects to client identifiers that are specified on the port. Five statements are related to application setup, four are related to LU name assignment, one maps connection parameters, and one maps monitoring rules. After a connection request is accepted, Telnet uses the mapping statements to map, or assign, as many of the eleven objects to the client as possible. This set of objects is used for the duration of the connection. For more information, see "Mapping Objects to Client Identifiers" on page 595.

The sample profile in SEZAINST(TNPROF) contains additional statements that are included as comments. These statements provide examples of advanced functions. Many of these statements are installation-specific; you need to modify these statements to suit your installation.

Steps for customizing the TN3270E Telnet server configuration data set

Before you begin: You need to create the data set in which you will put the configuration information. You must also specify the profile data set name on the PROFILE DD statement in the procedure JCL that is used to start Telnet. The data set must be defined with format fixed block, and must have a record length of 56 - 256. The block size must be evenly divisible by the record length.

If you are using multiple TN3270E Telnet servers, ensure that each server uses unique LU names, or define shared LU name groups. If you do not use unique LU names or create shared LU name groups, then the second server that uses the same LU name will not be able to establish a session; either the OPEN ACB request will fail or the cross-domain session request will fail.

For information about updating Telnet configuration, see "Using the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration" on page 559.

Perform the following steps to customize the TN3270E Telnet server configuration data set. A sample configuration is in SEZAINST(EZBTNPRF).

1. Define Telnet server characteristics.

   The minimum required definition is the TELNETPARMS block with the PORT statement. The following functions are optional:

   - To associate Telnet with one TCP/IP stack, see "Associating Telnet with one TCP/IP stack" on page 567.
   - To set up Telnet in a sysplex to share LU names, see "Shared LU name groups for Telnet servers" on page 568.
   - To qualify a port with the destination IP address or link name to differentiate between Telnet services, see "Qualified ports" on page 572.
   - To use multiple Telnet ports, see "Multiple ports" on page 574.
   - To reduce ECSA storage use when supporting a large number of connections, see "Reducing demand for ECSA storage" on page 649.

2. Define connection characteristics at the server or port level.

   - To determine the connection type, see "Connection mode choices" on page 575.
   - For security, see "Connection security" on page 581.
   - For persistence, see "Connection persistence" on page 592.

3. Understand the concept of mapping Objects to Client Identifiers.

   To understand the concept of mapping Objects to Client Identifiers, see "Mapping Objects to Client Identifiers" on page 595.

4. After you identify all the clients in your network, determine which clients have unique characteristics (for example, a particular client should use a certain LU name) and need to remain exact Client Identifiers, and which clients can be combined into Client Identifier groups using wildcard values.

5. Use LU name mapping statements to assign LU names to connections based on the Client Identifier. This step is required. See "LU name mapping statements" on page 606.

6. Use application mapping statements to facilitate session setup based on the Client Identifier. See "Application mapping statements" on page 610.

7. Use the connection parameters mapping statement to change connection parameters based on specific Client Identifiers. To extend connection mode, security, and persistence choices to Client Identifiers, see "Connection parameters mapping statement" on page 613.

8. Consider advanced topic features for additional Telnet functions.
   - "Advanced LU name mapping topics" on page 613
   - "Advanced application topics" on page 625
   - "Device types and logmode considerations" on page 636
   - "Using the Telnet Solicitor or USS logon panel" on page 637
   - "SMF" on page 642
   - "Connection monitoring mapping statement" on page 642

You know you are done when you do not receive errors after you apply the profile.

Telnet CTRACE

Telnet uses the TCP/IP stack component name SYSTCPIP. Telnet CTRACE with only the Telnet option specified provides complete information about Telnet processes. You do not need other CTRACE options for debugging most Telnet problems.

A sample Telnet component trace is supplied. The member name is CTIEZBTN in SYS1.PARMLIB. You set up tracing for Telnet in the same way that you set up tracing for the TCP/IP stack; however, there are fewer trace options needed for Telnet. You can change the component trace in the JCL by specifying a new parmlib member in the form CTIEZB*xx*. For a complete description of the trace options and for information about how to set up tracing, see the TCP/IP services traces and IPCS support information in *z/OS Communications Server: IP Diagnosis Guide*.

The following subset of trace options is available in the SYSTCPIP component when it is set up for Telnet:

- ALL (excludes SERIAL, STORAGE, and TIMER)
- INIT (includes OPCMDS and OPMSGS)
- MESSAGE
- MIN or MINIMUM (includes INIT, OPCMDS, and OPMSGS)
- MISC
- NONE (or OFF)

- OPCMDS (includes INIT and OPMSGS)
- OPMSGS (includes INIT and OPCMDS)
- SERIAL
- STORAGE
- TELNET
- TIMER
- WORKUNIT

Managing Telnet

This topic describes information needed to manage Telnet, such as command and port information.

Telnet commands

Telnet commands are TCP/IP commands. You must specify the procedure name on all commands; otherwise, the command is processed by the default TCP/IP stack instead of by the Telnet procedure. For example, assuming that the Telnet procedure name is TN3270E, the profile display command is as follows:

```
D TCPIP,TN3270E,PROFILE
```

If the procedure does not exist or if you incorrectly type the TCPIP keyword, then the command is assumed to be a TCP/IP command and a TCP/IP error message is displayed.

You use the following VARY and DISPLAY commands to change and monitor Telnet functions and to debug problems. Telnet VARY and DISPLAY commands are described in *z/OS Communications Server: IP System Administrator's Commands*.

- Use Telnet VARY commands to change the state of Telnet ports, enable or disable the use of certain Telnet LU names, and manage diagnostic tools.
  - VARY TCPIP,*tnproc*,QUIESCE,PORT blocks any new connection requests but allows existing connections to continue activity.
  - VARY TCPIP,*tnproc*,RESUME,PORT ends the quiesce state and allows new connection requests.
  - VARY TCPIP,*tnproc*,STOP,PORT ends connections on the port and closes the port.
  - VARY TCPIP,*tnproc*,OBEYFILE starts, restarts, or changes a port by updating the Telnet profile. Use the VARY TCPIP,*tnproc*,STOP and VARY TCPIP,*tnproc*,OBEYFILE commands to stop a Telnet port and then restart that port or start a new port without stopping the TCP/IP stack. You can also use these commands to increase the level of participation in the Telnet XCF group. A Telnet server that has joined the group becomes a standby LUNS, even if you used an OBEYFILE command to specify it to be a primary LUNS.

    Tip: When you issue a VARY TCPIP,*tnproc*,OBEYFILE command, the TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify.
  - VARY TCPIP,*tnproc*,ACT,*luname* activates LUs for use by the Telnet server. Specify ALL for *luname* to activate all inactive LUs with one command. This command has no effect on the VTAM state of the LU.
  - VARY TCPIP,*tnproc*,INACT,*luname* inactivates LUs for use by the Telnet server. If an LU is already in use, the command fails. This command has no effect on the VTAM state of the LU.
  - VARY TCPIP,*tnproc*,DEBUG,OFF turns off all debug activity that might have been turned on to debug a problem.

  - VARY TCPIP,*tnproc*,ABENDTRAP sets an abend trap based on unique Telnet return codes set in Telnet modules.
- Use Telnet VARY commands to change the state of a LUNS, and to enable or disable the use of certain LU names by a LUNS.
  - VARY TCPIP,*tnproc*,LUNS,START starts the takeover process by which a standby LUNS becomes the active LUNS.
  - VARY TCPIP,*tnproc*,LUNS,QUIESCE instructs a standby LUNS to stop monitoring the active LUNS. In case of a LUNS failure, this Telnet server will not be a takeover candidate. The Telnet server must be a takeover candidate for you to make changes to the LUNS using the OBEYFILE command.
  - VARY TCPIP,*tnproc*,LUNS,RESUME ends the quiesce state and instructs a LUNS to resume monitoring the active LUNS. In case of a LUNS failure, this Telnet will be a takeover candidate.
  - VARY TCPIP,*tnproc*,LUNS,ACT,*luname* activates LUs for use by the LUNS. Specify ALL for *luname* to activate all inactive LUs with one command. This command has no effect on the VTAM state of the LU.
  - VARY TCPIP,*tnproc*,LUNS,INACT,*luname* inactivates LUs for use by the LUNS. If an LU is already in use, the command fails. This command has no effect on the VTAM state of the LU.
- Use Telnet DISPLAY commands to review classic Telnet information.
  - D TCPIP,*tnproc*,PROFile displays summary or detail information about parameter statements from the TELNETGLOBALS or TELNETPARMS blocks.
  - D TCPIP,*tnproc*,OBJect displays summary or detail information about mapping statements from the Object perspective.
  - D TCPIP,*tnproc*,CLientID displays summary or detail information about mapping statements from the Client Identifier perspective.
  - D TCPIP,*tnproc*,CONN displays summary or detail information about client connections.
  - D TCPIP,*tnproc*,INACTLUS displays all LUs that have been inactivated by the operator or by Telnet as a result of OPEN ACB or multilevel security problems.
  - D TCPIP,*tnproc*,STOR displays the maintenance level of a module or the amount of storage used by Telnet.
- Use Telnet DISPLAY commands to review information about Telnet in an XCF group.
  - D TCPIP,*tnproc*,XCF<,GRoup> displays the status of all members of the Telnet XCF group.
  - D TCPIP,*tnproc*,XCF,STats displays the performance status of the XCF Telnet server. If the Telnet server is a LUNS, the performance statistics between it and all LUNRs are reported.
- Use Telnet DISPLAY commands to review information about Telnet performing as a LUNS.
  - D TCPIP,*tnproc*,LUNS,OBJect displays summary or detail information about shared LUNR Objects on the LUNS.
  - D TCPIP,*tnproc*,LUNS,INACTLUS displays all the LUs that are inactive on the LUNS.

Using the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration

When you use the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration, new profile statements create a new configuration that is used by all

connections that are accepted after you updated the file. Existing connections continue to use the configuration that was in effect when those connections were accepted. The TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify. The new configuration that you create is *not* a cumulative update from the previous profile. If you need to make only one change in the new profile, change the old profile or copy the profile to another data set member and make the change.

After you have updated the Telnet configuration file and the VARY TCPIP,*tnproc*,OBEYFILE command processing completes, the new profile is labeled as the current profile, and the replaced profile becomes profile 0001. If you make another update, the new update becomes the current profile and the replaced profile becomes profile 0002. If you updated the profile for a subset of the active ports, the ports that you did not update remain unchanged. You can suppress profile debug messages by coding DEBUG OFF or DEBUG SUMMARY in the TELNETGLOBALS block and then placing the TELNETGLOBALS block in front of all other Telnet statement blocks.

New connections are associated with the current profile and use the mappings and parameters that are defined by that profile for the life of the connection. Even if you issue a VARY TCPIP,*tnproc*,OBEYFILE command to update the port, existing connections remain associated with the same profile. The statements of profiles that are not the current profile remain in effect and continue to support all connections that were established when that profile was the current profile. When all connections that are associated with a non-current profile have ended, the storage for the non-current profile mapping rules is freed and the profile is considered inactive.

The structural layout of the profiles and how connections are associated with profiles are shown in Figure 63 on page 561.

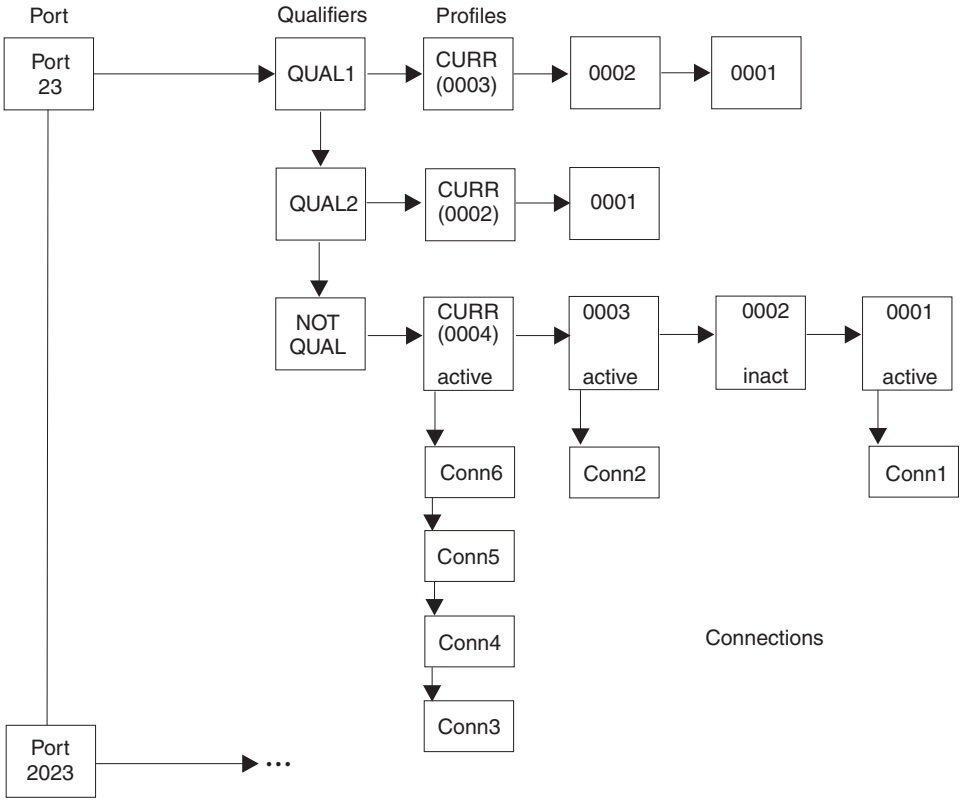

Figure 63. Telnet profiles and connections

OMVS shutdown

The TN3270E Telnet server application uses UNIX System Services; when OMVS is shut down, Telnet services are no longer available. To prevent Telnet from abnormally ending, Telnet is automatically stopped prior to OMVS shutdown, and can be restarted after OMVS is restarted.

Telnet automatically registers with OMVS; because of this registration, OMVS notifies Telnet when OMVS shutdown is requested, and OMVS waits for Telnet to stop. When Telnet is notified of the OMVS shutdown, it immediately begins to stop, as if the MVS STOP command had been issued. Once Telnet is stopped, OMVS shutdown is no longer blocked by the Telnet server.

If you plan to shut down OMVS, be sure your Telnet users are logged off before you shut down OMVS.

Telnet diagnostic tools

In addition to general diagnostic tools such as CTRACE and dumps which are described in *z/OS Communications Server: IP Diagnosis Guide*, there are several Telnet-specific diagnostic tools available.

DEBUG messages

Telnet-specific debug messages can be turned on or off to diagnose Telnet problems related to client connections, Telnet tasks, or configuration processing. Several types of debug messages are available.

- Exception messages indicate that a problem was detected and are issued for connection, task, and configuration processing. Exception level debug is the default level.
- Summary messages indicate important status changes and are available for connection processing.
- Detail messages are issued when an important event occurs other than an error and are available for connection and task processing.
- Trace messages show detail data that is coming into and out of Telnet and are available for connection and configuration processing.

Message generation is controlled with the DEBUG statement. For information about the DEBUG statement, see *z/OS Communications Server: IP Configuration Reference*.

Connection processing debug options are as follows:

- Exception

  The DEBUG CONN EXCEPTION statement issues a message at the time of failure that displays the client IP address and port, connection ID, Telnet LU name, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message EZZ6035I return code details, see *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*.

  The DEBUG CONN EXCEPTION statement causes the CONN DROP message to be issued only for error conditions and inactivity reasons. DEBUG CONN EXCEPTION is the default. If more than one connection is dropped for the same reason within 15 seconds, a single message with LU name MULTIPLE will be issued. For example, if MSG07 is not coded in the DEBUG CONN DETAIL example, the connection will be dropped after the lookup failure. The CONN DROP message will include the return code and indicate that an error caused the connection drop. The following message will be produced whether or not DEBUG was coded because of the error condition.

```
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 CONN DROP  ERR 3012
  IP..PORT: 1.12.13.14..456          EZBTPGLU
```

- Summary

  The DEBUG CONN SUMMARY statement provides tracking for the status of a connection. A summary message is written when:

  – A connection request is accepted by Telnet.
  – Connection negotiation is complete.
  – A session is established with the host application.
  – A session is dropped.
  – A connection is dropped.

  LU name, Connection ID, and client IP address and port are included in each message. In the example below an end user connects to port 23. The connection is negotiated as a TN3270E connection and a session with TSO is established. The session is dropped because of client disconnect (CLNTDISC) and then the connection is dropped because of client disconnect.

```
EZZ6034I TNSERV11 CONN 00000011 LU **N/A**  ACCEPTED      23
  IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 NEGOTIATED TN3270E
  IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 IN SESSION TSO0001
  IP..PORT: 1.12.13.14..456
```

```
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 SESS DROP  CLNTDISC
  IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 CONN DROP  CLNTDISC
  IP..PORT: 1.12.13.14..456
```

In addition to tracking major state changes and providing key information, the statements can be used for diagnostic purposes. For example, an end user might be attempting a connection and something is not working. The ACCEPTED, NEGOTIATED, and IN SESSION messages are major connection milestones. Using the information provided and knowing whether or not these messages are displayed can provide many clues about the connection request. The SESS DROP and CONN DROP messages give a variety of reasons about why the drop occurred.

- Detail

  You can use the DEBUG CONN DETAIL statement if the DEBUG CONN SUMMARY messages do not provide enough information to solve a problem. In addition to the summary messages, the DEBUG CONN DETAIL statement issues a message at the time of failure that displays the client IP address and port, connection ID, Telnet LU name, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to the system administrator and others will be helpful to IBM service. For message EZZ6035I return code details, see *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*.

  In the example below the end user specified an application not in the Telnet profile and then disconnected at the client emulator.

```
EZZ6035I TNSERV11 DEBUG DETAIL CONN DETAIL
  IP..PORT: 1.12.13.14..456
  CONN: 00000011  LU: TCPM1001  MOD: EZBTPGLU
  RCODE: 3012-00  Application name is invalid.
  PARM1: 00000000 PARM2: 00000000 PARM3: 00000000

EZZ6035I TNSERV11 DEBUG DETAIL CONN DETAIL
  IP..PORT: 1.12.13.14..456
  CONN: 00000011  LU: TCPM1001  MOD: EZBTTRCV
  RCODE: 1001-02  Client disconnected from the connection.
  PARM1: FFFFFFFF PARM2: 00000461 PARM3: 00000000
```

- Trace

  The DEBUG CONN TRACE statement generates messages that contain data that was sent to and from the client, sent to and from VTAM, and sent to and from an LU name exit for a single connection. The TRACE option allows you to quickly see why a client is not connecting or why a session hangs. Be careful where you specify DEBUG CONN TRACE. Every connection that maps to the statement generates many messages. DEBUG CONN TRACE should be specified in a PARMSGROUP block that is mapped to only a few connections. Even when DEBUG CONN TRACE is specified in a PARMSGROUP block, it could flood the message console quickly if the connection is very active.

```
EZZ6034I TNSERV11 CONN 00000080 LU **N/A** ACCEPTED
  IP..PORT: 9.14.6.42..36484

```

Task processing debug options are as follows:

- Exception

  The DEBUG TASK EXCEPTION statement issues a message at the time of a failure that displays the task, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message EZZ6035I return code details, see *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*. DEBUG TASK EXCEPTION is the default for task processing debug.

  The following exception message indicates that Telnet failed to join the XCF group because the group already contains the maximum number of members allowed.

```
EZZ6035I TLUNR1   DEBUG TASK   EXCEPTION
TASK: XCF                     MOD: EZBTXXCF
RCODE: A006-01  Telnet failed to join the XCF group.
PARM1: 0000000C PARM2: 00000004 PARM3: MAX GROUPS OR MEMBERS
```

- Detail

  The DEBUG TASK DETAIL statement issues a diagnostic message at certain event points that displays the task, detecting module name, unique return code and brief explanation, and additional parameters if relevant. The Detail option shows event milestones for different scenarios, enabling you to see some events of interest other than errors. Some messages will be helpful to the system administrator and others will be helpful to IBM service. For message EZZ6035I return code details, see *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*.

  The following detail message indicates that an outstanding receive failed for job TLUNR1 on MVS023.

```
EZZ6035I TLUNR1   DEBUG TASK   DETAIL
TASK: XCFRECV                MOD: EZBTXRCV
RCODE: A014-01  LUNS/LUNR receive failed.
PARM1: 00000000 PARM2: 00000000 PARM3: MVS023   TLUNR1
```

Configuration processing debug options are as follows:

- Exception

  The DEBUG CONFIG EXCEPTION statement issues a message at the time of a failure that displays the line number, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message EZZ6035I return code details, see *z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)*. DEBUG CONFIG EXCEPTION is the default for configuration processing debug.

  The following message indicates that the value for scaninterval on line 35 is outside of the acceptable range.

```
EZZ6035I TLUNS1   DEBUG CONFIG EXCEPTION
LINE:       35              MOD: EZBTMPRP
RCODE: 805B-00  Value outside acceptable range for statement.
PARM1:          PARM2: SCANINTE PARM3:
```

- Trace

  The DEBUG CONFIG TRACE statement generates a statement message listing all words associated with the statement and a formatted control block message for each Telnet statement. This option can flood the message console if you have a very large configuration file. The CONFIG messages can be limited to a

smaller, specified set of statements. If you specify a subset of statements, DEBUG CONFIG messages are issued only from those statements. If a large amount of CONFIG data is required, you can suppress the DEBUG messages by specifying the CTRACE option on the DEBUG statement. With the CTRACE option, the messages will be in the CTRACE but will not flood the console or joblog. CTRACE is the default option.

The sample below shows data sent to the console for profile statement LUGROUP:

```
DEBUG CONFIG TRACE,LUGROUP CONSOLE

EZZ6035I TNSERV11 DEBUG CONFIG TRACE
  LINE:       82              MOD: EZBTMPRF
    LUGRP1 TCPM1094 TCPM1102
  PARM1: 00000003 PARM2: 00000052 PARM3: LUGROUP

EZZ6035I TNSERV11 TNSERV11 DEBUG CONFIG TRACE
  LINE:       82              MOD: EZBTMPRF
         E3C5D3C3 00000000 00000058 00005502 |TELC............|
         00000036 00000000 00000052 00000000 |................|
         00000000 00000000 00000000 00000000 |................|
         D3E4C7D9 D7F14040 00000000 00000000 |LUGRP1  ........|

         E3C3D7D4 F1F1F0F2                   |TCPM1102        |
  PARM1: 00000058 PARM2: 00000036 PARM3: LUGROUP
```

The DEBUG OFF statement ensures that all debug messages are suppressed, including the exception CONN DROP messages.

The DEBUG CONN parameter can cause flooding of the operator's console. Console flooding concerns can be dealt with in several ways.

- Most DEBUG messages are, by default, assigned to routing code 11, the JOBLOG. The DEBUG option JOBLOG can be used for the same effect. However, the master console also receives routing code 11 messages by default. To stop the messages from going to the master console, issue VARY CN(01),DROUT=(11), which drops routing code 11 from the console. Another DEBUG option, CONSOLE, will direct the messages to the master console, routing code 2, and the teleprocessing console, routing code 8. The CTRACE option suppresses messages completely while continuing tracing at the debug level.
- If DEBUG messages are being used primarily for problem diagnosis, the VARY TCPIP,*tnproc*,OBEYFILE command can be used to keep the number of messages low. Bring up Telnet initially without DEBUG coded. When a problem appears, issue a VARY TCPIP,*tnproc*,OBEYFILE command for a Telnet profile that includes the DEBUG statement. Only new connections to the new profile will produce messages. Once data is obtained, issue another VARY TCPIP,*tnproc*,OBEYFILE command for a Telnet profile that omits the DEBUG statement.
- If the Client Identifier of the client having the problem is known, include DEBUG in a PARMSGROUP statement. Using PARMSMAP, map that group to the client. Debug messages for only that client will be issued.

The VARY TCPIP,*tnproc*,TELNET,DEBUG,OFF command can be issued to turn off DEBUG for all connections associated with all profiles, including the current profile. It will also turn off TASK and CONFIG DEBUG messages. To turn on DEBUG again, issue a VARY TCPIP,*tnproc*,OBEYFILE command with the Debug option specified in the Telnet profile. Summary messages for CONN DROP due to errors or time-outs will also be suppressed. Use DEBUG EXCEPTION to retain these messages.

MSG07

The MSG07 parameter is very helpful when diagnosing problems. It allows Telnet to send a message to the client indicating an error occurred and what the error was. Something simple like a mistyped application name can be corrected by the end user without additional help. Even for more difficult problems, MSG07 provides a good starting point. It is recommended that MSG07 always be coded unless there are reasons not to send error messages to the client.

Abend trap

The VARY TCPIP,*tnproc*,TELNET,ABENDTRAP,*module,rcode,instance* command can be used to set up an abend based on the variables specified. Abendtrap has three variables:

module Is required. It is the module detecting the error. It can have a wildcard value by using asterisk (*) at the end. If a single * is used, any module reporting the specified return code will cause an abend. The module name "OFF" turns off an active trap.

rcode Is optional. It is the return code reported and cannot have a wildcard value.

instance Is optional. It is the instance of the return code and cannot have a wildcard value.

Below is an example setting the abend trap and then issuing a profile display to verify the trap is set. In the example, when EZBTTRCV reports an error code of 1001, Telnet will issue an abend with reason code '3133'x. The state of the trap changes from "ACTIVE" to "TRIPPED". No more abends will be issued. Once tripped, the abendtrap command must be issued again to activate the trap. While the trap is active, the abend trap can be turned off by specifying "OFF" as the module name. An active trap cannot be changed directly. The current trap must be tripped or turned off before a new command is accepted.

```
V TCPIP,TCPCS6,T,ABENDTRAP,EZBTTRCV,1001

```

TESTMODE

The TESTMODE parameter in TELNETPARMS allows a profile to be processed by Telnet but then dropped before it becomes an active profile. Using TESTMODE ensures that LU assignments, security levels, and other Telnet parameters are not compromised due to profile syntax errors.

Displays

Use the DISPLAY commands to verify that the configuration is what you thought it was, that connections are mapping to the correct parameters and Objects, and to check XCF Telnet LUNS and LUNR status and performance. For details about the commands available, see “Managing Telnet” on page 558 and *z/OS Communications Server: IP System Administrator's Commands*.

Tracing

If you cannot resolve a problem using the available tools, IBM service will likely need a CTRACE with option Telnet. For details, see "Telnet CTRACE" on page 557. You might also need to activate one of the following additional traces:

- Full data trace

  If the problem is data related, use the FULLDATATRACE statement to trace all the data coming into and leaving Telnet rather than tracing only the first 64 bytes of data. FULLDATATRACE will cause a trace-wrap condition more quickly so it should be set only if needed. It should be set in PARMSGROUP instead of TELNETPARMS if a subset of clients can be identified.

- Telnet subagent trace

  For Telnet SNMP subagent problems, use the TNSATRACE keyword on the TNSACONFIG statement in PROFILE.TCPIP at startup. This will generate trace points throughout Telnet subagent processing, in addition to tracing data passed between the Telnet subagent, Telnet, and the TCP/IP stack. Subagent tracing can also be enabled after Telnet has been started by using the VARY TCPIP,*tnproc*,OBEYFILE command. To enable tracing using the VARY TCPIP,*tnproc*,OBEYFILE command, the subagent must first be disabled and then re-enabled with the TNSATRACE keyword. Trace data is written to the syslog daemon. Subagent tracing can be disabled using the NOTNSATRACE keyword.

- DBCS trace

  If the problem is with a DBCS connection, use the DBCSTRACE statement in the TELNETPARMS block or in the PARMSGROUP block to produce DBCS-specific trace entries in the SYSPRINT and TNDBCSER data sets.

Telnet configuration data set customization details

This topic includes details for "Steps for customizing the TN3270E Telnet server configuration data set" on page 556.

Associating Telnet with one TCP/IP stack

In an INET environment where only a single TCP/IP stack can be running, Telnet client connections are automatically associated with the active stack, and you do not need to explicitly associate the Telnet server to the stack.

In a common INET (CINET) environment, Telnet is associated with all stacks that are running. When multiple stacks are supporting a single Telnet server, Netstat displays might not display all Telnet connections. The only connections that are displayed are connections that are supported by the stack from which the command is issued. If another stack is started while Telnet is active, the current LISTEN for the port is cancelled and is reissued automatically to include the new stack. If you explicitly associate Telnet to one TCP/IP stack, all Telnet clients must connect through that stack.

If you want to explicitly associate Telnet with one stack for control purposes or for functionality support, use the TCPIPJOBNAME statement in the TELNETGLOBALS block when you start Telnet. If you use the TCPIPJOBNAME statement, you must continue to use it on all future profile updates to set affinity to the same stack.

The Telnet SNMP subagent requires that you explicitly associate Telnet with a single TCP/IP stack. Telnet SNMP subagent activation requires that you register the stack name with the agent. If you do not specify the TCPIPJOBNAME statement, then Telnet blocks the subagent activation request. The Telnet SNMP subagent can register with only one agent, and each agent can support only one

Telnet subagent. If you are going to use the Telnet SNMP subagent, plan for one agent per Telnet subagent. If multiple Telnet SNMP subagents initialize to the same agent, the agent forwards all data requests to the first subagent that connected, and all other initialization attempts are queued. If the first subagent ends, then the next subagent in the queue receives all data requests.

Shared LU name groups for Telnet servers

SNA architecture requires every LU in a VTAM network to have a unique name. Multiple Telnet servers create added administrative effort to ensure that LU names are unique among the servers. However, if your environment uses multiple Telnet servers running on a single system or in a sysplex, then you can designate one Telnet server to be the LU name server (LUNS). The LUNS manages LU name assignments from LU groups among the group of Telnet servers, each known as an LU name requester (LUNR).

Shared LU groups are defined at each LUNR and sent to the LUNS. Shared LU group definitions can be the same or different at each LUNR. The LUNS allocates an LU name to a particular LUNR only if that LUNR defined the LU in a shared LU group. The LUNS manages LU names by ensuring that only one LUNR at a time is using a particular LU name. You can use load balancing to distribute Telnet client connections across several LUNR Telnet servers that have identical shared LU name configurations.

A single Telnet server can support both shared and unshared LU groups. Existing unshared LU group definitions continue to be managed at the local Telnet level.

You can configure a Telnet server to be only a LUNS, or a Telnet server can be a LUNS and also function as a regular Telnet server. Running Telnet as only a LUNS in its own address space has the following advantages:

- Telnet port server functions will not compete with the LUNS for resources within the address space.
- You can separate Telnet roles, which makes problem diagnosis easier.
- You can stop and restart the Telnet LUNS without stopping the Telnet ports, and you can stop and restart the Telnet port servers without stopping the Telnet LUNS.
- You can set the Telnet LUNS priority to a different priority than that of Telnet port servers.

Telnet uses XCF local group services to define the set of Telnet servers that participate in a shared LU name management group. You specify the level of participation of a particular Telnet server with shared LU name management by specifying or omitting the XCFGROUP block. For configuration details, see “Steps for defining a LUNS and a LUNR” on page 570.

- Classic Telnet server

  If you do not specify the XCFGROUP block for a server or you specify NOJOIN in the XCFGROUP block, the server does not join the XCFGROUP and cannot participate in shared LU name management.
  - The server does not join an XCF group
  - The server is not included in the Telnet XCF,GROUP display
  - Shared LU group Objects cannot be defined on the server

  This is the default behavior of a Telnet server.
- XCF Telnet server

If you do specify the XCFGROUP block for a server and you specify JOIN in the XCFGROUP block, the server joins the Telnet XCF group and is able to participate in shared LU name management.

- The server is included in the Telnet XCF,GROUP display that can be issued for any XCF Telnet server that is in the same sysplex group
- The health of the Telnet server is monitored by XCF
- The server supports shared LU group Objects
- The server can be an LU name requester (LUNR)

  The LUNR is in standby state; it becomes active when shared LU group Objects are found while processing a profile. If you issue a VARY OBEYFILE command and there is no active profile that has shared LU group Objects, then the LUNR reverts to standby state.

- XCF LUNS Telnet server

  If you specify the XCFGROUP block for a server and include the appropriate statements, you can configure the server to have LUNS capability.

  - The server has all the characteristics of an XCF Telnet server
  - The server is an LU name server (LUNS)

After you have configured the level of participation, you can use the VARY OBEYFILE command to move the Telnet server to a higher level; however, you cannot use the VARY OBEYFILE command to move the server to a lower level.

There can be only one active LUNS in a sysplex; that LUNS manages requests for shared LU names so that the names are used by only one Telnet server at a time. The remaining Telnet servers are LU name requesters (LUNRs) that request LU names from the LUNS. The LUNR Telnet server connects to an administration listener socket that is created by the LUNS Telnet server. This TCP connection transmits all LU name requests and responses; this connection is not used for status signalling between the XCF Telnet servers. XCF services including XCF user state field updates, XCF status monitoring, and XCF group events are used to communicate LUNS and LUNR state changes and health.

You can configure a LUNS as a primary or a backup LUNS. When the Telnet server is started, a primary LUNS checks to determine whether there is already an active LUNS in the XCF group. If there is not, that primary LUNS attempts to become the active LUNS. If there is already an active LUNS, the primary LUNS becomes a standby LUNS. If several Telnet servers that are designated as a primary LUNS are started concurrently, then the race winner becomes the active LUNS and the others become standby. A backup LUNS always becomes a standby LUNS.

When an active LUNS fails, the following sequence of events automatically occurs:

1. All the LU name servers that are in standby mode examine the list of LU name servers that are in standby mode.
2. The standby LUNS that has the highest configured rank, regardless of whether that LUNS was started as a primary or backup LUNS, automatically becomes the active LUNS.

   If several standby LU name servers have the same rank, then all those servers attempt to take over. The race winner becomes the new active LUNS and the others return to standby.

You can initiate manual takeover of a Telnet LUNS at any time. You can direct an operator command to any LUNS that is in standby or joined mode and tell it to start and become the active LUNS. The current LUNS will change to standby mode.

You can define all the Telnet servers in a sysplex that participate in shared LU name management to join the same XCF group. However, if your environment has one or more of the following characteristics, then you should partition the sysplex into Telnet subplexes:

- All Telnet servers in a Telnet XCF group must have IP connectivity to each other. If your sysplex is partitioned into TCP/IP subplexes that do not have connected routes to each other, then you should partition the sysplex into Telnet subplexes along the same TCP/IP boundaries.
- All Telnet servers in a Telnet XCF group should run on VTAMs in the same network. If your sysplex is partitioned into VTAM subplexes and the VTAMs are in different networks, then you should partition the sysplex into Telnet subplexes along the same VTAM network boundaries.
- If you use several Telnet ports, each with a large set of shared LU names that do not overlap, and you load balance these ports across several Telnet servers, you might want to partition the sysplex into Telnet subplexes along the Telnet port boundaries. Subplexes reduce the shared LU name management workload on the LUNS and provide operational independence of the LUNS. All Telnet servers that are DVIPA targets of the same distributed port should be members of the same Telnet subplex.

A static VIPA is the best type of IP address to use for the LUNS administrative listener socket. Dynamic VIPA can work for the LUNS administrative listener, but there are cases in which dynamic VIPA can cause confusion.

- If VIPADEFINE moves the IP address away from the LUNS, LUNRs already connected to the LUNS will continue to be able to send requests and receive replies. However, a new LUNR attempting to connect will be directed to the new TCP/IP stack, and the LUNS will not be there.
- VIPARANGE will work if you can guarantee that each LUNS is supported by a different TCP/IP stack, and that the LUNS is the application that creates the IP address. If not, and the creating application ends, the LUNS socket will be closed. A standby LUNS on the same stack would be a problem. The standby LUNS sets up its listener before the original LUNS finishes cleanup. When the original LUNS finishes, the new LUNS listener socket will be closed.

For information about the XCFGROUP block, see *z/OS Communications Server: IP Configuration Reference*. For information about Telnet LUNS display, XCF display, and LUNS VARY commands, see *z/OS Communications Server: IP System Administrator's Commands*.

Steps for defining a LUNS and a LUNR:

Before you begin: Determine which LU names are going to be shared and determine the setup of the LU groups. If you are running the Telnet server on multiple systems, ensure that all systems can function in a sysplex. The systems must have at least an XCF group connection. You do not need a coupling facility.

Perform the following steps to configure an LU name server (LUNS) or an LU name requester (LUNR):

1. On the XCFGROUP statement block on the TELNETGLOBALS statement block, define the level of participation in the Telnet XCF group and in shared LU name management. Specify the following:
   - Specify the NOJOIN parameter (or do not include the XCFGROUP block) if this Telnet server should not join the Telnet XCF group. If you specify NOJOIN (or omit the XCFGROUP block), the server is not included in the XCF,GROUP display and does not allow the definition of shared LU group objects.
   - Specify the JOIN parameter if this Telnet server should join the Telnet XCF group. JOIN is the default if you code XCFGROUP. If you specify JOIN or it is in effect by default, the server is included in the XCF,GROUP display that is issued by any other XCF Telnet server; the server has LUNR capability and supports shared LU group objects. With additional XCFGROUP statements, the server can have LUNS capability.
2. Determine whether you need to partition your Telnet server sysplex into Telnet subplexes.

   Do one of the following:
   - If you are not partitioning your sysplex into subplexes, do not code the SUBPLEX parameter on the XCFGROUP statement. All Telnet servers in the sysplex that participate in shared LU name management join the default Telnet XCF group EZZTLUNS.
   - If you are partitioning your sysplex, configure the SUBPLEX parameter with a suffix that is 1 - 4 characters in length. The specified suffix is right-justified and overlays the end of the string EZZTLUNS to form a unique subplex string. For example, if the suffix value is 23, Telnet joins XCF group EZZTLU23.
3. Determine the frequency with which you want to monitor the health of the Telnet LUNS and LUNR.

   Use the XCFMONITOR parameter to set the frequency. At the specified time interval, Telnet checks the health of the LUNS, LUNR, and XCF Telnet tasks, and checks the health of the connection between the LUNS and LUNR. If any of these tasks or the connection appear to be unresponsive, message EZZ6099I is issued and the X indicator is set under the PDMON column in the XCFGROUP display. No action is taken by Telnet to correct the issue. A short time value can lead to false indications in a busy system. A long time value might not provide feedback quickly enough so that you can take appropriate action. The default value is a good compromise between these two possibilities.
4. To configure a LUNR, perform the following steps:
   a. Configure the following parameters on the XCFGROUP statement:
      - CONNECTTIMEOUT: You can use this parameter for a LUNR only. Specify the length of time that a LUNR attempts to establish a connection to the LUNS before quiescing its LUNR capabilities. If the CONNECTTIMEOUT time elapses and the LUNR has not been able to connect with the LUNS, then the LUNR drops all connections that are waiting in negotiation for an LU name and quiesces all ports that have shared groups. Dropping connections that are in negotiation state enables the client to retry connecting to Telnet. Quiescing the port alerts a distributor that it should send requests to other working Telnet LUNRs. When the client connection is dropped and the client reconnects to the distributor, the connection is directed to a working LUNR. When the LUNS-LUNR connection is established, the port is automatically

resumed and new client connections are again routed to this LUNR. Setting the CONNECTTIMEOUT time to 0 causes client connections to remain in LU name negotiation until LUNS-LUNR communication is established.

- RECOVERYTIMEOUT: You can use this parameter for a LUNR only. Specify the length of time that the LUNR attempts to establish a connection when the LUNS is in RECOVER state before dropping active client connections that have shared LU names assigned to them. A new LUNS in RECOVER state cannot become active until it has received updates from all LUNRs that have shared LUs that are in use. If a LUNR cannot communicate with the LUNS during recovery time and the LUNR has shared LUs assigned, then the LUNS cannot become active and none of the LUNRs are able to receive LU name assignments. If the LUNR drops all active client connections with shared LUs, then the LUNS is alerted through XCF that the LUNR no longer owns shared LUs, and the LUNS can then become active.

b. Define the shared LU groups for the LUNR.

   Use the SLUGROUP and SPRTGROUP statements to define the shared LUs.

5. To configure a LUNS, specify LUNS on the XCFGROUP statement and configure the following parameters on the LUNS statement:
   - *ipaddr port*: Specify the IP address and port on which the LUNS will listen for its administrative connection to communicate with LUNRs.
   - PRIMARY or BACKUP: Specify whether this Telnet server is a primary LUNS or a backup LUNS.
   - RANK *nnn*: Specify the start rank of this LUNS, relative to others, when this LUNS is in standby mode and the active LUNS fails.

You have configured your Telnet servers correctly when you can issue a D TCPIP,*tnproc*,XCF,GROUP command and see the appropriate LUNS or LUNR status for each server. You should be able to connect a client to the LUNR and at the LUNS you should be able to issue a D TCPIP,*tnproc*,LUNS,OBJ command to verify that an LU was allocated from the LUNS.

Qualified ports

In some cases all clients need to use the same port number, but the Telnet parameters need to be differentiated by destination IP address or destination linkname. The destination IP address can be either an IPv4 or IPv6 IP address.

For example, two TN3270E Telnet servers are going to be merged into one server. Currently, server 1 is bound to IP address 1.1.1.1 and is running with a set of definitions for port 23. Server 2 is bound to IP address 2.2.2.2 and is running with a different set of definitions for port 23. Before the servers are merged into one, end users connect to either 1.1.1.1,port 23 or 2.2.2.2,port 23, depending on which Telnet services the users want. The sample definition statements are:

```
Server 1

 TelnetParms
  Port 23
  Inactive 600      ; Drop after 10 minutes of no activity
 EndTelnetParms

 BeginVTAM
  Port 23
  DefaultLus TCPABC01..TCPABC49 EndDefaultLus
```

```
 DefaultAppl TSO
EndVTAM

Server 2

 TelnetParms
  Port 23
  Inactive 0        ; Never drop
 EndTelnetParms

 BeginVTAM
  Port 23
  DefaultLus TCPABC50..TCPABC99 EndDefaultLus
  DefaultAppl CICS
 EndVTAM
```

After the servers are merged, both home addresses are supported by a single server. One way to keep the Telnet definitions separate is to change the port number in one of the definition sets. For instance, the port 23 definitions associated with the old server 2 could be changed to be port 2023. The end result is one TN3270E Telnet server with port 23 and port 2023, where port 23 has the definitions used in the old server 1 and port 2023 has the definitions used in the old server 2. The definitions are still separate. However, all the end users who were connecting to 2.2.2.2 port 23 now have to change their clients to port 2023. The sample definition statements are changed as follows:

```
Merged Server

 TelnetParms
  Port 23
  Inactive 600      ; Drop after 10 minutes of no activity
 EndTelnetParms

 BeginVTAM
  Port 23
  DefaultLus TCPABC01..TCPABC49 EndDefaultLus
  DefaultAppl TSO
 EndVTAM

 TelnetParms
  Port 2023
  Inactive 0        ; Never drop
 EndTelnetParms

 BeginVTAM
  Port 2023
  DefaultLus TCPABC50..TCPABC99 EndDefaultLus
  DefaultAppl CICS
 EndVTAM
```

With port qualification, the system administrator can qualify the port number with the destination IP address or linkname to keep the Telnet services separate. In this case, the destination IP address is used. The qualified port allows the users of either old stack to connect without making any changes to their client. The sample definition statements would be changed to:

```
Merged Server

 TelnetParms
  Port 23,1.1.1.1
  Inactive 600      ; Drop after 10 minutes of no activity
 EndTelnetParms

 BeginVTAM
  Port 23,1.1.1.1
```

```
 DefaultLus TCPABC01..TCPABC49 EndDefaultLus
 DefaultAppl TSO
EndVTAM

TelnetParms
 Port 23,2.2.2.2
 Inactive 0        ; Never drop
EndTelnetParms

BeginVTAM
 Port 23,2.2.2.2
 DefaultLus TCPABC50..TCPABC99 EndDefaultLus
 DefaultAppl CICS
EndVTAM
```

You cannot QUIESCE, RESUME, or STOP a qualified portion of a port. If the port has several qualified port profiles, the VARY TCPIP,*tnproc*,QUIESCE, the VARY TCPIP,*tnproc*,RESUME, and the VARY TCPIP,*tnproc*,STOP commands affect all qualified port profiles associated with the port being quiesced, resumed, or stopped. In the example above, V TCPIP,*tnproc*,T,STOP,PORT=23 will stop port 23,1.1.1.1 and port 23,2.2.2.2. It is not possible to stop port 23,1.1.1.1 or port 23,2.2.2.2 individually. All display commands that allow port specification allow you to specify a qualified port. If just the port number is specified, only the unqualified port, if it exists, is displayed. The qualified port profiles are not displayed. DBCSTRANSFORM can be active on only one port, but can be active on one, some, or all of the qualified profiles of that port.

Multiple ports

Telnet supports up to 255 ports on one server. A unique TELNETPARMS block must be created for each port or qualified port. Telnet allows the use of the same BEGINVTAM block for all ports, some ports, or a unique BEGINVTAM block for each port. Both TELNETPARMS and BEGINVTAM blocks are required for each port started or modified by a VARY TCPIP,*tnproc*,OBEYFILE command. There are several reasons that more than one Telnet port or qualified port might be needed. The most common reasons are to simplify the setup of clients on the workstation and the logon process, and to differentiate client security needs.

Assigning a single application to a port simplifies the setup of clients on the workstation and the logon process. Workstation clients can be labeled with the associated application name and then be set up to connect to the appropriate port or qualified port. With a client per application on the workstation, the end user can select the needed client, connect, and be immediately in session with the application defined on the DEFAULTAPPL statement in BEGINVTAM. This implementation requires a unique BEGINVTAM block for each port due to the unique DEFAULTAPPL statements. The example below shows how to set up TSO, IMS, and CICS on ports 23, 2023, and 4023, respectively. The same LU names are used in each BEGINVTAM block. Telnet maintains a master LU "in-use" registry across all ports so that the same LU name will not be used by two different ports.

```
TELNETPARMS
      PORT  23
ENDTELNETPARMS
TELNETPARMS
      PORT  2023
ENDTELNETPARMS
TELNETPARMS
      PORT  4023
ENDTELNETPARMS

BEGINVTAM
      PORT  23
```

```
      DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
      DEFAULTAPPL   TSO
ENDVTAM
BEGINVTAM
      PORT  2023
      DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
      DEFAULTAPPL   IMS
ENDVTAM
BEGINVTAM
      PORT  4023
      DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
      DEFAULTAPPL   CICS
ENDVTAM
```

Assigning different security levels to different ports is an easy way to differentiate client security needs. External connections might require SSL security, while internal connections do not. Other than that difference, all other aspects of the Telnet profile can be the same. For example, external clients can connect to port 23 of a firewall that converts the request to the Telnet secure port 992. Internal clients would connect directly to the Telnet basic port 23. The statements below show how two ports allow implementation of different security levels. Note the same BEGINVTAM block is used for both ports, which can significantly reduce profile maintenance complexity. The PORT statement in BEGINVTAM links the BEGINVTAM block to the multiple TELNETPARMS blocks defined.

```
TELNETPARMS
      PORT  23
ENDTELNETPARMS
TELNETPARMS
      TTLSPORT  992
ENDTELNETPARMS
BEGINVTAM
      PORT  23 992
      DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
      ALLOWAPPL   *
ENDVTAM
```

If a profile that contains a new port number is processed, it is treated as an additional port, and the VARY TCPIP,*tnproc*,OBEYFILE command request will succeed if all parameters for the new port are correctly specified. Existing, non-referenced ports remain active and unchanged. You can use the VARY TCPIP,*tnproc*,TELNET,STOP command to stop a port.

Connection mode choices

Telnet supports several connection types. The negotiation process is hierarchical in the order listed below:

- TN3270 Enhanced (TN3270E)
- TN3270
- Linemode
  - Standard
  - Binary
  - Transform

TN3270E is the default connection mode for Telnet. If the client refuses TN3270E mode, Telnet tries TN3270 mode. If the client refuses TN3270 mode, Telnet tries Linemode. Telnet does not support Network Virtual Terminal (NVT) mode, except to allow the negotiation of TN3270E, TN3270, or linemode connections.

Note: The Type of Service (ToS) byte, also known as the Differentiated Services field, is not managed directly by Telnet. If you want to use Differentiated Services for Telnet, use the Quality of Service (QoS) support discussed in Chapter 17, "Quality of service," on page 873.

TN3270E and TN3270 are very similar. If the TN3270E functions are not needed, the end user does not notice any difference between TN3270E and TN3270 connections. In some cases, older clients do not properly refuse the server request for a TN3270E connection, and the connection is dropped. In these unusual cases, use the NOTN3270E parameter to disable the TN3270E function for those clients. Similarly, use the NOSNAEXT parameter for any client that does not properly negotiate the extension functions (Contention Resolution and SNA Sense). TN3270E/NOTN3270E and SNAEXT/NOSNAEXT parameters can be coded at all three parameter block levels for different levels of granularity.

TN3270E and TN3270 clients can receive a Telnet solicitor panel to submit an application name, User ID, and password to Telnet. The cursor is positioned on the application line unless the OLDSOLICITOR parameter is specified which causes the cursor to be positioned on the user line. See "Using the Telnet Solicitor or USS logon panel" on page 637 for detailed information.

The ATTN key function is supported over TN3270, TN3270E, and Transform Linemode connections. It is not supported over Standard or Binary Linemode. Default LOGMODEs for TN3270E connections are SNA, and default LOGMODEs for TN3270 and Transform connections are non-SNA. Telnet processes the ATTN key differently for SNA and non-SNA LOGMODEs. In addition, Telnet can be configured to handle double ATTNs sent by some clients by specifying SINGLEATTN. See "Device types and logmode considerations" on page 636 for more information.

For TN3270E, LU assignment is done during connection negotiation. For TN3270, LU assignment is done at application selection time. To delay LU assignment until application selection time for TN3270E, specify the SIMCLIENTLU parameter. See "LU mapping by application name" on page 620 and "LU mapping selection rules" on page 622 for details.

You might experience unexpected results if you start a Telnet session from within an application that is already connected using Telnet. For example, if you start a new Telnet session from within a TSO session that was established on a TN3270E connection, the keyboard will unlock when it seems it should not. This happens when an unlock keyboard intended for only the original, first session is sent from Telnet. The second session should remain locked but does not. An unlock keyboard intended for only the first session has the affect of unlocking the keyboard for both the first and second session since both are represented by the same client.

Some host applications send 3270 read commands (for example, X'F2' read buffer) to the client during the course of a session. Telnet sends an unlock keyboard sequence (that is, X'F1C2') before the read command is sent to the client. This is the default behavior or can be specified by coding UNLOCKKEYBOARD BEFOREREAD. In some cases, a problem can arise if the keyboard is unlocked prior to the read command being forwarded to the client. The unlock keyboard sequence allows transmission of buffered keyboard data to the host application. The buffered keyboard data is not expected in response to a read command. The UNLOCKKEYBOARD AFTERREAD parameter can be used to send the unlock keyboard sequence after the read command rather than before. In most cases, the default value will suffice and there is no need to code or change the setting of this

parameter. Certain applications, however, will issue error messages when buffered keyboard data is unexpectedly received from the client. In these cases, UNLOCKKEYBOARD AFTERREAD can be coded to resolve the application error.

Some applications expect the end user to initiate session data traffic. If a USSMSG10 screen or solicitor panel was used to initiate the session, the keyboard is locked. A BIND flows to the client on a TN3270E connection alerting the client to unlock the keyboard. A non-TN3270E connection does not support sending a BIND to the client. Therefore, when a BIND is received from the application, Telnet sends an unlock keyboard to the client on a non-TN3270E connection to ensure the end user can initiate data traffic if necessary. This behavior is the default or can be specified by coding UNLOCKKEYBOARD TN3270BIND. In some cases, the unlock keyboard might not be correctly interpreted by an older client. If this is the case, UNLOCKKEYBOARD NOTN3270BIND can be coded to stop Telnet from sending an unlock keyboard when a BIND is received.

The two unlock keyboard functions must be specified on a single UNLOCKKEYBOARD statement. If only one is specified, it is assumed the other is the default value. The UNLOCKKEYBOARD parameter can be coded at all three parameter block levels for different levels of granularity.

TN3270 Enhanced: TN3270 Enhanced (TN3270E) connections support full-screen 3270 emulation that is sometimes referred to as TN3270 Extended. Do not confuse TN3270E function with the IBM 327x device types that end in -E (for example, 3278-2-E). In these cases, the *E* indicates that the terminal supports Extended field attributes such as color and highlighting and is not related to Telnet functions.

Telnet is often used as the primary method of connection between client workstations and the SNA mainframe environment. To make this form of remote connection as seamless as possible, Telnet terminal emulation simulates actual SNA terminals as closely as possible. To accomplish this, RFC1647 and RFC2355 (both known as TN3270E) add the ability to specify device names at connection time, add support for printer devices, and add additional SNA functions. An Internet draft, RFC 2355 Extensions, adds Contention Resolution and SNA Sense code support.

Device name specification
Telnet assigns LUs based on the LU mapping statements supplied. Clients are assigned a device name (Telnet LU name) based on those statements. However, a TN3270E client can optionally specify that a particular device name be assigned, or it can specify that a device name from a pool of LUs be assigned. If the specified device name is allowed for this client based on the LU mapping statements and the LU is available, Telnet assigns the specified device name. If the specified device pool is allowed for this client based on the LU mapping statements and an LU within the pool is available, Telnet assigns a device name from the specified pool. Otherwise, the request is rejected with an appropriate reason code, and the connection is dropped. See “Mapping Objects to Client Identifiers” on page 595 for additional LU mapping information.

328x printer support
Many Telnet clients emulate 328x class printers (device type IBM-3287-1). Most support both SNA Character Stream (SCS) as an LU1 and 3270 data stream as an LU3. The support of each is negotiated at connection time. When connected in TN3270E mode, Telnet supports these emulators in a manner similar to terminal LUs. Telnet can be configured to initiate a session at connection time or simply open an ACB to let the application

initiate the session. The bind initiating each session is sent to the client, and the bind informs the emulator which data stream to expect. The VTAM application perceives the Telnet LU to be an an actual 3287-class printer and sends the SCS or 3270 data to the Telnet LU. Telnet passes the data on to the client, which prints the data. Telnet printer support allows you to use a single product, Telnet, to control both SNA terminals and SNA printers.

Some Telnet client printer emulators can request to be associated with a terminal device name by specifying the terminal device name during connection negotiation. Using printer association, end users can connect their Telnet terminals to an application and then have Telnet assign an associated printer device name based on the terminal name. To associate printers with terminals, Telnet must have a printer device pool of LUs defined and a terminal device pool of LUs defined with each having the same number of device names. For more information, see "Associated printer function" on page 617.

Additional negotiated TN3270E support

Responses and SysReq functions are supported by most clients that support TN3270E connections. Contention Resolution and SNA Sense support are newer and less prevalent.

- Responses - The client or host VTAM application can request that it receive definite, exception, or no response. Client responses to application requests provide more accurate response information for application-based monitoring tools compared to TN3270 connections. For TN3270 connections, Telnet must intercept response requests from the host and respond on behalf of the client, incorrectly reducing measured response time. Telnet monitoring will provide accurate response time information for either TN3270E or TN3270 connections.
- SysReq function - The end user can request that a current session be dropped by entering LOGOFF (in upper, lower, or mixed case) after pressing the SysReq key. If LUSESSIONPEND is not mapped to the client, the connection will be dropped. Otherwise, a USSMSG10 screen is sent to the client. If, instead of entering LOGOFF, the SysReq key is pressed a second time and if the application supports LUSTAT 082B (presentation screen is lost), the previous screen is resent to the client emulator.
- Contention Resolution - Improves communication between the client and host VTAM application regarding which owns the send state. Contention Resolution includes the following:
  - Keyboard Restore Indicator (KRI) - Whenever the host VTAM application sends End Bracket (EB), Telnet sends a KRI to the client. This directly notifies the client that the keyboard can be unlocked. Without the KRI indicator, Telnet would have to make sure a WCC with the unlock keyboard flag set is sent to the client. The KRI flag is set whether or not the keyboard restore flag in the WCC byte is set.
  - Start Data Indicator (SDI) - When the host VTAM application sends change direction or end bracket, Telnet sends the SDI to the client. This allows the client to know exactly when data can be sent to Telnet.
  - BID - A BID sent from the host VTAM application is forwarded to the client instead of being intercepted and handled by Telnet. This allows the client to manage the BID process itself.

  - Signal Indicator - A signal received from the host VTAM application is forwarded to the client. When the client responds to the signal, Telnet sends a change direction indicator to the host VTAM application.
- SNA Sense Support - Allows the client to include SNA sense codes in a response message. The client retains the option of letting Telnet map the errors to an appropriate sense code by not turning on the SNA-Sense-Code indicator in the response message.

TN3270: TN3270 connections support full-screen 3270 emulation. TN3270 connections do not support:

- Device name or pool name specification
- Printers
- Client involvement with responses, SysReq, Start Data Indicator, BID, Signal or SNA Sense data.

RFC1646 defines device name specification and printer support for TN3270 connections. However, this RFC is not supported on the TN3270 Telnet server. If either of these requests is received on a TN3270 connection, the server will drop the connection.

Linemode: In some cases, the client or the application does not support full-screen presentation, or the end user needs to work in a linemode environment. For these reasons, most emulators support linemode. Linemode supports a *go-ahead* function to simulate a half-duplex format. With *go-ahead* negotiated, the partner cannot send data until it receives a *go-ahead* from the current sender of data. In most cases, sessions are naturally half-duplex and the *go-ahead* adds unneeded transmissions. Therefore, the Telnet default is to Suppress Go Ahead (SGA). If *go-ahead* is needed to maintain a half-duplex format, use the NOSGA parameter. SGA or NOSGA can be coded at all three parameter block levels for different levels of granularity.

Telnet supports the following types of Linemode connections:

- Standard
- Binary
- Transform

Standard Linemode is assumed if neither DBCS transform nor BINARY linemode parameters are specified, or if the device type is not supported by transform. Standard Linemode is the only connection mode that requires translation by Telnet. Telnet provides multicultural support for standard Linemode connections. ASCII and EBCDIC code pages are the basis for translation. Telnet uses the ICONV services available in the C runtime library. For custom code page information, see the ICONV services in *z/OS XL C/C++ Programming Guide*. When ASCII and EBCDIC code pages are specified, a conversion descriptor will be given to Telnet. Telnet creates ASCII-EBCDIC and EBCDIC-ASCII translation tables based on the conversion descriptor. The CODEPAGE parameter is used to specify the code page names. For example:

```
CODEPAGE ISO8859-1 IBM1047
```

The possible results from CODEPAGE processing are:

- If a conversion descriptor is not returned, CODEPAGE is not coded, or there is an error in the syntax, a default code page of ISO8859-1 will be used for ASCII, and the language environment code page taken from locale information will be used as the EBCDIC code page.
- If a conversion descriptor is not returned again, a default code page of IBM-1047 will be used for EBCDIC.
- If a conversion descriptor is not returned again, predefined translation tables within Telnet will be used. These tables are similar, but not exactly the same as the tables which would have been generated if ISO8859-1 and IBM-1047 had worked. Some of the differences are noted below:

```
EBCDIC           ASCII
x'0D25' -----> x'0D0085' using ISO8859-1/IBM-1047
x'0D25' -----> x'0D0A'   using internal tables
x'15'   <----  x'0A'     using ISO8859-1/IBM-1047
x'25'   <----  x'0A'     using internal tables
```

No message is issued to the console if the first conversion succeeds. If there is any conversion failure a message is issued. If one of the later conversions succeeds, a message is issued indicating success.

If your Linemode connection does not perform correctly, the default translation tables may be causing the problem. Try the internal Telnet translation tables by specifying TNSTD for both ASCII and EBCDIC choices. For example:

```
CodePage TNSTD TNSTD
```

The internal code pages must be used together. If only one of the two internal tables is specified, then the other internal table will also be used.

CODEPAGE can be coded at all three parameter block levels for different levels of granularity.

Binary Linemode is set using the BINARYLINEMODE parameter. It indicates that Telnet should not do translation. The ASCII data from the client should be passed as-is to the VTAM application. BINARYLINEMODE or NOBINARYLINEMODE can be coded at all three parameter block levels for different levels of granularity.

Transform Linemode is set using the DBCSTRANSFORM parameter. When coded, all data that passes through Telnet will be *transformed* from DBCS or SBCS ASCII full screen to 3270 full screen for all supported device types. If the device type is not supported, Standard or Binary Linemode is used. DBCSTRANSFORM can be coded in TELNETPARMS or PARMSGROUP for different levels of granularity. It cannot be coded in TELNETGLOBALS. A unique logmode for transform can be set using TELNETDEVICE with a device type of TRANSFORM. Any logmode used must not support extended graphics.

Note: Transform can be used by only one port when multiple ports are active on one TCP/IP stack. DBCSTRANSFORM supports a maximum of 250 concurrent connections.

DBCSTRANSFORM can be used for either the VT100 single-byte character set (SBCS) or VT282 double-byte character set (DBCS) transform mode. When DBCSTRANSFORM is specified and the TCP/IP procedure JCL has been modified as shown below, ASCII-based terminal emulators (VT100 or VT282) will appear as full-screen 3270 terminals. Telnet receives ASCII data from the client and transforms it into SBCS or DBCS EBCDIC data, depending on the terminal type. Telnet adds appropriate SNA control bytes to give the appearance that the data is

coming from a 3270 terminal. Telnet receives EBCDIC data from the host application and transforms the SNA control bytes and data into appropriate ASCII control bytes and data. The data is sent to the ASCII-based terminal where it is displayed in 3270 full-screen emulation. DBCSTRANSFORM requires additional special Data Definition (DD) statements in the TCP/IP procedure.

You must add the following three DD statements to the TCP/IP procedure JCL to support Transform:

```
//TNDBCSCN DD DSN=TCPIP.SEZAINST(TNDBCSCN),DISP=SHR
//TNDBCSXL DD DSN=TCPIP.SEZAXLD2,DISP=SHR
//TNDBCSER DD SYSOUT=*
```

- The TNDBCSCN DD statement must point to the configuration data set for 3270 DBCS transform mode. This configuration data set specifies the default DBCS conversion mode that will take effect at initialization time. Specify the CODEKIND and CHARMODE parameters according to the required DBCS code page. If CODEKIND and CHARMODE are not specified, or if the TNDBCSCN DD statement is not added, by default, CODEKIND is SJISKANJI and CHARMODE is ALPHABET. A sample can be found in SEZAINST(TNDBCSCN).
- The TNDBCSXL DD statement must point to the data set containing binary translation table code files for 3270 DBCS transform mode. The installation data set, SEZAXLD2, contains the default binary translation table code files. The binary translation table code files for 3270 Transform can be customized by using the CONVXLAT command. See *z/OS Communications Server: IP Configuration Reference* for more information about customizing translation table code files. If the TNDBCSXL DD statement is not added, the following message will appear and an abend will occur:

  ```
  IEC130I PASCAL01 DD STATEMENT MISSING
  ```
- The TNDBCSER DD statement defines where Transform-specific error messages are recorded. This DD statement can specify an output data set or SYSOUT=*. If the TNDBCSER DD statement is not added, transform initialization will fail.

Specifying the DBCSTRACE parameter sends detailed trace output from 3270 Transform to the location specified in the SYSPRINT output DD statement. Additional detailed trace output is also sent to TNDBCSER. Both data sets will contain detailed trace data. DBCSTRACE or NODBCSTRACE can be coded in TELNETPARMS or PARMSGROUP for different levels of granularity. They cannot be coded in TELNETGLOBALS.

Connection security

This topic describes data overrun security, Transport Layer Security (TLS), and Network Access Control.

Data overrun security: Use the following parameters to protect against data overrun.

MAXRECEIVE: This parameter limits the number of bytes received from a client without an End Of Record (EOR) being received. If the data received exceeds the limit, the connection is dropped. This parameter protects against a client stuck in a send-data loop. In general, large file transfers will not be affected because the sending client typically divides the file into smaller records that are sent. The receiving application rebuilds the file as the smaller records are received.

MAXVTAMSENDQ: This parameter limits the number of data segments (RPLs) queued to be sent to VTAM. If the queue size exceeds the limit, the connection is

dropped. This parameter protects against using up large amounts of storage to hold data destined for a host application that is not receiving data.

MAXREQSESS: This parameter limits the number of session requests received by Telnet in a 10-second period. For this parameter, a BIND received by Telnet defines a session request. If the number of BINDs received in a 10-second period exceeds the limit, an error is reported. This parameter protects against session logon loops that are possibly created by an automatic CLSDST-PASS to an inactive session. This parameter cannot protect against logon loops caused by an inactive default application and a client using auto-reconnect.

MAXRUCHAIN: This parameter limits the number of chained RUs that can be received over a given session from a host application without a corresponding end chain RU. If the number of RUs exceeds the limit, the session is dropped. This parameter protects against using up large amounts of storage to hold data destined for a client in session with the host application.

The MAXRECEIVE, MAXVTAMSENDQ, MAXREQSESS, and MAXRUCHAIN parameters can be coded at all three parameter block levels for different levels of granularity.

Auto-reconnect loop: Without MSG07 coded a client connection error causes Telnet to drop the connection. The error may be an inactive DEFAULTAPPL or an LU assignment error. If the client has AUTO-RECONNECT specified, a continuous loop of retries occurs. The best protection against this is to code the MSG07 parameter which keeps the client from being disconnected. However, other applications can be chosen from the error screen returned to the end user. To block end users from other applications, use the DEFONLY parameter.

Transport Layer Security: The TN3270E Telnet server (Telnet) provides the ability to secure Telnet connections with Transport Layer Security (TLS) or the Secure Sockets Layer (SSL) protocol. Telnet supports the TLSv1.1, TLSv1.0, SSLv3, and SSLv2 protocols, which, collectively, are referred to as the TLS protocol. References to RACF apply to any SAF-compliant security product that contains the required support. Telnet can be set up to use Application Transparent Transport Layer Security (AT-TLS) in TCP/IP, or a subset of the functions available in AT-TLS can be configured in the Telnet profile. A port using AT-TLS security configuration is referred to as a TTLSPORT port, and a port using Telnet profile security configuration is referred to as a SECUREPORT port. A secure port is either a TTLSPORT port or a SECUREPORT port. A basic port is one that does not use the TLS protocol. Connections are either secure or basic. The flows between Telnet and VTAM are unchanged.

The expired Internet Engineering Task Force (IETF) *TLS-based Telnet security* draft is supported in Telnet. This draft allows a Telnet negotiation to determine whether the client wants or supports TLS protocol prior to beginning the secure handshake. The default action that Telnet takes for a secure port is to first attempt a TLS handshake. If the client does not start the handshake within the specified handshake timeout time, an attempt is made to negotiate TLS as defined by the expired TLS-based Telnet security draft. If the client responds that it wants a secure connection, the handshake is started; if the client rejects the TLS negotiation request, the connection is closed. In this way, installations can support both types of secure clients without knowing which protocol the client is using. The default action can be changed by specifying the CONNTYPE statement described later in this topic. You can also use the CONNTYPE statement to support secure and basic connections on the same port.

Telnet server authentication and client authentication are described in Appendix B, "TLS/SSL security," on page 1461. The Telnet server supports level 1, level 2 and level 3 client authentication. Client authentication is done with the CLIENTAUTH parameter. Level 2 and level 3 client authentication use RACF services to translate the client certificate to an associated user ID. That user ID can also be used as a client identifier.

TTLSPORT utilizes AT-TLS, which supports many System SSL functions that are not supported by the Telnet profile configuration. For example, the following functions are supported by AT-TLS and not by Telnet profile configuration:

- Dynamic refresh of a key ring
- Support new or multiple key rings
- Specify the label of the certificate to be used for authentication, instead of using the default certificate
- Support SSL Session Key Refresh
- Support SSL Session Reuse
- Support SSL Sysplex Session ID Caching
- Trace decrypted SSL data for Telnet in a data trace
- More granular error messages in syslog for easier debugging

When using SECUREPORT ports, the Telnet profile security configuration supports the following subset of System SSL functions:

- Key ring specification using the KEYRING statement
- Cipher specification using the ENCRYPTION statement
- Client authentication level using the CLIENTAUTH statement
- CRL LDAP server specification using the CRLLDAPSERVER statement
- Control SSLv2 protocol usage with the SSLV2 or NOSSLV2 statement
- Set the handshake timeout using the SSLTIMEOUT statement

TTLSPORT ports and SECUREPORT ports can coexist in the same Telnet server.

AT-TLS has one limitation when compared to Telnet profile configuration. AT-TLS policy does not support mapping security parameters to connections based on client hostname. You can do this with Telnet profile configuration by coding security parameter statements in a PARMSGROUP statement and using the PARMSMAP statement to map the group to a hostname or a hostname group. If you currently have this configuration, you must continue to use Telnet profile configuration.

Telnet Transport Layer Security setup: The TTLSPORT statement or the SECUREPORT statement in the TELNETPARMS block is required to define a port as a secure port that is using AT-TLS or Telnet profile statements to configure the secure connections.

The CONNTYPE statement is an optional statement on secure ports that provides more control over how connections initiate the TLS handshake, whether or not the connection is secure, and whether the connection is available for use. Valid CONNTYPE statement options are as follows:

- SECURE

  Indicates that the TLS handshake is used to start the connection. If the client does not start the handshake within the time specified by the handshake timeout

time, an attempt is made to perform a negotiated TLS handshake (as defined by the expired IETF TLS-based Telnet security draft). If the client rejects TLS, the connection is closed.

- NEGTSECURE

  Indicates that the client supports the expired IETF TLS-based Telnet security draft. A Telnet negotiation with the client determines whether the client is willing to enter into a secure connection. If the client agrees, a TLS handshake is started and secure protocols are used for all subsequent communication. If the client rejects TLS, the connection is closed. You should consider using this option only if you know that the Telnet secure clients connecting into the port are all using the protocol defined by the expired TLS-based Telnet security draft. With this option, the TLS handshake is not attempted until a positive response to the Telnet DO_StartTLS IAC is received. This avoids the timeout delay that can occur when a TLS handshake is immediately started (as occurs with the CONNTYPE SECURE option), but the client is expecting the protocol used by the expired TLS-based Telnet security draft. Use the SECURE option instead of the NEGTSECURE option in case some clients in your network do not support the expired TLS-based Telnet security draft.
- BASIC

  Indicates that a basic connection is established.
- ANY

  Indicates that the connection can be either secure or basic. Telnet first tries a standard TLS handshake. If the handshake times out, a negotiated TLS connection (see the CONNTYPE NEGTSECURE option description) is attempted:
  - If the client is willing to enter into a secure connection, secure protocols are used for all subsequent communication.
  - If the client is not willing to enter into a secure connection, a basic connection is established.
- NONE

  Indicates that no connection is allowed and the connection will be closed. If this option is specified in the TELNETPARMS block, a PARMSMAP statement must cover every allowable connection, and the related PARMSGROUP statement must specify the connection type on the CONNTYPE statement.

If the CONNTYPE statement is not specified, by default, secure ports are CONNTYPE SECURE and basic ports are CONNTYPE BASIC.

Using one port for both basic and secure connections: You can use the CONNTYPE statement to modify connection types on a single port. Allowing a port to support both basic and secure connections assumes that either of the following are true:

- The installation allows the client to determine the connection type.
- A subset of the connections that should use a particular connection security type can be identified by Client Identifier.

In the first case, specify CONNTYPE ANY. If the port was defined as a secure port but the client wants a basic connection, there is a slight delay before connection negotiation begins. This is because when CONNTYPE ANY is coded, Telnet first attempts a TLS handshake to ensure that the client is not requesting TLS support. It is only after the handshake times out and negotiated security is rejected that the basic connection negotiation begins.

In the second case, the TELNETPARMS block should specify the default connection security type (see the CONNTYPE statement). For connections with different connection security requirements, do the following:

- Identify the clients by Client Identifier.
- Create a group using the PARMSGROUP statement with the alternate CONNTYPE definitions.
- Map the group created with the PARMSGROUP statement to the clients using the PARMSMAP statement.

Configuring Telnet security using AT-TLS: The TTLSPORT statement in the TELNETPARMS block indicates that the port uses AT-TLS to manage System SSL. All TTLSPORT ports must be defined by specifying a TELNETPARMS block for each port.

Other than the CONNTYPE statement, all security configuration is done in AT-TLS policy. For details about AT-TLS setup, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193. For Policy Agent setup and AT-TLS policy statements, see *z/OS Communications Server: IP Configuration Reference*. A sample list of tasks to perform for AT-TLS policy includes the following:

1. Be sure that the TCP/IP stack profile includes the TCPCONFIG statement with the TTLS parameter.
2. Permit Policy Agent and any other required administrative application to the RACF resource EZB.INITSTACK.*sysname.tcpname* in the SERVAUTH class.
3. Define the pagent environment file on the STDENV DD statement in Policy Agent JCL. For example:

   ```
   //STDENV   DD PATH='/etc/pagent/pagent.env',PATHOPTS=(ORDONLY)
   ```

4. In the pagent environment file, point to a configuration file. For example:

   ```
   PAGENT_CONFIG_FILE=//'SYS1.TCPPARMS(PAGENT)'
   ```

5. In the configuration file, set up policy files for each TCP/IP stack image. For example:

   ```
   TcpImage TCP1 /etc/pagent/TCP1.policy FLUSH
   TcpImage TCP2 /etc/pagent/TCP2.policy FLUSH
   ```

6. In the TcpImage file, point to the TTLS configuration file. For example:

   ```
   TTLSConfig /etc/pagent/pagttls1.ttls
   ```

7. In the TTLS configuration file, code the TTLSRule, TTLSGroupAction, TTLSEnvironment, and TTLSConnectionAction statements.

   Be sure to set the ApplicationControlled parameter to the value On in the TTLSEnvironmentAdvancedParms statement. For example:

   ```
   TTLSRule        tn_serv1
   {
     LocalPortRange 23
     Direction      Inbound
     Jobname TCP1
     TTLSGroupActionRef tn_grp_act
     TTLSEnvironmentActionRef tn_env_act
   }

   TTLSGroupAction tn_grp_act
   {
    TTLSEnabled On
    Trace  7
    GroupUserInstance  1
   }
   ```

```
TTLSEnvironmentAction tn_env_act
{
  HandshakeRole Server
  TTLSKeyringParms
  {
     Keyring TNsafkeyring
  }
  TTLSEnvironmentAdvancedParms
  {
   ApplicationControlled On
  }
 EnvironmentUserInstance  1
}
```

8. Verify that the policy is correctly entered by using the z/OS UNIX **pasearch** command to query information from the z/OS UNIX Policy Agent.

   Issue the **pasearch -t** command from the z/OS UNIX System Services shell. If you have multiple TCP/IP stacks that are active, issue the **pasearch -t -p** *procname* command to query a specific TCP/IP stack. The **pasearch** command is a Policy API (PAPI) application. If you have never run a PAPI application, you might receive a message indicating that the papi.dll file was not found. For more information about PAPI and running PAPI applications, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Converting Telnet profile statements to equivalent AT-TLS policy statements: If you are currently using the SECUREPORT statement in your Telnet profile, Table 28 describes how to convert Telnet profile statements to equivalent AT-TLS policy statements.

Table 28. Converting Telnet profile statements to AT-TLS policy statements

Telnet statement	AT-TLS equivalent statement	AT-TLS policy statement
CLIENTAUTH NONE	HandshakeRole Server	TTLSConnectionAction or TTLSEnvironmentAction
CLIENTAUTH SSLCERT	HandshakeRole ServerWithClientAuth and ClientAuthType Required	TTLSConnectionAction or TTLSEnvironmentAction / TTLSEnvironmentAdvancedParms within TTLSEnvironmentAction
CLIENTAUTH SAFCERT	HandshakeRole ServerWithClientAuth and ClientAuthType SAFCHECK	TTLSConnectionAction or TTLSEnvironmentAction / TTLSEnvironmentAdvancedParms within TTLSEnvironmentAction
CRLLDAPSERVER	GSK_LDAP_Server and GSK_LDAP_Server_Port	TTLSGskLdapParms within TTLSEnvironmentAction
ENCRYPTION	TTLSCipherParms	TTLSConnectionAction or TTLSEnvironmentAction
KEYRING	Keyring	TTLSKeyRingParms within TTLSEnvironmentAction
SSLV2	SSLv2	TTLSEnvironmentAdvancedParms within TTLSEnvironmentAction or TTLSConnectionAdvancedParms within TTLSConnectionAction
SSLTIMEOUT	HandshakeTimeout	TTLSEnvironmentAdvancedParms within TTLSEnvironmentAction or TTLSConnectionAdvancedParms within TTLSConnectionAction

Tip: There are many variations possible with the Telnet profile statement CLIENTAUTH. In AT-TLS, whether or not client authentication is done is controlled by the HandshakeRole parameter on either the TTLSEnvironmentAction or TTLSConnectionAction statements. If the connection needs client authentication, the level of authentication is controlled with the ClientAuthType parameter on the TTLSEnvironmentAdvancedParms statement.

- If you have both CLIENTAUTH SSLCERT and CLIENTAUTH SAFCERT in different ParmsGroup statements in your Telnet configuration, you need two TTLSEnvironmentAction statements; one TTLSEnvironmentAction statement for ClientAuthType Required and one TTLSEnvironmentAction statement for ClientAuthType SAFCheck. Two TTLSRule statements, each referencing a different TTLSEnvironmentAction statement in AT-TLS, replace the two PARMSMAP statements in the Telnet profile.
- If you have a mixture of CLIENTAUTH NONE and CLIENTAUTH SAFCERT, you need a TTLSEnvironmentAction statement with HandshakeRole ServerWithClientAuth, and a TTLSConnectionAction statement with HandshakeRole Server. Two TTLSRule statements in AT-TLS (one with the TTLSConnectionAction statement and one without) replace the two PARMSMAP statements in the Telnet profile. You could instead create a second TTLSEnvironmentAction statement with HandshakeRole Server, but many more resources are associated with a TTLSEnvironmentAction statement compared to a TTLSConnectionAction statement.

Configuring Telnet security using Telnet profile statements: System SSL environment initialization based on the Telnet profile configuration occurs when the first SECUREPORT port is activated; initialization does not occur again unless all SECUREPORT ports are stopped (V TCPIP,*tnproc*,T,STOP,PORT=SECURE). Whether or not hardware encryption is used is based on its availability at the time of Telnet initialization. For ICSF to be used by Telnet, ICSF must be available to System SSL. A crypto assist status message is issued to sysout when the first Telnet secure port is activated. For more information about hardware encryption, see Appendix B, "TLS/SSL security," on page 1461.

To implement secure connections, Telnet must have APF-authorized access to the System SSL DLLs. The System SSL DLLs are located in SYS1.SIEALNKE by default. System SSL uses the C runtime library (SCEERUN) and the C/C++ standard library, which must also be accessible to Telnet. To access these libraries, either add them to the linklist or specify them in the Telnet procedure's STEPLIB. If accessed through the linklist, the linklist must be authorized (LNKAUTH=LNKLST specified in the IEASYS*xx* parmlib member) or the libraries must be explicitly APF authorized. If accessed through a STEPLIB, the libraries must be APF authorized and DISP=SHR must be specified. The Telnet profile must also be updated. An overview of the SSL-related profile parameters follows. For a detailed description of the parameters, see *z/OS Communications Server: IP Configuration Reference*.

Two statements are required to define a SECUREPORT port:

- SECUREPORT

  The SECUREPORT port designation statement in the TELNETPARMS block indicates that the port uses Telnet profile configuration to manage System SSL. All SECUREPORT ports must be defined by specifying a TELNETPARMS block for each port.
- KEYRING

A server certificate is required for the server authentication process defined by the SSL protocol. This certificate is stored in a key ring. The key ring type and location is specified in the KEYRING statement. Only one key ring can be used by Telnet.

The key ring can be defined in the TELNETGLOBALS or TELNETPARMS block. Using the TELNETGLOBALS block is the preferred definition method because it ensures that the same key ring has been defined for all SECUREPORT ports. If specified in the TELNETPARMS block, the same key ring type and file must be specified for each SECUREPORT port. The first key ring file name read is considered the correct key ring file name. The TELNETGLOBALS key ring is read first, and then the TELNETPARMS key rings are read in reverse order. Any key ring that does not match the first is rejected and the port update fails. You can verify that your port is secure by issuing a D TCPIP,*tnproc*,T,PROFILE command. The first column under the security heading indicates the port type. You see an S for a SECUREPORT port, a T for a TTLSPORT port, or a B for a basic port. Near the bottom of the display, you see the key ring name that Telnet is using.

The following steps are required to enable TLS support for Telnet, with server authentication:

1. Generate the Telnet private key and server certificate.
2. Configure Telnet to include one or more SECUREPORT ports; in the TELNETGLOBALS block or the TELNETPARMS block, specify the name of the key ring that you created in the previous step. For example, specify one of the following:
   - KEYRING HFS /usr/ssl/server.kdb

     In this example, two files, server.kdb and server.sth, were created using the gskkyman utility. The server's certificate is contained in the server.kdb file and designated as the default certificate.

     The key database and the password stash file must reside in the same directory.
   - KEYRING SAF serverkeyring

     In this example, RACF is used to manage keys and certificates. The server certificate is connected to a key ring called SERVERKEYRING and designated as the default certificate.
3. Restart Telnet or issue the VARY TCPIP,*tnproc*,OBEYFILE command with the updated configuration files.

Optional security statements: You can specify optional security statements only for SECUREPORT ports in the TELNETGLOBALS, TELNETPARMS, or PARMSGROUP blocks. The statements specified in the PARMSGROUP block apply to only the clients mapped to the PARMSGROUP block by the PARMSMAP statement, and override the statements specified in the TELNETPARMS or TELNETGLOBALS block. The statements specified in the TELNETPARMS block apply to any connection for that port, if not overridden by a PARMSGROUP statement. The statements specified in the TELNETGLOBALS block apply to any connection for any port, if not overridden by a TELNETPARMS or PARMSGROUP statement.

The CONNTYPE statement is described in "Telnet Transport Layer Security setup" on page 583.

The ENCRYPTION statement is used to limit the encryption algorithms to only those included in the statement. If this statement is not specified, all encryption algorithms that can be specified are used by Telnet. For the encryption ciphers that

can be specified and for the default order used by Telnet if the ENCRYPTION statement is not used, see *z/OS Communications Server: IP Configuration Reference*. The following are some reasons for using the ENCRYPTION statement:

- The applications supported on this port require a high level of security and the installation wants all data encrypted using a particular encryption cipher.
- Certain connections are local and the installation does not require encryption for local clients. NULL encryption can be specified for this subset of connections.

The SSLV2 statement enables the use of the SSLv2 protocol. The default value is NOSSLV2, which prohibits the use of the SSLv2 protocol. The SSLv2 protocol might be necessary if SSLv3, TLSv1.0, or TLSv1.1 is not supported by the client.

The CLIENTAUTH statement indicates that the client must send a client certificate to the server. If this statement is not specified, a client certificate is not requested during the SSL handshake, and no certificate-based client authentication is performed. The level of validation performed depends on the option specified.

Valid CLIENTAUTH options are:

- SSLCERT (Level 1)

  To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server (that is, a certificate for the CA that issued the client certificate is listed as trusted in the server's key ring).
- SAFCERT (Level 2 and 3)

  The level 1 checking provided by SSLCERT is performed, and level 2 checking is performed to verify that the certificate has been registered with RACF (or another SAF-compliant security product that supports certificate registration). Additionally, if the RACF SERVAUTH class is active and a RACF resource has been defined for the port, level 3 client authentication is in effect and the connection is allowed only if the user ID associated with the client certificate has READ access to the RACF resource.
- NONE

  No client certificate is requested.

The CRLLDAPSERVER statement is specified in the TELNETGLOBALS block, and defines the name or IP address and port of the certificate revocation list (CRL) LDAP server. The CRL LDAP server is used only if client certificates are received (CLIENTAUTH is specified). If CLIENTAUTH and the CRLLDAPSERVER statement have been specified, the certificate revocation list is checked during client authentication. If the client's certificate is found on the certificate revocation list, the connection is closed. Up to five CRL LDAP servers can be defined to Telnet.

You cannot change the key ring (name, type, or contents) or the CRL LDAP server (name or location) using the VARY TCPIP,*tnproc*,OBEYFILE command while SECUREPORT ports are active. To change the key ring or the CRL LDAP server, first stop all SECUREPORT ports (V TCPIP,*tnproc*,T,STOP,PORT=S). Then issue the VARY TCPIP,*tnproc*,OBEYFILE command to restart the SECUREPORT ports with a new key ring or CRL LDAP server. If the CRL LDAP server is stopped or connectivity is lost, System SSL might not recognize a subsequent reconnection. This situation must be handled like the CRL LDAP server change.

Telnet profile example: This example defines three ports with the following characteristics:

- Port 23 allows only basic connections.

- Ports 992 is enabled for secure connections defined by Telnet profile statements.
- Port 1023 is enabled for secure connections defined by AT-TLS policy.
- Port 992 allows only secure connections. No client authentication is requested.
- Port 1023 allows both basic and secure connections. The installation wants the following characteristics for port 1023:
  - The system administrator is at IP address 10.1.3.3 and wants the capability to choose to connect with secure or basic connections.
  - Buildings A and B are local and do not need connection security. The clients in these buildings have identifiable subnetworks. The installation wants these clients to use basic connections to avoid the encryption overhead.
  - Connection security (SSLCERT or Required) is used on all other connections.
  - All secure connections require client authentication and use the DES or triple DES encryption algorithms.

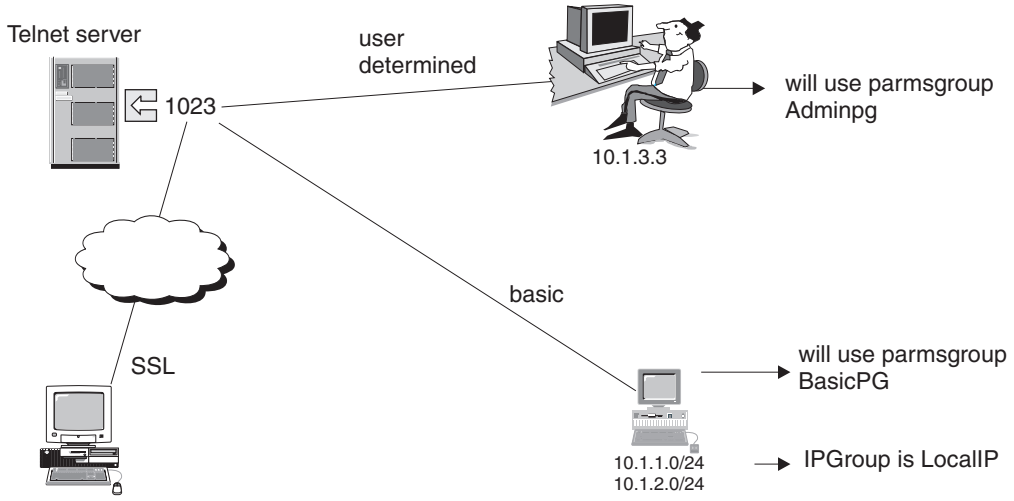

Figure 64. Port 1023 connection characteristics

Note: Definitions that are applicable to TLS connection security are the only definitions shown; additional parameters might be needed. Assume that all connections go through TCP/IP stack with job name TCP1.

TCP/IP configuration statements:

```
 TCPCONFIG TTLS
```

Telnet profile statements:

```
TELNETPARMS            ; basic port does not support secure connections
 Port 23
ENDTELNETPARMS

TELNETPARMS                        ; port that allows only secure connections
 SECUREPORT 992                    ; no client authentication requested
 KEYRING hfs /usr/keyring/tcp1.kdb ; keyring used by all SECUREPORTs
ENDTELNETPARMS                     ; any supported encryption algorithm

TELNETPARMS            ; port that allows secure and BASIC connections.
 TTLSPORT 1023         ; note: BEGINVTAM block has PARMSGROUP that may override CONNTYPE
 CONNTYPE SECURE       ; SECURE is default
ENDTELNETPARMS
```

```
BEGINVTAM
 Port 1023
 ...                    ; Mapping statements
 IPGROUP LocalIP
   255.255.255.0:10.1.1.0
   255.255.255.0:10.1.2.0
 ENDIPGROUP

   ApplicationControlled On
  }
  EnvironmentUserInstance  1
}
```

Network Access Control: Network Access Control (NAC) limits user access to certain IP security zones defined by the NETACCESS statement. A security product, such as RACF, is used to check the permission of user IDs to send data to or receive data from these security zones. The NAC user ID is based on the Telnet address space user ID information.

The NACUSERID parameter provides more control over Network Access Control checking for Telnet. This parameter is used to associate Telnet ports with a

specified user ID that is defined to the security server. The user ID specified on the NACUSERID parameter must be a valid user ID defined to the security server. If not, the Telnet port will fail initialization. NACUSERID can be coded in TELNETGLOBALS to affect all ports or TELNETPARMS to affect a single port. NACUSERID cannot be coded in PARMSGROUP. Specify NONACUSERID to disable a higher level specification. For example, a TN3270E Telnet server with an address space user ID of user1 can specify in TELNETGLOBALS the statement NACUSERID user2. If one port should instead be controlled by user1, the TELNETPARMS statement for that port should be NONACUSERID to disable the user2 specification in TELNETGLOBALS.

When Telnet is modified with a VARY TCPIP,*tnproc*,OBEYFILE command, the NACUSERIDs are reverified for the Telnet ports defined in the data set referenced by the command. If a Telnet port has NACUSERID *NAC_name_1*, you cannot use the VARY TCPIP,*tnproc*,OBEYFILE command to change that port's NACUSERID to *NAC_name_2*. The port must first be stopped, and then started with the new *NAC_name_2* value using the VARY TCPIP,*tnproc*,OBEYFILE command.

The NETACCESS statement in the TCP/IP profile is used to configure portions of your IP network into named security zones. Each defined security zone must have a SERVAUTH profile for the resource named EZB.NETACCESS.*sysname.tcpname.zonename*. The user ID associated with the Telnet port must have READ access to the security zone that maps its bind address (0.0.0.0/32 for INADDR_ANY or ::/128 for the IPv6 unspecified address, in6addr_any, unless overridden by the PORT statement in the TCP/IP profile) and to every security zone that maps client IP addresses that Telnet is to accept connections from on this port.

For more information, see “Network access control” on page 120.

Connection persistence

Several timers are available in Telnet to control how long connections stay up. The list includes:

- INACTIVE - How long a terminal connection can be idle with no SNA data traffic before the connection is dropped.
- PRTINACTIVE - How long a printer connection can be idle with no SNA data traffic before the connection is dropped.
- PROFILEINACTIVE - How long a Telnet connection can be active with no active SNA session, while it is associated with a Telnet profile that is not the current profile.
- KEEPINACTIVE - How long a KEEPOPEN connection can be idle with no SNA session before the connection is dropped. When a KEEPOPEN connection is in session with a SNA application the INACTIVE timer is used instead of the KEEPINACTIVE timer.
- SCANINTERVAL - How often Telnet runs the list of connections looking for potentially lost connections. Because of the methodology, it also determines how long Telnet will wait for a TIMEMARK response before assuming the connection is lost.
- TIMEMARK - How long a connection is active without receiving any data before Telnet sends a TIMEMARK command which acts as an "are you there".
- SSLTIMEOUT - How long Telnet will wait for an SSL handshake initiation from the client before the request is dropped.

To facilitate these timers, Telnet records the time at which data is received from the client, received from VTAM, or sent to VTAM. Data received from the client is used by SCANINTERVAL/TIMEMARK to measure idle time on the connection. Data received from or sent to VTAM is used by the INACTIVE family of timers to measure idle time without SNA data traffic.

SSLTIMEOUT is different than the other timers. Telnet does not run this timer. The time value is passed to the SSL handshake process. If SSL does not get a response from the client within SSLTIMEOUT period of time, the handshake request fails. Telnet will then proceed to the next available connection negotiation method or drop the connection.

The INACTIVE family of timers: INACTIVE, PRTINACTIVE, PROFILEINACTIVE, and KEEPINACTIVE all share one timer associated with a port profile to reduce system overhead. The timer with the smallest value defined in TELNETGLOBALS, TELNETPARMS, or PARMSGROUP for that port profile is used to define how often the connections are checked.

For example, assume KEEPINACTIVE is defined as 1800, PROFILEINACTIVE is 1800 by default, INACTIVE is defined as 3000, and PRTINACTIVE is defined as 5400 in a profile. The Telnet timer will run every 1800 seconds. Therefore, every time the timer expires, Telnet will check each KEEPOPEN connection not in session to see if there has been a SNA session created in the prior 1800 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-K. For PROFILEINACTIVE, Telnet checks each connection associated with a profile that is not current to determine whether a SNA session existed in the previous 1800 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-PF. Telnet will also check each terminal connection to see if there has been any SNA data traffic in the prior 3000 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-S. Telnet also will check each printer connection to see if there has been any SNA data traffic in the prior 5400 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-P.

Setting KEEPOPEN to the smallest time was done as an example. Any of the four timers could be the smallest. Also, since all inactivity checks are done by one timer, a connection check could occur just before the connection would be considered timed out. The connection will remain active until the next check is made.

Using the example above, if a terminal connection has had no SNA activity in the past 2999 seconds when a check is made, the connection is not dropped. Another check is done 1800 seconds later and the connection is dropped, but the connection will have remained active for 4799 seconds instead of the specified 3000 seconds.

SCANINTERVAL and TIMEMARK: SCANINTERVAL and TIMEMARK are used together to determine if a connection has been lost. These parameters can be specified in TELNETGLOBALS, TELNETPARMS, and PARMSGROUP. The smallest SCANINTERVAL value is used to define how often the connections are checked. If TIMEMARK is smaller than SCANINTERVAL, TIMEMARK is set equal to SCANINTERVAL. Whenever data is received from the client, Telnet records the time. Telnet checks all connections at regular intervals defined by the SCANINTERVAL value. Each connection is checked to see if any data has been received from the client in the past TIMEMARK period of time. If not, a TIMEMARK command is sent to the client which acts as an "are you there" and Telnet remembers a TIMEMARK was sent to this client. During the next check at SCANINTERVAL time later, each connection is again checked to see if any data

has been received from the client. If not, and a TIMEMARK was sent on the previous check, the connection is dropped with DEBUG SUMMARY message CONN DROP reason TIMEMARK.

For example, assume the values for SCANINTERVAL and TIMEMARK are 1800 and 10800, respectively. That means every 30 minutes all connections are checked to see if any data has been received in the last 3 hours. If not, a TIMEMARK is sent to the client. 30 minutes later Telnet checks the connections again. If the client responded to the TIMEMARK or sent in actual data of some type Telnet leaves the connection active. If nothing has been received Telnet drops the connection.

A SCANINTERVAL check could occur just before the last data received is old enough to trigger sending a TIMEMARK. The connection remains active until the next SCANINTERVAL is made. Then a TIMEMARK is sent, and at the next SCANINTERVAL the connection is dropped.

Using the example above, SCANINTERVAL checks a connection that received data 2 hours, 59 minutes ago. No TIMEMARK is sent. The next SCANINTERVAL runs 30 minutes later. Now the data received time is greater than 3 hours and a TIMEMARK is sent. At the next SCANINTERVAL, the connection is dropped. The connection's last activity was 3 hours 59 minutes ago.

Tip: Use Scaninterval and Timemark to find abandoned connections that do not require quick reset. Scaninterval and Timemark are intended to eventually clean up abandoned connections. They should not be used as an immediate reset function. If immediate reset of lost connections is needed, use the CheckClientConn parameter.

Setting the timers: Caution must be used in setting these timers. Setting the INACTIVE family of timers or SCANINTERVAL timer too low could cause excessive CPU usage. Setting the TIMEMARK value too low could also cause excessive flooding of the network with TIMEMARK commands or high storage usage. For example, these timers should take into account extended breaks such as lunch. If TIMEMARK is smaller than the lunch break time, the network may be flooded with TIMEMARK commands around the lunch hour. Be aware of the default values and be sure to set appropriate values for the situation.

MSG07 and LUSESSIONPEND: MSG07 and LUSESSIONPEND are Telnet parameter statements that define what Telnet should do in case of a session setup error and after normal logoff when the client is emulating a terminal. These parameters do not affect a printer connection.

- Connection negotiation error - If any problems occur during negotiation nothing can be done to keep the connection. If appropriate, Telnet will send the client an error code to help inform the client why the connection was dropped and issue a CONN DROP DEBUG message at the console.
- Session setup error - If a problem occurs during session setup such as an application name that is not valid, session request failure, or a BIND error, Telnet will drop the connection and issue a CONN DROP DEBUG message. The end user cannot get to any application other than the default. No error messages are sent to the end user and auto-reconnect loops are possible. For these reasons it is recommended that MSG07 always be used. If the MSG07 parameter is coded, the connection will not be dropped and an error message will be sent to the end user. MSG07 function applies to any connection mode whether or not USS tables are mapped to the client. If a USS table is used, the end user can press the CLEAR key to return to the USSMSG10 screen. If the

LUMAP-DEFAPPL or PRTMAP-DEFAPPL statement is coded and the default application is not available, an error screen will be sent to the client whether or not MSG07 is coded.

- Normal Session Logoff - When the end user logs off a session using a normal logoff, Telnet drops the connection. If the end user typically logs on to another application after logging off the first application, it might be more efficient if the user were presented another solicitor (or USSMSG10) panel or if Telnet initiated a new session with the default application after logoff. This can be accomplished by coding the LUSESSIONPEND parameter. Code LUSESSIONPEND to go through the initial database lookup again after session logoff. Later results will be identical to the first lookup. If a default application for the client exists, Telnet will immediately initiate another session request. Otherwise, a USSMSG10 screen or solicitor panel will be sent to the end user. When LUSESSIONPEND is coded, the connection remains active but terminal LU ACBs are closed.
- SYSREQ LOGOFF - When the end user logs off a session using a "SYSREQ LOGOFF" sequence (TN3270E connection supported) and LUSESSIONPEND is coded, Telnet does not drop the connection. Instead, the user is presented with a solicitor (or USSMSG10) panel. If DEFAULTAPPL is in effect, Telnet again requests a session with the default application.
- USS LOGOFF - When the end user issues a LOGOFF command from the USSMSG10 panel, the connection is dropped whether or not the LUSESSIONPEND parameter is coded.

Mapping Objects to Client Identifiers

Telnet provides flexibility for mapping Objects to clients based on Client Identifiers. This topic provides definitions, rules, and examples of many mapping methods. Examples start with simple concepts, then progress to more complicated concepts showing interaction between mapping statements. All mapping statements are specified in the BEGINVTAM block. See *z/OS Communications Server: IP Configuration Reference* for statement rules not discussed here.

The general relationship of mapping statements is:

MAP OBJECTS to clients based on **CLIENT IDENTIFIER**

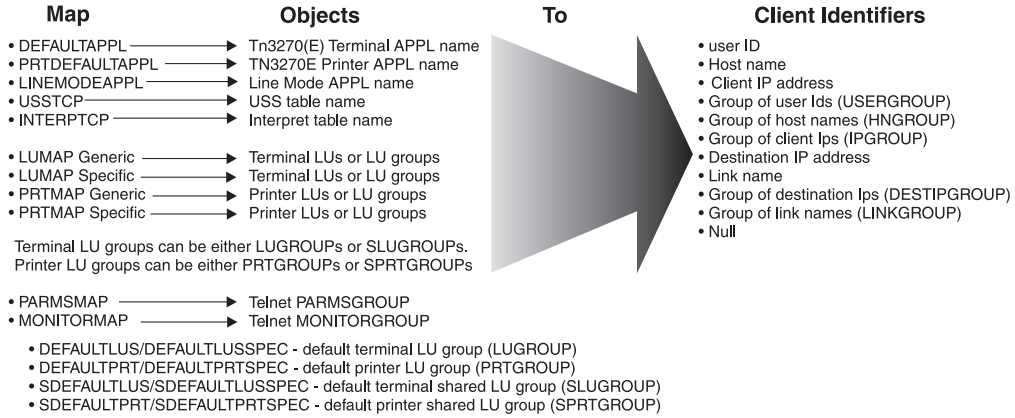

Figure 65. Mapping model

Telnet tries to assign all 11 Objects to a client based on the mapping statements when the connection is accepted. The search for Objects continues until all Objects are found or until all mapping statements are checked.

Objects: When a client connection request is made, Telnet must assign an LU name to represent the client. Optionally, a USS table, default application, unique parameters defined in the PARMSGROUP statement, or network monitoring can be assigned to the connection. See "Mapping Objects to Client Identifiers" on page 595 for details about how these objects are mapped to clients. The complete list of objects follows:

- TN3270(E) terminal application name – The DEFAULTAPPL mapping statement maps the TN3270(E) terminal application Object to a terminal client. When a TN3270 or TN3270E connection is negotiated, Telnet immediately initiates a session request to the VTAM application.
- TN3270E printer application name – The PRTDEFAULTAPPL mapping statement maps the TN3270E printer application Object to a printer client. When a TN3270E printer connection is negotiated, Telnet immediately initiates a session request to the VTAM application.
- Line Mode application name – The LINEMODEAPPL mapping statement maps the linemode application Object to a client. When a linemode connection is negotiated, Telnet will immediately initiate a session request to the VTAM application.
- USS table name – The USSTCP mapping statement maps the USS table Object to a client. When a TN3270 or a TN3270E connection is negotiated, Telnet will send a USSMSG10 screen to the client. A special case condition exists when an application name and a USS table are both mapped to the client by the exact same Client Identifier. In this case, Telnet will immediately initiate a session request to the VTAM application and use the USS table for error messages.
- Interpret table name – The INTERPTCP mapping statement maps the Interpret table Object to a client. When a TN3270 or a TN3270E connection is negotiated, Telnet uses the Interpret table to modify USS commands. The client must have a USS table mapped to it for the Interpret table to be used.
- Terminal LU, local LU group (LUGROUP), or shared LU group (SLUGROUP) (Generic) - The Generic LUMAP mapping statement maps a single LU, LUGROUP, or SLUGROUP Object to a client.
  - For single LU mappings, Telnet assigns the LU name to the connection if the LU is available.
  - For LUGROUP mappings, Telnet assigns an available LU from the group to the connection.
  - For SLUGROUP mappings, Telnet requests that the LUNS allocate an available LU from the group and then assigns it to the connection.

  An LU is required to represent the client when a VTAM session is initiated. DEFAULTLUS is a default local terminal LUGROUP Object mapped Generically to the NULL Client Identifier. SDEFAULTLUS is a default shared terminal SLUGROUP Object mapped Generically to the NULL Client Identifier.
- Terminal LU, LUGROUP, or SLUGROUP (Specific) - The Specific LUMAP mapping statement maps a single LU, LUGROUP, or SLUGROUP Object to a client.

  Unlike the Generic mapping in which Telnet assigns the LU, the Specific mapping requires the client to specify the LU name that it wants. Telnet verifies that the LU is mapped and available. The specified LU name can be either a mapped single LU, an LU within a mapped LUGROUP or SLUGROUP, or the group name of the mapped LUGROUP or SLUGROUP.
  - If the client specifies an LU name within a SLUGROUP, Telnet requests the LUNS to verify that the LU is available and allocate the LU to this Telnet.

- If the client specifies an LUGROUP name, Telnet assigns an available LU from within the group.
- If the client specifies an SLUGROUP name, Telnet requests the LUNS to allocate an available LU from the group and then assigns the LU.

DEFAULTLUSSPEC is a default local terminal LUGROUP Object mapped Specifically to the NULL Client Identifier. SDEFAULTLUSSPEC is a default shared terminal SLUGROUP Object mapped Specifically to the NULL Client Identifier.

- Printer LU, local printer group (PRTGROUP), or shared printer group (SPRTGROUP) (Generic) - The Generic PRTMAP mapping statement maps a single LU, PRTGROUP, or SPRTGROUP Object to a client.
  - For single LU mappings, Telnet assigns the LU name to the connection if the LU is available.
  - For PRTGROUP mappings, Telnet assigns an available LU from the group to the connection.
  - For SPRTGROUP mappings, Telnet requests the LUNS to allocate an available LU from the group and then assigns it to the connection.

  An LU is required to represent the client when a VTAM session is initiated. DEFAULTPRT is a default local printer PRTGROUP Object mapped Generically to the NULL Client Identifier. SDEFAULTPRT is a default shared printer SPRTGROUP Object mapped Generically to the NULL Client Identifier.
- Printer LU, PRTGROUP, or SPRTGROUP (Specific) - The Specific PRTMAP mapping statement maps a single LU, PRTGROUP, or SPRTGROUP Object to a client.

  Unlike the Generic mapping in which Telnet assigns the LU, the Specific mapping requires the client to specify the LU name that it wants. Telnet verifies that the LU is mapped and available. The specified LU name can be either a mapped single LU, an LU within a mapped PRTGROUP or SPRTGROUP, or the group name of the mapped PRTGROUP or SPRTGROUP.
  - If the client specifies an LU name within a SPRTGROUP, Telnet requests that the LUNS verify that the LU is available and allocate the LU to this Telnet.
  - If the client specifies a PRTGROUP name, Telnet assigns an available LU from within the group.
  - If the client specifies a SPRTGROUP name, Telnet requests that the LUNS allocate an available LU from the group and then assigns the LU.

  DEFAULTPRTSPEC is a default local printer PRTGROUP Object mapped Specifically to the NULL Client Identifier. SDEFAULTPRTSPEC is a default shared printer SPRTGROUP Object mapped Specifically to the NULL Client Identifier.
- Telnet PARMSGROUP – The PARMSMAP mapping statement maps the PARMSGROUP Object to a client. The parameters in the group override parameter values specified in either TELNETGLOBALS or TELNETPARMS.
- Telnet MONITORGROUP – The MONITORMAP mapping statement maps the MONITORGROUP Object to a client. The parameters in the group define what monitoring measurements will be done for a mapped client. For details, see "Connection monitoring mapping statement" on page 642.

Rule: All LUGROUPs and all PRTGROUPs, whether local or shared, that are used on a given profile must have unique names.

The two following statements are not Objects but can affect application and LU Object usage:

- ALLOWAPPL – This statement allows client access to applications and optionally maps or confirms the mapping of an LU name to the client based on the application name chosen. DEFAULTAPPL application names are presumed allowed and do not require the ALLOWAPPL statement for Telnet acceptance. However, ALLOWAPPL may be used by default applications for LU assignment and other advanced functions.
- RESTRICTAPPL – This statement restricts Telnet acceptance of application names to only users that specify an acceptable User ID and password. It also optionally maps or confirms the mapping of an LU name to the client based on the application name and User ID chosen.

Client Identifiers: One client can be represented by many different Client Identifiers. For example, Telnet might assign an LU based on client host name, assign an application based on a client IP address, and assign a USS table based on connection link or interface name. See "Mapping Objects to Client Identifiers" on page 595 for details about how these Client Identifiers are used to map Objects. In some cases, two different Client Identifiers that represent the same client are used on mapping statements to map the same type of Object. In these cases, Telnet must determine which Client Identifier to use when assigning the Object. See "Client Identifier selection rules" on page 601 for more details. The complete list of Client Identifiers and mapping examples follow:

- User ID or USERGROUP name - If the CLIENTAUTH SAFCERT parameter is used with a secure connection, the client is required to send its client certificate to Telnet for client authentication. The SAFCERT option indicates that the client certificate can be translated to a User ID by a security product such as RACF. Telnet translates the certificate as soon as the SSL handshake is done. The resulting User ID is associated with the connection. Objects can be mapped to the connection based on an exact User ID, or Objects can be mapped to a USERGROUP name containing exact User IDs and wildcarded User IDs. For example, mobile employees need to be assigned a unique set of LU names and the manager must always be assigned LU name LUMOBL01. These employees are not within a secure network and always use client authenticated secure connections. Their certificates are translated to User IDs by Telnet.

  ```
  USERGROUP   USGMOBL1
     MOBL0002 MOBL0003
     MOBL1%%C
  ENDUSERGROUP
  LUGROUP LUGMOBL1
     LUMOBL02..LUMOBL20
  ENDLUGROUP
  LUMAP  LUMOBL01  USERID,MOBL0001       ; mgr mapping
  LUMAP  LUGMOBL1  USERGRP,USGMOBL1      ; employee mapping
  ```

  Rule: The specification of the Client Identifier type USERID is required on the mapping statement. If you do not specify this type, Telnet assumes that the name is a link or interface name.

  Tip: The specification of the Client Identifier type USERGRP is optional. The following statement is equivalent to the last LUMAP statement in the previous example:

  ```
  LUMAP  LUGMOBL1  USGMOBL1
  ```

- Host name or HNGROUP name - If the network dynamically assigns IP addresses, the same client will not have the same IP address from one connection to the next. With static host names, Objects can be mapped to clients based on their host name, or Objects can be mapped to HNGROUP names containing exact host names and wildcarded host names. For example,

LUADMNM is mapped to exact host name ADMIN.DEPT1.GROUP1.COM, and application INVENTRY is mapped to HNGROUP name HNGINV.

```
HNGROUP HNGINV
   INV1.DEPT1.GROUP1.COM
   *.DEPT3.GROUP1.COM
   **.GROUP3.COM
ENDHNGROUP
LUMAP LUADMNM  HOSTNAME,ADMIN.DEPT1.GROUP1.COM
DEFAULTAPPL    INVENTRY  HNGRP,HNGINV
```

Tip: The specification of the Client Identifier types HOSTNAME and HNGRP is optional. The following two mapping statements are equivalent to the last two statements in the previous example:

```
LUMAP LUADMNM  ADMIN.DEPT1.GROUP1.COM
DEFAULTAPPL    INVENTRY  HNGINV
```

- Client (source) IP address or IPGROUP name - Client IP address is the most common method used to map Objects to the client. In a static network, Objects can be mapped to clients based on the exact IP address, or Objects can be mapped to IPGROUP names containing exact IP addresses and subnets. For example, LUADMN is mapped to exact IP address 1.1.1.1, and application PAYROLL is mapped to IPGROUP name IPGPAY.

  ```
  IPGROUP IPGPAY
     1.1.2.2  1.1.2.3                  ;IPv4 addresses
     255.255.0.0:2.2.0.0               ;IPv4 subnet
     2001:0DB8:9:11:15:4               ;IPv6 address
     6C11:10::0/96                     ;IPv6 subnet
     6.1.3.4..6.1.3.8                  ;IPv4 range
     2AB0::12:5:1321..2AB0::12:5:1410  ;IPv6 range
  ENDIPGROUP
  LUMAP LUADMN IPADDR,1.1.1.1
  DEFAULTAPPL  PAYROLL IPGRP,IPGPAY
  ```

  Tips:

  – The specification of the Client Identifier types IPADDR and IPGRP is optional. The following two mapping statements are equivalent to the last two statements in the previous example:

    ```
    LUMAP LUADMN 1.1.1.1
    DEFAULTAPPL  PAYROLL IPGPAY
    ```

  – The IP/subnet combinations of 0.0.0.0:0.0.0.0 (IPv4 only) and 0::0/0 (IPv4 and IPv6) are special cases that include all connections. This might be useful if you want to have a default mapping with a higher priority than the NULL client identifier.

  – The client IP address can be either an IPv4 or IPv6 IP address. IP address ranges can also be specified and are treated as if individual IP addresses were coded. An IPv4 range can vary in the last octet only. An IPv6 range can vary in the last two hexadecimal bytes only.

- Destination IP address or DESTIPGROUP name - A destination IP address is the host address that is the destination for a Telnet connection. Linkname can be used as a Client Identifier to map Objects to destination IP addresses when the linkname is static and defined in the profile. However, if the destination IP address is a dynamic Virtual IP Address (VIPA) , the linkname is not known before the VIPA is created. In this case, destination IP address is the ideal solution. In other cases, specifying the destination IP address in the Telnet profile may be more clear than specifying the linkname. For example, two TCP/IP stacks are backups for each other. Telnet connections to stack 1 (VIPA 5.5.5.1) use logon manager application APPL1 by default, and connections to stack 2 (VIPA 51CB:C3E4::9:4) use logon manager application APPL2 by default. If one of the stacks becomes unavailable, the other will take over and

dynamically add the failing stack's VIPA. The dynamic linkname created is not easily predicted. Use the following statements in the profile of each stack to ensure users connecting to 5.5.5.1 always get APPL1 and users connecting to 51CB:C3E4::9:4 always get APPL2 regardless of which stack is used.

```
DEFAULTAPPL  APPL1 DESTIP,5.5.5.1
DEFAULTAPPL  APPL2 DESTIP,51CB:C3E4::9:4
```

Rule: The specification of the Client Identifier type DESTIP is required on the mapping statement. If you do not specify this type, Telnet assumes that the IP addresses are client (source) IP addresses.

Tip: When the destination IP address is the IP address of a dynamic XCF address, multiple linkname values can be associated with the IP address. Telnet will use the first linkname associated with the IP address in the home list. If a dynamic XCF destination is used as a Client Identifier, it is recommended that DESTIP be used instead of linkname. Results can vary using linkname.

- Linkname or LINKGROUP name - A linkname is defined by the TCP/IP LINK or INTERFACE statement. The linkname defines a host IP address that is a destination address for clients connecting to Telnet. Linkname can be useful in cases where Object assignment is dependent on the client destination IP address instead of the client source IP address. Several linknames may be defined and the same LU mapping or other Object mapping may be desired for several linknames. In this case, a LINKGROUP can be defined and used on a single mapping statement. For example, based on the statements below, a client connecting to LINK1 IP address will be assigned an LU from the LUGROUP name LUGLNKS and will establish a session with TPX1. A client connecting to LINK2 IP address will be assigned an LU from the LUGROUP name LUGLNKS and will establish a session with TPX2. Because LINK1 and LINK2 are not group names, host names, or IP addresses, they are assumed to be linknames. The Client Identifier type, LINKNAME, can be used for clarity but is not required.

  ```
  LINKGROUP    LNKGRP1
     LINK1 LINK2
  ENDLINKGROUP
  LUMAP        LUGLNKS  LINKGRP,LNKGRP1
  DEFAULTAPPL  TPX1     LINKNAME,LINK1
  DEFAULTAPPL  TPX2     LINKNAME,LINK2
  ```

  Tips:

  – The specification of the Client Identifier types LINKNAME and LINKGRP is optional. The following three mapping statements are equivalent to the last three statements in the previous example:

    ```
    LUMAP        LUGLNKS  LNKGRP1
    DEFAULTAPPL  TPX1     LINK1
    DEFAULTAPPL  TPX2     LINK2
    ```

  – When the destination IP address is the IP address of a dynamic XCF address, multiple linkname values can be associated with the IP address. Telnet will use the first linkname associated with the IP address in the home list. If a dynamic XCF destination is used as a Client Identifier, it is recommended that DESTIP be used instead of linkname. Results can vary using linkname.

- NULL (no Client Identifier) - The NULL Client Identifier type indicates that no Client Identifier was specified. The NULL Client Identifier is valid on the DEFAULTAPPL, LINEMODEAPPL, USSTCP, and INTERPTCP mapping statements. It is the implied Client Identifier for the DEFAULTLUS, DEFAULTLUSSPEC, DEFAULTPRT, and DEFAULTPRTSPEC Objects. ParmsGroup and MonitorGroup are the only Objects that cannot be mapped to the NULL Client Identifier. The NULL Client Identifier mapped Objects are the last Objects checked when assigning Objects to a client. For example, assume a client does not match any Client Identifier in the profile for DEFAULTAPPL or

USSTCP. You can put the end user into session with a security application, named SecAppl, that can verify the end user is authorized to use the company's system. The Client Identifier field is blank.

```
DEFAULTAPPL SECAPPL
```

Client Identifier selection rules: When Client Identifiers are used together, conflicts might occur. For example, host name NAME1.HOST1.COM may also be IP address 1.2.3.4. If the following DEFAULTAPPL statements exist, only one of the applications can be chosen.

```
DEFAULTAPPL  TSO  NAME1.HOST1.COM
DEFAULTAPPL  CICS 1.2.3.4
```

If USSTCP and DEFAULTAPPL have the same Client Identifier, DEFAULTAPPL will be used. For detailed information, see "Resolving DEFAULTAPPL and USS table conflicts" on page 611.

Telnet uses a very specific Client Identifier hierarchy when assigning Objects, as shown in "The mapping rule search order"

The mapping rule search order:

- **Exact client identifier:**
  - 1) User ID, 2) hostname, 3) IP address
- **Exact client identifier in a group definition:**
  - 4) User group, 5) hostname group, 6) IP address group
- **Wildcard match for client identifier in a group definition:**
  - 7) User group, 8) hostname group, 9) IP address group
- **Exact destination:**
  - 10) destination IP address, 11) link or interface name
- **Exact destination in a group definition:**
  - 12) destination IP address group, 13) link or interface name group
- **Wild card match for destination in a group definition:**
  - 14) destination IP address group, 15) link or interface name group
- **Null client ID**
  - 16) DEFAULTAPPL, LINEMODEAPPL, USSTCP, INTERPTCP, DEFAULTLUS, DEFAULTLUSSPEC, DEFAULTPRT, DEFAULTPRTSPEC

Examples:

- **Exact client identifier:**

```
1)  LUMAP   LU1     USERID,USER1
2)  LUMAP   LU2     NAME1.HOST1.COM
3)  LUMAP   LU3     1.2.3.4
```

  Client Identifier type USERID is required. If not specified, USER1 is assumed to be a link or interface name.

- **Exact client identifier in a group definition:**

```
LUGROUP   LUGRP1    LU100..LU199   ENDLUGROUP
LUGROUP   LUGRP2    LU200..LU299   ENDLUGROUP
LUGROUP   LUGRP3    LU300..LU399   ENDLUGROUP

    USERGROUP USRGRP1
      USER1 USER2 USER3
    ENDUSERGROUP
```

```
    HNGROUP  HNGRP1
         NAME2.HOST1.COM  NAME2.HOST3.COM
    ENDHNGROUP

    IPGROUP  IPGRP1
      1.2.3.5     1.2.3.6
      1.3.4.7..1.3.4.E
    ENDIPGROUP

4)  LUMAP   LUGRP1   USRGRP1
5)  LUMAP   LUGRP2   HNGRP1
6)  LUMAP   LUGRP3   IPGRP1
```

- **Wild card match for client identifier in a group definition:**

```
    USERGROUP USRGRP2
      USER%%  TCPU*
    ENDUSERGROUP

    HNGROUP  HNGRP2

15) LUMAP LUGRP2 LNKGRP2
```

- **Null client ID**

```
16) DEFAULTAPPL     TSO
    LINEMODEAPPL    CICS
    USSTCP          USSTAB1
    INTERPTCP       INTTAB1
    DEFAULTLUS
      LU01..LU99
    ENDDEFAULTLUS
```

NULL is a single Client Identifier. The order of the examples has no significance. If DEFAULTAPPL and USSTCP mapping statements both have the NULL Client Identifier, the DEFAULTAPPL will be used regardless of order. For more information, see "Resolving DEFAULTAPPL and USS table conflicts" on page 611.

Object assignment examples: A client can be known by several different Client Identifiers. These Client Identifiers are used to assign as many Objects as possible to the connection based on the profile mapping statements. Telnet starts with the highest priority Client Identifier of the client and assigns all Objects mapped by that Client Identifier. If all 11 Objects are not assigned, Telnet uses the next highest priority Client Identifier (for prioritization details, see "Client Identifier selection rules" on page 601) and assigns all Objects mapped by that Client Identifier. This Object assignment process continues by using lower and lower priority Client Identifiers until all 11 Object types are found or until all of the matching Client Identifier mappings have been checked. If an Object is mapped by multiple Client Identifiers, only the Object mapped by the highest Client Identifier is used. It is unlikely all Objects are assigned to connections because not all Objects are always mapped. For example, many profiles do not contain PRTDEFAULTAPPL or INTERPTCP mapping statements. In this case, the printer default appl and Interpret table Objects will not be assigned.

Figure 66 on page 604 is a graphical representation of the following Telnet mapping statements. The numbered mapping statements correspond to the numbered buttons in the figure. The mappings that specify USERGROUP USGRP1 generate buttons 4 through 8 for exact user ID in a group and buttons 12 through 16 for wildcard user ID in a group.

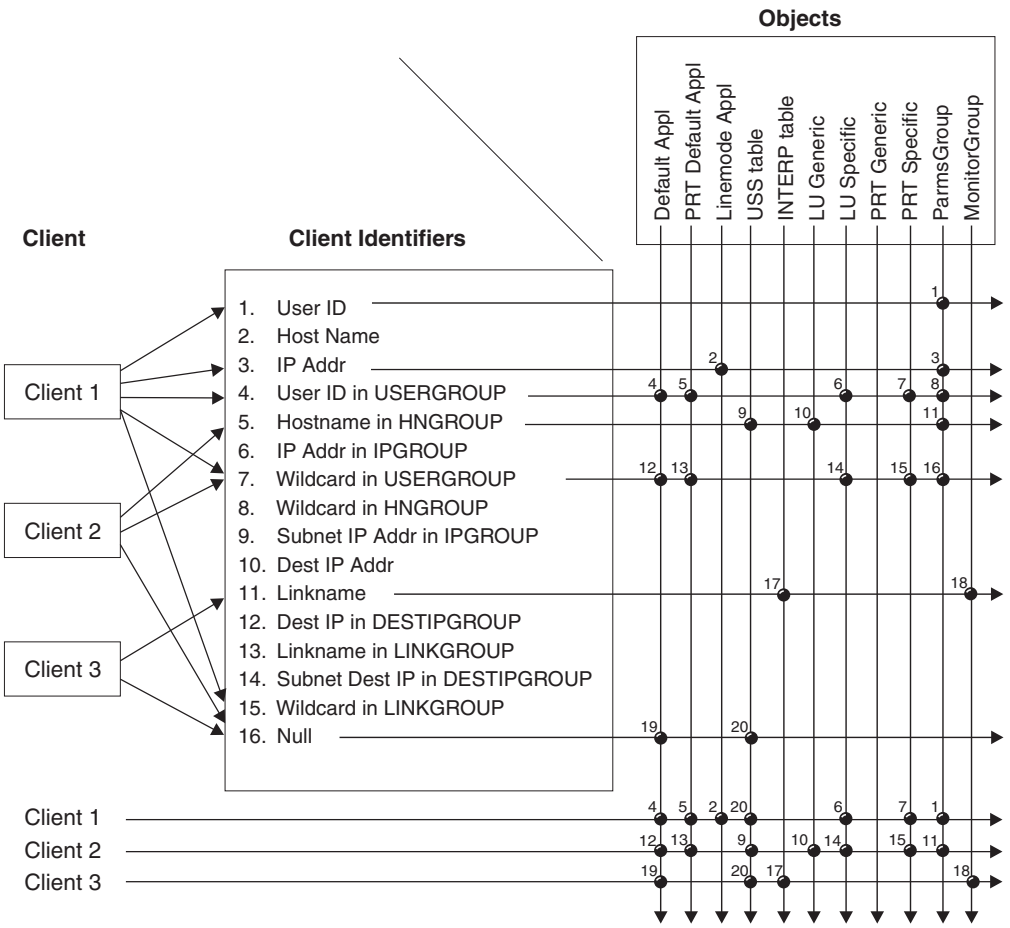

Figure 66. Search method

Client mappings: For this example, assume the following:

- Client 1 connects from IP address 9.9.9.9 using client authentication and is assigned PAYUSR1. The client does not have a host name ending in GROUP3.COM and does not have a link name LINK1.
- Client 2 connects from IP address 9.1.1.1 using client authentication and is assigned PAYUSR5. The client has the host name USER5.GROUP3.COM and does not have a link name LINK1.
- Client 3 connects from IP address 9.2.2.2 without client authentication and has the host name USER3.GROUP1.COM. The client connects to link name LINK1.

Based on Figure 66, the clients are assigned objects as shown in Table 29.

Table 29. Client mappings

Button	Object type	Name	Mapping results by client
1	ParmsGroup	PGALL	1: Assigned, exact user ID match 2: Ignored, no exact user ID match 3: Ignored, no exact user ID match

LU name mapping statements

Every connection must be represented by an LU name before a session can be initiated. The time of LU assignment depends on the connection type. In general, for TN3270E clients, the LU name is assigned early during connection negotiation before an application name is known. For all other types of clients, the LU name is assigned immediately after application name selection. For details and exceptions to this rule, see "Advanced LU name mapping topics" on page 613. Mapping statements define which LU name is assigned to the connection.

DEFAULTLUS: The simplest way to assign LUs is to create a default LU group that Telnet can use for all terminal connections. DEFAULTLUS is a combination statement that defines the LUs in a default group and maps the group to the NULL Client Identifier. If the client's Client Identifiers do not match any LU mapping statements, the client is identified by the NULL Client Identifier and will be assigned LUs from the default group.

For example, use the following statement to create an LU group with a numeric range of LUG1001 to LUG1100. When Telnet assigns an LU to a terminal connection, it will assign the next available LU from that group of 100 LUs.

```
DEFAULTLUS  LUG1001..LUG1100..FFFFNNN  ENDDEFAULTLUS
```

By default, Telnet uses a sequential selection method to assign LUs from the LU group. No LU name will be reused until all the names in the group have been used. Specifying NOSEQUENTIALLU changes the selection process to always start at the beginning and find the first name available. If the range is large and a large number of LUs are already assigned, NOSEQUENTIALLU might degrade LU lookup performance.

DEFAULTPRT: The DEFAULTPRT statement is used to create a default LU pool that Telnet will use for all printer connections. For example, use the following statement to create an LU group with a numeric range of PRTG1001 to PRTG1100. When Telnet assigns an LU to a printer connection, it will assign the next available LU from that group.

```
DEFAULTPRT  PRTG1001..PRTG1100..FFFFFNNN  ENDDEFAULTPRT
```

LUMAP, PRTMAP, LUGROUP, PRTGROUP: The LUMAP and PRTMAP statements allow you to map LUs to connections based on the Client Identifier for terminal emulators and printer emulators, respectively. For example, use the following statements to map LU name LUT001 to any terminal client identified by the client IP address 1.1.1.1 and map LU name PRT001 to any printer client identified by client IP address 2.2.2.2.

```
LUMAP  LUT001  1.1.1.1
PRTMAP PRT001  2.2.2.2
```

A local or shared LU group can be used when it is not necessary to have an exact LU name to Client Identifier match. For example, use the following statements to create a terminal LU group and a printer LU group, and map both groups to the Client Identifier IPGPAY. When a terminal client connects, Telnet will assign an LU from LUGRP1. When a printer client connects, Telnet will assign an LU from PRTGRP1.

```
LUGROUP   LUGRP1    LUT101..LUT400..FFFNNN   ENDLUGROUP
PRTGROUP  PRTGRP1   PRT101..PRT400..FFFNNN   ENDPRTGROUP

IPGROUP IPGPAY   255.255.0.0:9.8.0.0  ENDIPGROUP

LUMAP    LUGRP1   IPGPAY
PRTMAP   PRTGRP1  IPGPAY
```

If these same LUs can be mapped by more than one Telnet, put them into shared LU groups instead by adding an S to the object type as follows:

```
SLUGROUP   LUGRP1    LUT101..LUT400..FFFNNN   ENDSLUGROUP
SPRTGROUP  PRTGRP1   PRT101..PRT400..FFFNNN   ENDSPRTGROUP
```

Once all 300 LUs are assigned, the next client connection request will fail. In this way, the LUGROUP Object can limit the number of clients connected at one time.

If a client connection is known by a Client Identifier that has an LU group mapping, only that mapping will be used to assign an LU name. The DEFAULTLUS group will not be used. It is used only in the case when no other LU mapping exists.

LU range specification: Telnet LU range rules allow for almost any type of LU range needed. Ranges can be alphabetic (A), numeric (N), alphanumeric (B), hexadecimal (X), or a complete wildcard (?), which includes alphanumeric and the three national characters (@,#,$). The range type can be different for each character position. Within the LU range, any character position can be fixed (F). To conform with VTAM LU naming convention, the first character must be alphabetic or a national character. If the first character is a range, only the alphabetic range can be used.

An LU range is created by specifying a starting LU name, an ending LU name, and the range rules to be used. For example, the following statement creates a range from TCPM1000 to TCPM1100.

```
TCPM1000..TCPM1100..FFFFFNNN
```

The three components are:

- Starting LU name (TCPM1000)
- Ending LU name (TCPM1100)
- Range rules (FFFFFNNN)

All three components must be the same length, the Starting LU name overall must be lower than the Ending LU name, and each character position value must be appropriate for the specified range rule.

Tip: In the above example, the character 1 following the character M is defined as fixed because it cannot change. The range rule cannot specify N even though it seems to be part of the number range.

The ascending order of characters is 0-9, A-Z, @, #, $.

If the range rule is omitted, Telnet assumes the following style, where LowerRange and UpperRange must be all numeric or all alphabetic:

```
LuBase+LowerRange..LuBase+UpperRange
```

Numeric values are lower than alphabetic values to facilitate the use of hexadecimal ranges. The range rules are:

```
Range        Rule       Characters
Numeric       N          0-9
Alphabetic    A          A-Z
AlphaNumeric  B          0-9,A-Z
Hexadecimal   X          0-9,A-F
Wildcard      ?          0-9,A-Z,@,#,$
```

The maximum number of LUs per range is 4294967295 and the maximum number of LUs per group is 4294967295.

The creation of LU name values from the range specification begins at the Starting LU and increments the rightmost variable position first, moving to the left as each variable position reaches its range maximum. The process is like an odometer, except that each position can have different basing instead of all positions being base 10. For example, the following statement has 223 LU name entries.

```
LU555..LU777..FFNNN
```

The breakdown of the range is:

```
LU555->LU559,                                                 5
LU560->LU569, LU570->LU579, LU580->LU589, LU590->LU599,      40
LU600->LU699,                                               100
LU700->LU769, LU770->LU777                                   78
                                                            ===
Total  ---------------------------------------------------> 223
```

The LU names increment just as the numbers on an odometer would. A less intuitive case involves an alphabetic range of 1407 LU name entries.

```
LUCCC..LUEEE..FFAAA
```

The breakdown of the range is:

```
LUCCC->LUCCZ,                                                  24
LUCDA->LUCDZ, LUCEA->LUCEZ, LUCFA->LUCFZ, ... LUCZA->LUCZZ,   598
LUDAA->LUDZZ,                                                  676
LUEAA->LUEDZ, LUEEA->LUEEE                                     109
                                                              ====
Total  ------------------------------------------------------> 1407
```

It is important to realize that these ranges do *not* break down in the following patterns:

```
LUCCC->LUCCE, LUCDC->LUCDE, LUCEC->LUCEE, ...
LU555->LU557, LU565->LU567, LU575->LU577, ...
```

It is an incorrect assumption that the LU name after LUCCE would be LUCDC. The correct LU name after LUCCE is LUCCF. The LU names increment to LUCCZ and the next name is LUCDA. When the rightmost position reaches the range maximum, the position to its left is incremented by one, and the rightmost position starts at the range beginning, not the character specified in the Starting LU name.

All range types are handled the same way. The position is incremented to its maximum value and then wraps to the beginning range value, not the specified

Starting LU name value. By the same logic, the position is incremented to the ending range value and not the Ending LU name value.

All LU names increment the same way. A more complicated example mixes fixed and variable character positions with several different range types. The LU range has 39744 LUs.

```
LUAD1800..LUGD98FZ..FFAFNFXB
```

Calculating the number of LUs is easier if the fixed positions are removed. For purposes of calculating the number of LUs, the range is specified as follows:

```
A100..G9FZ..ANXB
```

This breaks down as follows:

```
A100->A10Z, D110->D11Z, ... A190->A19Z, A1A0->A1AZ ... A1F0->A1FZ    576
A200->A2FZ, A300->A3FZ, ... A900->A9FZ                              4608
B000->B9FZ, C000->C9FZ, ... F000->F9FZ                             28800
G000->G9FZ                                                          5760
                                                                    =====
Total ------------------------------------------------------------> 39744
```

SEQUENTIALLU: Telnet, by default, uses a sequential method to choose LUs from a group.

```
LUGROUP  LUGRP1
     LU001..LU120..FFNNN
     LU201..LU250..FFNNN
     LU240..LU280..FFNNN
     LU010..LU050..FFFNN
ENDLUGROUP
```

From the previous example, the first LU assigned is LU001, second is LU002, and so on. If five clients repeatedly connect and disconnect, they will be assigned new LUs farther into the range each time:

- When the end of the first range is reached, selection goes to the beginning of the second range.
- At the end of the second range, selection goes to the beginning of the third range.
- At the end of the third range, selection goes to the beginning of the fourth range.
- At the end of the fourth range, selection goes to the beginning of the first range again.

Telnet does not enforce an overall ascension in LU name selection. The selection process begins at the first name of the first range and progresses to the last name of the last range. In the example, after LU250 is assigned from range 2, LU240 from range 3 is attempted next. After LU280, LU010 is attempted. After LU050, the process starts over and LU001 is attempted.

The SEQUENTIALLU function can be turned off by coding NOSEQUENTIALLU. In this case, the five LUs that are repeatedly connecting and disconnecting would never use any LU names other than LU001, LU002, LU003, LU004, and LU005. NOSEQUENTIALLU might degradate LU lookup performance when a large range is specified and only LUs at the end of the range are available. Every connection has to relearn that most of the LUs are already in use. SEQUENTIALLU allows Telnet to start its search near the last chosen LU where LUs are more likely to be available. SEQUENTIALLU and NOSEQUENTIALLU parameters can be coded at all three parameter block levels for different levels of granularity.

If several clients are connecting at the same time, the order of LU assignment might not be in exactly the same order as the connection IDs due to process timing between connection ID assignment and LU name assignment.

If single LU names are in a group with LU ranges, the single LU names are selected before any LU range names are selected, regardless of their order. In the example below, LUAAA, LUBBB, LUCCC, and LUDDD are all processed before any of the range LU names.

```
 Profile LUGROUP                                LUGROUP as used by Telnet

LUGROUP  LUGRP2                                   LUGROUP  LUGRP2
     LUAAA                                             LUAAA
     LU001..LU120..FFNNN                               LUDDD
     LU201..LU250..FFFNN                               LUBBB
     LUDDD                                             LUCCC
     LUBBB                                             LU001..LU120..FFNNN
     LU240..LU280..FFFNN                               LU201..LU250..FFFNN
     LU010..LU050..FFFNN                               LU240..LU280..FFFNN
     LUCCC                                             LU010..LU050..FFFNN
ENDLUGROUP                                        ENDLUGROUP
```

Application mapping statements

When a client connects, Telnet either immediately initiates a session request to an MVS host VTAM application or solicits the end user for an application name.

DEFAULTAPPL: The DEFAULTAPPL mapping statement is used to assign an application name to the connection and immediately initiate a session with that application, and not solicit the end user for an application name. The DEFAULTAPPL statement applies only to terminal emulators connecting in TN3270, TN3270E, or DBCSTRANSFORM mode. For example, use the following statement to map the default application PAYROLL to any TN3270(E) terminal client identified by the IPGROUP IPGPAY. When a TN3270(E) client connects, Telnet will immediately initiate a session to the PAYROLL application.

```
DEFAULTAPPL PAYROLL IPGPAY
```

PRTDEFAULTAPPL and LINEMODEAPPL: The PRTDEFAULTAPPL mapping statement is used to assign an application to a printer emulator client connecting in TN3270E mode. The LINEMODEAPPL mapping statement is used to assign an application to a client connecting in standard or binary LINE mode. For example, use the following statements to map the default application PAYPRINT to any TN3270E printer client identified by the IPGROUP IPGPAY and to map the default application TSO to any linemode client identified by the linkname LINK1. When the printer client connects, Telnet will immediately initiate a session to the PAYPRINT application. When a linemode client connects, Telnet will immediately initiate a session to the TSO application.

```
PRTDEFAULTAPPL PAYPRINT IPGPAY
LINEMODEAPPL  TSO  LINK1
```

The DEFAULTAPPL, PRTDEFAULTAPPL, and LINEMODEAPPL statements imply a basic ALLOWAPPL statement for the application name if no ALLOWAPPL or RESTRICTAPPL is explicitly coded.

USSTCP: If the end user needs the ability to choose an application, custom solicitation panels can be created using unformatted system services (USS) message tables. These tables are mapped to clients using the USSTCP mapping statement. For example, use the following statement to map a USS table, USSTAB1, to any

TN3270(E) client identified by any linkname that starts with LINK. When a TN3270(E) client connects, Telnet will immediately send a custom logon screen (USSMSG10) from the USS table.

```
LINKGROUP  LNKGRP1  LINK*   ENDLINKGROUP
USSTCP USSTAB1 LINKGRP1
```

Assembled USS tables used by VTAM can also be used by Telnet.

INTERPTCP: In some cases, the application name must be generated based on the name provided by the end user or the name might be dependent on the LU name representing the client. The INTERPRET table can provide this function. Telnet uses the input from the USSMSG10 screen as input to the INTERPRET table translation list or uses the USSMSG10 input and the LU name as input to one of the INTERPRET table user-written exits. Because USS logon data is required input to the INTERPRET process, any client with an INTERPRET table mapping must also have a USS table mapping. For example, use the following statement to map an INTERPRET table, INTTAB1, to any TN3270(E) client identified by the linkname LINK1. When a TN3270(E) client connects to LINK1, Telnet will immediately send a custom logon screen (USSMSG10) from the USS table. The end user responds with a USS logon command. LINK1 client input is then processed through the INTTAB1 INTERPRET table to derive an application name. Telnet uses the derived name to initiate a session.

```
LINKGROUP LNKGRP1
     LINK*
ENDLINKGROUP
USSTCP    USSTAB1 LNKGRP1
INTERPTCP INTTAB1 LINK1
```

Assembled interpret tables used by VTAM can also be used by Telnet.

If neither a default application nor a USS table is mapped to the connection, the Telnet Solicitor panel is sent to the end user. For a detailed discussion of the Telnet Solicitor, USS table, and INTERPRET table, see “Using the Telnet Solicitor or USS logon panel” on page 637.

Resolving DEFAULTAPPL and USS table conflicts: If both a default application and a USS table are mapped to the same Client Identifier, Telnet will use the default application to immediately initiate a session. If each is mapped by a different Client Identifier, the Object mapped by the higher priority Client Identifier is used. In all cases, any error messages are sent using the USS table messages. For example, if CICS and USSTAB1 are both mapped to destination IP address 1.1.1.1, Telnet will initiate a session with CICS and use the USS messages for any session setup errors.

If CICS is mapped to USERID USER1 and USSTAB1 is mapped to client IP address 5.5.5.5, Telnet will initiate a session with CICS and use the USS messages for any session setup errors.

If CICS is mapped to linkname LINK1 and USSTAB1 is mapped to hostname TEST1.IBM.COM, Telnet will send a USSMSG10 logon panel to the end user. The USS messages will be used for any session setup errors. The default application mapping of CICS will never be used.

ALLOWAPPL: Telnet will not initiate a session for a solicited application name unless the name is allowed. The ALLOWAPPL statement is used to configure Telnet to allow the initiation request. For example, CICS01 and CICS02 are allowable names.

```
ALLOWAPPL CICS01
ALLOWAPPL CICS02
```

The ALLOWAPPL name can have a wildcard value by using an asterisk (*). For example, if there are no other CICS regions, these lines could be reduced to the following:

```
ALLOWAPPL CICS*
```

All application names can be allowed by coding the following:

```
ALLOWAPPL *
```

Default application names do not need to be explicitly allowed. However, if the default application issues a CLSDST-PASS to another application name for the session, the second application must be in the ALLOWAPPL list. For example, TSO is the default application for the NULL Client Identifier. TSO typically passes the session to TSO00001, TSO00002, and so on. The following default application mapping will initiate a session with TSO, but when TSO issues a CLSDST-PASS the new bind to Telnet will have TSO00001 as the application name.

```
DEFAULTAPPL TSO
```

Telnet will fail this session request because TSO00001 is not allowed. Add an ALLOWAPPL statement to allow the TSO* names as follows:

```
DEFAULTAPPL TSO
ALLOWAPPL   TSO*
```

RESTRICTAPPL: In addition to the ALLOWAPPL statement, Telnet provides more restrictive access to applications. The RESTRICTAPPL statement requires the end user to enter a valid RACF user ID and password before the application name is used to initiate a session. This user ID is different than the Client Identifier user ID derived from the client certificate. This user ID is used only as a security check.

For example, use the following statement to allow users USER1, USER2, USER3, USER4, and USER5 access to the PAYROLL application. At the Solicitor panel, the end user enters USER1/password and the PAYROLL application name. Telnet verifies USER1/password is valid and then immediately initiates a session with PAYROLL.

```
RESTRICTAPPL PAYROLL
   USER USER1
   USER USER2
   USER USER3
   USER USER4
   USER USER5
```

Like ALLOWAPPL, the application name can have a wildcard value by using an asterisk (*). The USER value can also have a wildcard value by using an asterisk. The user ID/password combination is used by Telnet to verify the password given for that user ID. In no way is the user ID or password used by the application. No matter how the application name request arrived at the server (from DEFAULTAPPL or USSMSG10), Telnet uses the Solicitor panel to prompt for the user ID/password. Once the user ID is validated and a password is obtained, Telnet submits the user ID/password pair for authorization to a security program such as RACF. The user ID/password check authorizes the client to connect to the application through Telnet. The application itself might also ask for a user ID/password pair that can be completely different than the pair entered at the Telnet Solicitor panel. The user ID/password pair entered at the Telnet Solicitor panel is not in any way passed to the host application. The user ID/password pair

is solicited only after an application name is entered on the Solicitor (or USSMSG10) panel. If a second application is reached through the original application using CLSDST-PASS, the second application is verified and Telnet will solicit a new user ID/password pair if necessary.

When searching for a match with the input application name, Telnet will find the most specific match whether it is on the ALLOWAPPL or RESTRICTAPPL statement. If each statement has the same name specified, the RESTRICTAPPL entry is used. For example, TSO has its own user ID/password requirement and probably does not need the additional Telnet security check. However, the Telnet security check may be needed for all other applications. This example can be supported with the following statements.

```
RESTRICTAPPL   *
  USER   *
ALLOWAPPL   TSO*
```

Connection parameters mapping statement

Connection parameters are typically defined once at the port level. Sometimes it is useful to have different connection parameters depending on the Client Identifier. The PARMSGROUP and PARMSMAP statements allow connection parameters to be mapped at the Client Identifier level. This level of granularity applies to almost all parameters. See *z/OS Communications Server: IP Configuration Reference* for a list of Telnet parameters allowed in the PARMSGROUP block.

Assume the PAYROLL department is assigned the highest level of security and connections are being monitored with summary debug messages, general users are assigned negotiable security, and inventory employees are experiencing intermittent problems with Telnet connections that require detailed debug messages for resolution. The following statements assign the security and debug levels to the areas needed and do not affect other areas. See "Transport Layer Security" on page 582 for security information and "Telnet diagnostic tools" on page 561 for debug information.

```
HNGROUP   HNGINV
  **.GROUP3.COM
ENDHNGROUP
IPGROUP   IPGPAY
  255.255.0.0:2.2.0.0

ENDPARMSGROUP
PARMSGROUP   PRMGSEC1
  CONNTYPE SECURE
  ENCRYPTION SSL_3DES_SHA  ENDENCRYPTION
  DEBUG SUMMARY
ENDPARMSGROUP
PARMSGROUP   PRMGSEC2
  CONNTYPE NEGT
  ENCRYPTION SSL_RC4_MD5   ENDENCRYPTION
ENDPARMSGROUP
PARMSMAP   PRMGDBG  HNGINV
PARMSMAP   PRMGSEC1 IPGPAY
PARMSMAP   PRMGSEC2 IPGGEN
```

Advanced LU name mapping topics

Beyond the basic LU mapping statements, there are several functions available to the advanced user. This topic includes the following subtopics:

- Generic and Specific connection requests
- Mapping groups to Client Identifiers
- LU name assignment user exit
- Associated printer function
- Map default application and ParmsGroup by LU group
- Multiple LUMAP statements for one Client Identifier
- Keep LU for the Client Identifier
- LU group capacity warning
- LU mapping by application name
- LU mapping selection rules
- LU mapping with multilevel security active

Generic and Specific connection requests: There are three types of Telnet connection requests that dictate how Telnet chooses a name to represent the client. They are Generic requests, Specific requests, and associated printer requests. For details about associated printer requests, see "Associated printer function" on page 617. Most connection requests are Generic requests.

For Generic requests, Telnet has complete control over LU name assignment using the Generic mapping statements as a reference. All linemode and TN3270 connections use only Generic requests, and TN3270E terminal and printer emulators use Generic requests as their default request type. Specific mapping statements are ignored by Generic requests.

For Specific requests, the TN3270E client specifies the LU name to be used. Telnet validates the name using the Specific mapping statements as a reference. Requesting a Specific LU name allows a client to be assigned the same LU every time. This is important if the host application is LU name dependent, and the client does not have a constant Client Identifier to use for mapping an LU name. It is also important to block Telnet from assigning these LUs to Generic requests. That is why Specific mapping statements are ignored by Generic requests. If a Specific mapping does not find an LU match, Generic mapping statements are checked. Telnet confirms or denies the request during negotiation. If the LU mapping algorithms reject the client choice, Telnet sends a device type reject to the client. Most clients then notify the end user that the requested LU name is not valid or is already in use.

Default LU groups: DEFAULTLUS and DEFAULTPRT are default local LU groups for Generic requests from terminal and printer emulators. SDEFAULTLUS and SDEFAULTPRT are default shared LU groups for Generic requests from terminal and printer emulators. DEFAULTLUSSPEC and DEFAULTPRTSPEC are default local LU groups for Specific requests from terminal and printer emulators. SDEFAULTLUSSPEC and SDEFAULTPRTSPEC are default shared LU groups for Specific requests from terminal and printer emulators. DEFAULTLUS and DEFAULTPRT are explained in "LU name mapping statements" on page 606. Like the Generic pools, the Specific pools are checked only if there is no other LU mapping statement match. For example, use the following statements to create a terminal LU group with a numeric range of LUS1001 to LUS1100 and a printer LU group with a numeric range of PRTS1001 to PRTS1100. When Telnet receives a Specific connection request from a terminal, it will verify that the requested LU name is within the range specified.

```
DEFAULTLUSSPEC  LUS1001..LUS1100..FFFFNNN  ENDDEFAULTLUSSPEC
DEFAULTPRTSPEC  PRTS1001..PRTS1100..FFFFFNNN  ENDDEFAULTPRTSPEC
```

The sequential selection rules do not apply to Specific requests.

Mapping groups to Client Identifiers: The LUMAP and PRTMAP statements allow LUs to be mapped based on a Client Identifier. The LU group can be mapped Generically or Specifically. The default mapping is Generic. The keyword SPECIFIC must be coded to define a Specific mapping.

For example, use the following statements to create two LU groups. Map one group Generically to the IP group IPGPAY and map the other group Specifically to the same Client Identifier. When a Generic connection request is received, Telnet will assign the next available LU from LU group LUGRPGEN. When a Specific connection request is received, Telnet will verify the requested LU name is included in the LU group LUGRPSPC. If it is, Telnet will assign the LU name to the connection.

```
LUGROUP   LUGRPGEN  LUG101..LUG400..FFFXXX   ENDLUGROUP
LUGROUP   LUGRPSPC  LUS001..LUS100..FFFXXX   ENDLUGROUP

IPGROUP IPGPAY   255.255.0.0:9.8.0.0  ENDIPGROUP

LUMAP    LUGRPGEN   IPGPAY
LUMAP    LUGRPSPC   IPGPAY  SPECIFIC
```

Generic request connections can be assigned LUs only from Generically mapped LU groups. If no Generic mapping exists, the DEFAULTLUS group is checked. No Specific group is checked. This safeguards the Specific LU names from being used by Generic requests.

For Specific requests, Telnet first checks to see if the LU is in a Specifically mapped LU group. If the LU name is not found, the Generically mapped groups are searched. If neither LU group type contains the requested LU name, the connection request is rejected. The DEFAULTLUSSPEC group is *not* checked in this case because LU group mappings exist. If no LU group mappings exist, only the DEFAULTLUSSPEC group is checked. If the LU name is not found, the connection request is rejected. The Generic DEFAULTLUS group is *not* checked.

In addition to requesting an exact LU name, the client can request an LU group name. Telnet first searches within the mapped groups, assuming the name is an exact LU name. If that search fails, Telnet then checks the requested name against mapped Specific LU group names and then checks the name against mapped Generic LU group names. If the group name is found, the next available LU in the group is assigned using sequential LU selection unless it has been turned off.

The LU group itself is not defined as Generic or Specific. Rather, the LU group is *mapped* Generically or Specifically. It is possible to map the same LU group both Generically and Specifically. IBM recommends that you do not map the same group Generically and Specifically unless you are an advanced user.

LU name assignment user exit: Most LU assignment requirements can be satisfied using the Telnet LU group and LU mapping statements. However, there are cases when the LU assignment requirements are so specific that Telnet cannot satisfy them. In these cases, the LU name assignment user exit might be the solution. The LU name exit is defined like an LUGROUP and is mapped the same way LUGROUPs are mapped. The LUGROUP is defined as an exit by specifying *,EXIT* immediately after the LUGROUP name. For LUGROUPs, Telnet selects an LU from the group, verifies its availability, and assigns the LU to the connection. For LU name exits, Telnet calls the user-written assembler program passing a parameter list that contains client and other information. The program creates the

LU name, places it in the parameter list, and returns control to Telnet. Telnet will then verify the LU name's availability and assign the LU to the connection. An LU name exit cannot be dynamically updated. Once it is loaded, it remains unchanged until Telnet is recycled. To make a change without recycling Telnet, the exit name must be changed. The new name can then be added on a mapping statement. For a detailed description of the parameter list and coding requirements for the Telnet LU exit, see *z/OS Communications Server: IP Configuration Reference*.

Version 2 of the LU exit allows the exit to override Telnet profile assigned USS (3270 or SCS format) and interpret tables. The values assigned by the Telnet profile or blanks are passed into the exit. The exit can override any of the three values and Telnet will use the new values. For details on Telnet LU exit setup, see *z/OS Communications Server: IP Configuration Reference*.

In addition to client information, the parameter list includes any LU names or ranges that were coded in the LUGROUP, and the requested application name if known. Telnet does not use the LU list. The LUs specified can be used as seed values if the LU name exit wants to use them. The LUGROUP can be defined without any LUs specified. However, if the exit is used with multilevel security, at least one LU must be specified so the LUGROUP can be assigned a security label. For details, see "LU mapping with multilevel security active" on page 624.

The LU name exit is called when the LU is assigned, when the LU is released, when the LU is inactivated, and when the LU is activated. A different function code is used for each type of call. If you do not need a certain function, like tracking inactivated LUs, the LU name exit can be written to ignore the function code. Telnet allows only one connection at a time to use the LU name exit, which serializes its use in case any local tables are maintained in the exit.

As an example, assume LU names are to be assigned based on client port number and application requested. The SIMCLIENTLU parameter is used to postpone TN3270E LU assignment until the application name is known. The parameter list includes the client port number and the requested application name. In this case, no seed LU names are needed. The LU name exit will create LU names based on the port number and application name in the parameter list.

```
LUGROUP  LUEXIT1,EXIT
ENDLUGROUP
```

In another example, assume that the clients specify LUGROUP names that match the default applications on the LUMAP statement. The LU names are to be created based on the last two numbers of the IP address and a prefix that identifies the application. For example, TSO, IMS, and CICS are three current applications, and the prefix for each is TS, IM, and CI, respectively. The connection from IP address 9.1.240.111 specifies LUGROUP LUGTSO and is assigned the name TS240111. The connection from IP address 9.1.240.212 specifies LUGROUP LUGIMS and is assigned the name IM240212. The connection from IP address 9.1.89.7 specifies LUGROUP LUGTSO and is assigned the name TS089007. Three LU name exits are required (LUGTSO, LUGIMS, LUGCICS), but they are all functionally equivalent. The LU name specified in the LUGROUP statement is passed to the LU name exit as part of the parameter list, and that name is used by the exit as the prefix. The client IP address is also in the parameter list. To force Telnet to call each exit, the LU name exit must return a nonzero return code when the LU name sent by the client does not match the LUGROUP name. The LU name exit combines the prefix with the last portions of the IP address to create an LU name. The following statements can be used to support this scenario.

```
IPGROUP  IPGRP1  0.0.0.0:0.0.0.0  ENDIPGROUP  ; Matches all connections

LUGROUP  LUGTSO,EXIT    TS       ENDLUGROUP
LUGROUP  LUGIMS,EXIT    IM       ENDLUGROUP
LUGROUP  LUGCICS,EXIT   CI       ENDLUGROUP

LUMAP  LUGTSO  IPGRP1  DEFAPPL  TSO
LUMAP  LUGIMS  IPGRP1  DEFAPPL  IMS
LUMAP  LUGCICS IPGRP1  DEFAPPL  CICS
```

Capacity checks cannot be performed since Telnet has no way of knowing how many total LUs are available in the LU name exit.

Associated printer function: The associated printer function allows a printer emulator to specify an active LU terminal name during connection negotiation. Telnet understands this special request and knows to assign a printer LU name that is associated with the requested terminal LU name. You establish the association by linking a pool of terminal LUs (LUGROUP or SLUGROUP) with a pool of printer LUs (PRTGROUP or SPRTGROUP). The groups are linked with the LUMAP statement. The printer LU group name is linked to the terminal LU group name by adding the PRTGROUP name on the LUMAP statement.

The two LU groups *must* have the same number of LUs defined so the LUs can be paired. The groups must have the same number of single LU names, the same number of LU ranges, and the same number of LU names in each range. If the groups do not have the same number of LUs defined, error messages will be produced during profile processing.

Once the groups are linked, Telnet assigns the *n*th printer LU to a printer connection that requests association with the *n*th terminal LU. For example, a CICS table might specify that if terminal LU1 is requesting printer function, the output should be routed to printer PRT1. Within CICS, LU1 and PRT1 are associated with each other. Use the following statements to set up printer association.

```
LUGROUP  LUGCICS   LU1..LU9           ENDLUGROUP
PRTGROUP PRTCICS   PRT1..PRT9         ENDPRTGROUP
IPGROUP  IPGRP9    255.0.0.0:9.0.0.0  ENDIPGROUP
LUMAP  LUGCICS  IPGRP9  GENERIC  PRTCICS
```

To use shared groups, change the first two lines to indicate that the groups are shared:

```
SLUGROUP  LUGCICS   LU1..LU9           ENDSLUGROUP
SPRTGROUP PRTCICS   PRT1..PRT9         ENDSPRTGROUP
```

Rule: If you are using sysplex distributor to distribute connections across Telnet servers with associated printers, regardless of whether the LUs are in local groups or shared groups, you must use timed client affinity to ensure that the clients connect to the same Telnet server.

If the terminal connection matches a DEFAULTAPPL or LUMAP-DEFAPPL mapping statement, Telnet immediately initiates a session request for the specified application. If the printer connection matches a PRTDEFAULTAPPL mapping statement, Telnet immediately initiates a session request for the specified application. Building on the previous example, use the following statements to set CICS as the default application for both the terminal and printer connections:

```
LUMAP LUGCICS IPGRP9 GENERIC DEFAPPL CICS PRTCICS
PRTDEFAULTAPPL CICS
```

Neither the LU group nor the printer group can be an LU exit group. If either is an LU exit, the mapping statement will be rejected.

Drop the printer connection when dropping the terminal connection: In many cases, the associated printer connection should be dropped when the terminal connection is dropped. If you code the DROPASSOCPRINTER parameter, Telnet will monitor the terminal connection. When the terminal connection is dropped, Telnet will initiate the closing and dropping of the printer connection. The DROPASSOCPRINTER and NODROPASSOCPRINTER parameters can be coded at all three parameter block levels for different levels of granularity.

Map default application and ParmsGroup by LU group: The DEFAPPL option on the LUMAP statement allows a host VTAM application to be mapped with an LU name or LUGROUP name instead of using DEFAULTAPPL. The LUMAP-DEFAPPL combination is treated just like DEFAULTAPPL when a Client Identifier matches the LUMAP statement. The LUMAP-DEFAPPL combination also supports the LOGAPPL, FIRSTONLY, and DEFONLY parameters that are used by DEFAULTAPPL, PRTDEFAULTAPPL, and LINEMODEAPPL. The LUMAP-DEFAPPL combination is a powerful statement when used with multiple LUMAP statements for the same Client Identifier. If the LUMAP-DEFAPPL or PRTMAP-DEFAPPL statement is coded and the default application is not available, an error screen will be sent to the client whether or not MSG07 is coded.

The PMAP option on the LUMAP statement allows assignment of connection parameters based on LU or LU group name. When the LU is assigned, the parameter values specified in the PMAP PARMSGROUP will override the parameter value specified in TELNETGLOBALS, TELNETPARMS, or PARMSGROUP mapped to this connection's Client Identifier. For example, any client residing in subnet 9.0.0.0 that specifies the LU group LUGTSO will immediately have a session initiated to TSO with the LOGAPPL function, and the TIMEMARK time will be set for two hours instead of the default three hours.

```
IPGROUP    IPGRP9  255.0.0.0:9.0.0.0             ENDIPGROUP
LUGROUP    LUGTSO  TCPTSO01..TCPTSO99..FFFFFFNN  ENDLUGROUP
PARMSGROUP PGRPT2  TIMEMARK 7200                 ENDPARMSGROUP
LUMAP     LUGTSO  IPGRP9  DEFAPPL TSO LOGAPPL  PMAP PGRPT2
```

An LUMAP-DEFAPPL defined default application name is always used if specified, regardless of USSTCP mappings. LUMAP-DEFAPPL has a higher priority than any DEFAULTAPPL or USSTCP. The connection parameters assigned using LUMAP-PMAP will override any other setting of the parameters. However, not all parameters have a meaningful use by the time the LU is assigned. For example, NOTN3270E controls whether or not Telnet should negotiate for TN3270E. That negotiation is done before LU assignments. For information on which parameters can be properly applied with LUMAP-PMAP, see the parameter table in *z/OS Communications Server: IP Configuration Reference*.

The PRTMAP statement supports PRTMAP-DEFAPPL and PRTMAP-PMAP in the same manner as LUMAP-DEFAPPL and LUMAP-PMAP.

Multiple LUMAP statements: Another feature of Specific LU name requests is that the client can specify an LUGROUP name, and Telnet will assign an available LU from that pool. This capability is useful when different applications require different LU naming schemes, but each end user client does not need to use an exact LU name for each emulator. For example, an administrator can create three pools, one for each of three applications. Only three client emulators need to be set up. One for TSO which requests LU name LUTSO, one for CICS which requests LUCICS, and one for IMS which requests LUIMS. Assume the general users are in

subnet 3.0.0.0. Any client connecting with a Client Identifier of IPGGEN can be set up to issue a Specific request for LU pool LUTSO, LUCICS, or LUIMS, and will be assigned an LU from the appropriate pool.

After an LU is assigned, the DEFAPPL option will cause Telnet to immediately issue a session request for the appropriate application. If LOGAPPL is coded and the application is not active, VTAM will continue session initiation once the application is active.

In most cases, DEFAPPL on multiple Generic LUMAPs is not useful. LUs are assigned in order starting with the first LUMAP statement. One case that may be useful is if an application has a user limit but can be cloned. Assume the INVENTRY application can support only 20 users but can be cloned. Multiple LUMAPs with DEFAPPL will direct the first 20 HNGINV clients to INVENTRY, the next 20 HNGINV clients to INVENTR2, and the next 20 HNGINV clients to INVENTR3.

```
IPGROUP  IPGGEN
     255.0.0.0:3.0.0.0
ENDIPGROUP
LUGROUP  LUTSO   TSO00001..TSO00999  ENDLUGROUP
LUGROUP  LUCICS  CICS0001..CICS0999  ENDLUGROUP
LUGROUP  LUIMS   IMS00001..IMS00999  ENDLUGROUP
HNGROUP  HNGINV
  *.INVDEPT.COM
ENDHNGROUP
LUGROUP  LUGINV1 LUINV01..LUINV20    ENDLUGROUP
LUGROUP  LUGINV2 LUINV21..LUINV40    ENDLUGROUP
LUGROUP  LUGINV3 LUINV41..LUINV60    ENDLUGROUP
LUMAP   LUTSO     IPGGEN   SPECIFIC  DEFAPPL  TSO      LOGAPPL  FIRSTONLY
LUMAP   LUCICS    IPGGEN   SPECIFIC  DEFAPPL  CICS     LOGAPPL
LUMAP   LUIMS     IPGGEN   SPECIFIC  DEFAPPL  IMS      LOGAPPL
LUMAP   LUGINV1   HNGINV             DEFAPPL  INVENTRY LOGAPPL  DEFONLY
LUMAP   LUGINV2   HNGINV             DEFAPPL  INVENTR2 LOGAPPL  DEFONLY
LUMAP   LUGINV3   HNGINV             DEFAPPL  INVENTR3 LOGAPPL  DEFONLY
```

Pool name specification is a powerful mapping method because multiple LUMAP statements with different Objects can be used for a single Client Identifier.

Keep LU for the Client Identifier: An LU name can be kept (or reserved) for a period of time so no other client is assigned that name. Only the same Client Identifier reconnecting to Telnet within the specified time can be assigned that LU name. After the specified time, the LU name is again available for any connection. This function is useful when the application does not clean up session information quickly and a released LU is quickly reassigned to another end user by Telnet. The application thinks the new session is a continuation of the previous session but it is not. With KEEPLU, the LU will not be reassigned to a different Client Identifier for a period of time, long enough for the application to clean up its session information. The LU name is kept based on the highest Client Identifier by which the connection is known. It is either a User ID derived from a client certificate, a Hostname, or an IP address, respectively.

LU group capacity warning: An LU group capacity threshold can be specified on the LUGROUP, PRTGROUP, and default LU group statements. If specified, Telnet will check the number of LUs used in the group when an LU is assigned from the group. A message is issued when the group's in-use LU count is at or above the specified percentage of the total. Once the message is issued, no other message is issued until the in-use count has dropped below the threshold by 10% of the total. For example, an LU group has 200 LUs with a capacity threshold of 80%. When the 160th LU is assigned, EZZ6007I is issued. Ten percent of the total in the group

is 20. Therefore, after the number of in-use LUs has dropped to 140 or lower, another warning message will be issued when the in-use count rises to 160 again. If multiple LU groups have the same LU name, the only LU group checked is the group from which the LU is assigned to the client. The other LU groups might go over their capacity limits, but notification will not be issued until an LU is taken from the group. Below are examples for setting the capacity warning.

```
LUGROUP         LUGRP1,80%    TCPLU000..TCPLUF9F..FFFFFXNX
PRTGROUP        PRTGRP1,60%   TCPRT000..TCPRTFFF..FFFFFXXX
DEFAULTLUS      ,75%          LU000000..LU999999..FFNNNNNN
DEFAULTPRTSPEC  ,90%          PRTDEFS1..PRTDEFS9
```

Capacity checking cannot be done for LU groups that are defined as LU name exits. During VARY TCPIP,*tnproc*,OBEYFILE command processing, all LU groups are checked for in-use LU counts and a capacity warning message is issued if needed.

Tip: Be sure to leave a blank space between the default LU group statement and the capacity (,*nnn*%). Do not leave a blank space between a group name and the capacity.

LU mapping by application name: In some cases, only certain LU names are eligible to be in session with the host application. Or only certain LU names are eligible to represent user IDs. The LU and LUG parameters on the ALLOWAPPL and RESTRICTAPPL statements provide this checking function and allow some LU name mapping based on application name. The LUG parameter can represent either an LUGROUP, a PRTGROUP, or a group that is a mixture of terminal and printer LUs so that both terminal and printer emulators can access the application. If single LUs are specified, they are assumed to be terminal LUs.

For example, assume the only LUs eligible to use the inventory set of applications are the LUs in the inventory LU pools. A new LUGROUP pool named LUGINVT contains LUs from LUGINV1, LUGINV2, and LUGINV3. The ALLOWAPPL statement requires that any session request to the inventory applications have an LU name defined in LUGINVT. The LUG parameter must be used carefully. When specified, Telnet must match the LU using both the common mapping algorithms and the mapping by application. For RESTRICTAPPL, assume security authorization is required to get to the PAYROLL application, and each of the PAYxx user IDs must map to a certain LU.

```
LUGROUP   LUGINV1  LUINV01..LUINV20  ENDLUGROUP
LUGROUP   LUGINV2  LUINV21..LUINV40  ENDLUGROUP
LUGROUP   LUGINV3  LUINV41..LUINV60  ENDLUGROUP
LUGROUP   LUGINVT  LUINV01..LUINV60  ENDLUGROUP
ALLOWAPPL   INVENTR*  LUG   LUGINVT
RESTRICTAPPL   PAYROLL
  USER  PAY01     LU    LUPAY01
  USER  PAY02     LU    LUPAY02
        (user pay03 through pay20 not listed)
```

The LU group specified on the LUG parameter cannot be an LU exit. If it is, the ALLOWAPPL statement is rejected. Multiple LUs can be assigned individually using the LU keyword or a single LU group can be assigned using the LUG parameter. LU and LUG cannot be mixed on a single statement and only one LUG entry per statement is permitted. LU assignment based on application is a convenient way to limit the access to applications. However, this increases mapping complexity significantly when LU mapping statements and connection types are part of the overall mapping equation. Non-TN3270E connections or TN3270E connections with NOTN3270E or SIMCLIENTLU specified do not keep the LU name assigned to the connection after a session is dropped. For these

connection types, the end user can establish a session with different application names even if different LU names are mapped to the application names with the ALLOWAPPL or RESTRICTAPPL-USER statement. However, LU mapping based on application name does not work well with TN3270E connections because the LU is assigned during connection negotiation before the desired application name is known. In all CLSDST-PASS cases, the LU name cannot change when switching from the first application to the second because the LU's ACB is not closed during the switch. If the LU mapping by application name requires an LU name switch, the new session attempt will be failed by Telnet.

TN3270 connections do not assign an LU to represent the client until an application name is chosen. Therefore, the LU and LUG parameters can be used as sole LU mapping statements for TN3270 connections. For example, assume no other mapping statements exist (LUMAP or DEFAULTLUS), and either no TN3270E connections will be used or SIMCLIENTLU has been specified. The following ALLOWAPPL statements will map LUs to the appropriate application based on the application name chosen. The following RESTRICTAPPL statement will assign a single LU or LU pool to each user.

```
ALLOWAPPL   TSO*  LUG   LUGTSO
ALLOWAPPL   CICS  LUG   LUGCICS
ALLOWAPPL   IMS   LUG   LUGIMS
RESTRICTAPPL   APP*
  USER   USER1*   LUG  LUG10
  USER   USER01   LU   LU01
  USER   USER02   LU   LU02
```

Both of these assignment methods were very popular before TN3270E connections were introduced. TN3270E connections will likely achieve poor mapping results. An LU must be assigned during connection negotiation before the application name is known which will likely result in an LU mismatch later. TN3270E connections require that an LU mapping statement exist because an LU must be assigned to the connection during negotiations before an application name is known. Consider the following example:

```
DEFAULTLUS
  LU1 LU2 LU3 LU4
ENDDEFALTLUS
RESTRICTAPPL  APPL1
  USER  USER3  LU  LU3
ALLOWAPPL   APPL2  LU  LU4
```

Assume two TN3270 connections are started.

- Two solicitor screens appear.
- Specify APPL1, USER3, and a password. Telnet selects LU3 based on both the DEFAULTLUS and the RESTRICTAPPL statements.
- Specify APPL2. Telnet selects LU4 based on both the DEFAULTLUS and the ALLOWAPPL statements.

Assume two TN3270E connections are started.

- Two solicitor screens appear. Telnet assigns LU1 and LU2.
- Specify APPL1, USER3, and a password. Telnet fails the connection because of an LU mismatch.
- Specify APPL2. Telnet fails the connection because of an LU mismatch.

If LU name mapping by application name or user ID is desired with TN3270E clients, the following three solutions are available:

- If the same application or user ID is always used at the same client, individual LUMAP statements can be used to map the correct LU name to each client. Then every connection request will result in the correct LU assignment for that client. The assumptions are that the client keeps the same Client Identifier and only one client exists per Client Identifier.
- Map the NOTN3270E parameter to clients to disable all TN3270E function in Telnet so those connections will be TN3270, not TN3270E. The drawback is that all TN3270E function is disabled. This includes printer function, Generic/Specific function, and SNA function to the client. The TN3270E and NOTN3270E parameters can be coded at all three parameter block levels for different levels of granularity.
- Mapping the SIMCLIENTLU parameter is a less severe solution. This function will send a dummy LU name of EZBSIMLU to all TN3270E clients issuing Generic connection requests to satisfy the negotiation but will not assign a Telnet LU until an application name is chosen. This alternative preserves printer function, Specific requests, and SNA function to the client. The drawback is the name sent to the client is not the name Telnet ultimately uses to represent the client. Printer association will not work for these TN3270E Generic connections and any emulator programming that depends on the LU name will be using the dummy LU name. The SIMCLIENTLU and NOSIMCLIENTLU parameters can be coded at all three parameter block levels for different levels of granularity.

LU mapping selection rules: LU mapping selection can become complicated because of the many variations of mapping statements, TN3270E versus TN3270 connections, Generic versus Specific connection requests, printer association, and LU mappings based on application name. LU mapping is very different between TN3270E and TN3270 and will be discussed separately. But first, some general Mapping Rules for both TN3270E and TN3270 follow:

- If multiple LUMAP statements exist for a Client Identifier all Specific LUMAPs are searched (TN3270E only) and then all Generic LUMAPs are searched in the order they are listed in the profile.
- If the application is known during the LU lookup and the ALLOWAPPL or RESTRICTAPPL-USER statement has LUs listed, then the found LU must be in both the mapped LU group and in the application LU group.
- Once an LU match is found, the search stops.
- Telnet performs database lookup for Objects based on the Client Identifier. TN3270E connections require an Early Lookup so Telnet can give the client an LU name during connection negotiation. In all cases a Complete Lookup is done when the application name is known. Telnet performs an Early Lookup and a Complete Lookup for TN3270E connections. Telnet performs only a Complete Lookup for TN3270 and Linemode connections.

TN3270E LU mapping: TN3270E connections require an Early Lookup during connection negotiation. Telnet will use as much information as is available to assign an LU to the client. However, the eventual application is not known at this time unless an LUMAP-DEFAPPL or DEFAULTAPPL statement defines the application name. After connection negotiations are complete, Telnet will either send a logon solicitor (or USSMSG10) screen to the client or will perform a Complete Lookup using the application name obtained from the LUMAP-DEFAPPL or DEFAULTAPPL statement. If Complete Lookup is successful, Telnet will begin session initiation. If a solicitor (or USSMSG10) screen is sent to the client, an application name must be entered, at which time Telnet will perform a Complete Lookup. If LU mapping is being done based on application name, a conflict might occur between the application LU mapping and the LU already assigned to the connection. For TN3270E, once an LU name is assigned during

connection negotiation it can never change until the connection is dropped. The SIMCLIENTLU statement allows Telnet to assign LUs for TN3270E connections as though they were TN3270 connections. See "TN3270 LU mapping" on page 624 for mapping Generic TN3270E connection requests with SIMCLIENTLU. A request for a Specific LU from the Telnet Client will be treated as if SIMCLIENTLU were not specified. The exact lookup process for TN3270E (non-SIMCLIENTLU) is described below.

Early Lookup: An LU must be found during Early Lookup. LUMAP-DEFAPPL and DEFAULTAPPL statements are considered but not necessarily used. Possible lookup results are:

- An LU is found.
- An LU is not found, the connection is dropped.

Perform TN3270E Early Lookup in the following order. The process stops when LU lookup is successful. Printer connections use the same process, substituting PRTMAP and PRTDEFAULTAPPL.

- Check for LUMAP matches considering application lookup results and possible application-based LU mappings.
  1. For each Specific LUMAP used for Specific connection requests: If the Specific LUMAP has DEFAPPL, or DEFAULTAPPL was specified and the application lookup return code is either OK or USER_REQUIRED, then perform LU lookup.
  2. For each Generic LUMAP used for Specific or Generic connection requests: If the Generic LUMAP has DEFAPPL, or DEFAULTAPPL was specified and the application lookup return code is either OK or USER_REQUIRED, then perform LU lookup.
- Check for LUMAP matches without considering application lookup results.
  1. For each Specific LUMAP used for Specific connection requests: Ignore DEFAPPL and DEFAULTAPPL and perform LU lookup.
  2. For each Generic LUMAP used for Specific and Generic connection requests: Ignore DEFAPPL and DEFAULTAPPL and perform LU lookup.
- If LUMAP statements were *not checked* (different from *checked but no match*), use the appropriate Default LU pool considering application lookup results and possible application-based LU mappings. In this case the only relevant application is the DEFAULTAPPL, if specified. If the application lookup return code is either OK or USER_REQUIRED, then perform LU lookup.
- If LUMAP statements were not checked, try the appropriate Default LU pool without considering application lookup results. Perform LU lookup.

Complete Lookup: An application name is required for Complete Lookup. The application name is obtained from one of three sources in the order specified.

1. Input from the USER or VTAM (via CLSDST with OPTCD=PASS)
2. DEFAPPL parameter on the LUMAP statement
3. DEFAULTAPPL statement

Use the application name and the previously found LU to perform Complete Lookup. Possible lookup results are:

- The application is not valid.
- The application is valid (return code OK or USER_REQUIRED) for the existing LU.
- The application-based LU map does not match the already chosen LU.

TN3270 LU mapping: TN3270 connections only perform Complete Lookup after all information is known. LU lookup is not done during connection negotiation. Telnet will either send a solicitor (or USSMSG10) screen to the client or will perform Complete Lookup using the application name known through the LUMAP-DEFAPPL or DEFAULTAPPL statement. If Complete Lookup is successful, Telnet will begin session initiation. If not successful, the solicitor (or USSMSG07) screen is sent to the client without an LU being assigned to the connection or the connection is dropped. The LU is not assigned until the application name is valid. If the application name is a RESTRICTAPPL, the LU is not assigned until a user ID is specified. Application-based LU mappings have a very good chance of success due to the late LU mapping aspect of TN3270 connections. When SIMCLIENTLU is coded, Generic TN3270E connections have this same characteristic.

Complete Lookup: An application name is required for Complete Lookup. The application name is obtained from one of three sources in the order specified.

1. Input from the USER or VTAM (CLSDST with OPTCD=PASS)
2. DEFAPPL parameter on the LUMAP statement
3. DEFAULTAPPL statement

Use the application name to perform Complete Lookup. Possible lookup results are:

- The application is not valid.
- The application is valid but an LU is not found.
- The application is valid (return code OK) and an LU is found.
- The application LU map does not match the Client Identifier LU map.

If the application is not valid, no LU is assigned to the connection and an error message is sent to the client. If the application is valid, continue the LU lookup in the following order.

- Check for LUMAP matches considering application-based LU lookup results. Only Generic LUMAPs are searched. If the application lookup return code is OK, then perform LU lookup.
- If no LUMAP statements were used, check for application-based LU mappings. If the application lookup return code is OK and LUs are defined on the application statement, perform LU lookup.
- If no LUMAP or application-based LU mapping statements were used, use the DEFAULTLUS pool considering application lookup results. If the application lookup return code is OK, then perform LU lookup.

LU mapping with multilevel security active: Telnet can be in a multilevel secure environment that uses security labels. For more information on preparing for TCP/IP networking in a multilevel secure environment, see Chapter 4, “Preparing for TCP/IP networking in a multilevel secure environment,” on page 153 and *z/OS Planning for Multilevel Security and the Common Criteria*. To ensure correct security label comparisons, Network Access Control (NAC) must also be active for Telnet. For more information about NAC, see “Network Access Control” on page 591.

If multilevel security is active, Telnet ensures the security label of the selected LU is compatible with the security label of the client.

- Telnet retrieves the security label of the client when the connection is accepted.
- Telnet assigns a security label to all LUGROUPs based on the first LU name in the group. The first single LU name in the group is used. If no single LU names exist, the first LU name within the first LU range is used.

- If multilevel security is active, an LUGROUP EXIT is required to have at least one LU name in the group. The LU name is used to obtain a security label for the group. The name is passed to the exit in the parameter list and can be used or ignored by the exit.
- A single LU name on a mapping statement is treated as an LUGROUP with one LU name. That LU name is used to obtain the security label for the LUGROUP created by Telnet.

When multilevel security is active, LU lookup uses the following process:

1. The security label of the client is compared with that of the mapped LUGROUP. If the group is compatible, Telnet searches for an available LU in the group. If not compatible, the LUGROUP is skipped.
2. Telnet retrieves the security label of the selected LU and compares it with the security label of the LUGROUP. If the selected LU is not compatible with the LUGROUP, the LU is inactivated and no other LU in the group is tried.
3. If the LUGROUP was not compatible or no LU was available, the steps are repeated for each mapped LUGROUP until an LU is found or all LUGROUPs are checked.

Advanced application topics

In addition to the basic function of facilitating session setup, Telnet supports several advanced functions such as:

- Connection information passed on the CINIT control vector 64 (CV64)
- Session initiation management (LOGAPPL, QINIT, FIRSTONLY, and DEFONLY)
- Check client connection and connection/session takeover
- Queueing sessions
- Disconnect on session error
- Bypass RESTRICTAPPL with CERTAUTH
- Allow printer sessions with RESTRICTAPPL
- Keeping the ACB open
- Express Logon Feature

Connection information passed on the CINIT control vector 64: During session establishment, a VTAM session initiation record called a CINIT is created and sent to the primary application. Attached to the CINIT is a control vector 64 (CV64) that is created by Telnet to provide additional information about the Telnet connection. The CV64 control vector contains four sub-vectors. The CV64 control vector and the four sub-vectors are all defined as key/length vectors.

- CV64 - Start of control vector
  - Key/Length (2 bytes)

    X'64mm', where *mm* is (*ii* + 2) + 4 + (*hh* +2 (if SBV85 present)) + 19 (if SBV86 present)
- SBV81 - Flags and IP address
  - Key/Length (2 bytes)

    X'81ii', where *ii* is 06 for IPv4, 18 for IPv6
  - IP address type (1 byte)

    04 - IPv4

    06 - IPv6
  - Flags (1 byte)

    80 - Reserved for future use

40 - Reserved for future use

20 - On if secure connection

10 - On if secure connection flag is valid

08 - On if takeover of the connection is possible

04 - On if the TCP/IP stack supports IPv6 addresses and the client has an IPv4 address

02 - On if the Telnet server is the z/OS Communications Server TN3270E Telnet server

01 - On if the client is a TN3270E client and supports definite response

- IP address (4 bytes if IPv4, 16 bytes if IPv6)

- SBV82 - Port number
  - Key/Length (2 bytes)

    X'8202'
  - Port (2 bytes)
- SBV85 - Host name of the client (SBV85 is not always present)
  - Key/Length (2 bytes)

    X'85hh', where *hh* is 1 + DNS name length
  - Flags (1 byte)

    80 - On if DNS name is truncated to 128 bytes
  - DNS name (Maximum 128 bytes)
- SBV86 - Zone ID if specified for a client IPv6 address (SBV86 is not always present)
  - Key/Length (2 bytes)

    X'8611'
  - Flags (1 byte)

    80 - On if zone is truncated
  - Zone ID (16 bytes)

Session initiation management (LOGAPPL, QINIT, FIRSTONLY, and DEFONLY): The LOGAPPL, QINIT, FIRSTONLY, and DEFONLY options can be coded on DEFAULTAPPL, PRTDEFAULTAPPL, LINEMODEAPPL, LUMAP-DEFAPPL, or PRTMAP-DEFAPPL. For the remainder of this topic, DEFAULTAPPL represents all the default application statements.

LOGAPPL, QINIT: The LOGAPPL or QINIT functions keep the Telnet LU active if a Request Session fails due to the host VTAM application not being active. In addition, VTAM remembers the attempted Request Session and will initiate a session request to the Telnet LU on behalf of the application when the application becomes active. When the Request Session fails, Telnet sends the client a solicitor panel or USSMSG07 screen. The end user then has the option of logging on to a different host VTAM application (if DEFONLY is not coded). When this different session is started, VTAM drops the queued Request Session for the original session.

What happens at session logoff depends on whether or not LUSESSIONPEND and FIRSTONLY are coded and whether LOGAPPL or QINIT is coded. If LUSESSIONPEND is coded, the connection remains. Otherwise, it is dropped. If FIRSTONLY is coded, Telnet will send a USSMSG10 screen or Solicitor panel to the client. If FIRSTONLY is not coded, Telnet will initiate another session with the default application defined by the DEFAULTAPPL statement. LOGAPPL and QINIT have different results when logging off the original application. When

LOGAPPL is specified, a USSMSG10 or Solicitor panel is sent to the client. When QINIT is specified, Telnet requests a session with the default application.

FIRSTONLY, DEFONLY: Sometimes a default application is used at initial connection, but after LOGOFF a USSMSG10 or solicitor panel is more appropriate than redriving the default. In this case, code the FIRSTONLY parameter. This indicates the default should be used on the first session only. After a session has been established, any subsequent lookups will ignore the default and send the USSMSG10 screen or solicitor panel.

If MSG07, LUMAP-DEFAPPL, or PRTMAP-DEFAPPL is coded and the default application is inactive, an error screen will be sent to the client. The DEFONLY parameter will block a user-entered application choice if it is different than the default. This parameter prevents application choice while giving the end user error information.

The following table summarizes several possible session initiation failure scenarios.

- ReqSess OK - A Request Session to the default application succeeded or a Request Session to a second application from the USSMSG07 screen succeeded.
- ReqSess Fail - A Request Session to the default application failed.
- 2nd Appl Fail - A Request Session to a second application from the USSMSG07 screen failed.

Scenario / Mapping Statement	ReqSess OK	ReqSess Fail		2nd Appl Fail	
		MSG07	No MSG07	MSG07	No MSG07
DEFAULTAPPL name	1	2	5	2	N/A
DEFAULTAPPL name LOGAPPL DEFAULTAPPL name QINIT	1	3	3	4	4

Figure 67. Session initiation failures scenarios

FIRSTONLY is not a consideration because the first session has not been established.

1. In session.
2. Send USSMSG07 or Solicitor panel to client. Close the ACB.
3. Send USSMSG07 or Solicitor panel to client. Keep ACB open, queue original session request in VTAM.
4. Send USSMSG07 or Solicitor panel to client. Keep ACB open, keep the original queued session request in VTAM.
5. Drop connection.

The following table summarizes several possible session ending scenarios. The session is ending due to normal LOGOFF or session breakage (possibly caused by loss of the application).

- Original Application - User is in session with the original default application.
- CLSDST from Original Appl - User is in session with a second (or later) application after issuing a CLSDST-PASS from the original application.

Scenario / Mapping Statement	Original Application		2nd Appl or CLSDST from Orig	
	Logoff	Break	Logoff	Break
DEFAULTAPPL name DEFAULTAPPL name QINIT	1	1	1	1
DEFAULTAPPL name LOGAPPL	2	1	1	1
DEFAULTAPPL name FIRSTONLY LOGAPPL DEFAULTAPPL name FIRSTONLY QINIT	2	1	2	1

Figure 68. Session ending scenarios

In all cases, if LUSESSIONPEND is not coded the connection is dropped.

1. Request a session with the default application.
2. Send USSMSG10 or Solicitor panel to client. Close the ACB.

Check client connection and connection/session takeover: A Telnet client can detect the loss of connectivity to Telnet without Telnet being aware of the loss. This condition is typically caused by a temporary problem in the network, such as a router experiencing a failure. In many cases, the network can correct itself and client retransmission can recover the data flow. However, the user often terminates the Telnet TCP connection at the emulator without waiting for the network to recover. In other cases, such as when a single router supports the client, the Telnet TCP connection is eventually terminated by the client TCP/IP stack after a certain number of retransmissions fail. When network connectivity is restored, the user initiates a new connection to Telnet. Even though the user is reconnected, in many cases the original SNA session cannot be associated with the new TCP connection because the session continues to be associated with the original TCP connection.

Assume that the host application is TSO and the user is in session with TSO user ID USER1. The route is lost and the user disconnects. The user then establishes a new Telnet connection without specifying an LU name. Telnet assigns a different LU to represent the client. When the logon to user ID USER1 is attempted, TSO fails the logon attempt because USER1 is still in session with the original Telnet LU. If the user does specify the same LU name when reconnecting, the connection is rejected sooner. Telnet fails the request during Early Lookup, indicating that the LU is already in use. The problem with both situations is that Telnet assumes that the original connection is still active and that the SNA session is still associated with that original connection.

The user can not terminate the original TCP connection and SNA session. The user has two choices:

- Wait for an inactivity timer in Telnet to clean up the original SNA session and close the original TCP connection
- Wait for an inactivity timer in TSO to initiate session termination

In the second case, either Telnet is configured to close the connection at session termination (NOLUSSIONPEND), or when Telnet attempts to refresh the TCP connection, Telnet detects that the TCP connection is gone and closes its representation of the connection. The end result in all cases is that the original SNA session and the original TCP connection are cleaned up after the specified inactive period of time has elapsed.

The user would like to quickly close the original connection to free the LU and the SNA session. If you specify the CheckClientConn parameter, Telnet checks the connectivity of all pre-existing connections associated with the client identifier of the new connection being established. The check is performed by sending a Timemark to each existing connection. The new connection is delayed early in the connection negotiation until all existing connections have responded or the specified wait time has elapsed. When all connections have responded, setup of the new connection continues. If some connections do not respond, then after the specified time elapses, Telnet closes any connections that did not receive a response. As soon as all of the unresponsive connections are closed, setup of the new connection continues. The new connection is held until cleanup is performed to ensure that an LU is available and that the previous SNA session is cleaned up before the new connection continues negotiation. The CheckClientConn parameter is useful when multiple emulators exist on a single client and the user can tolerate the session being disconnected.

Rule: If you are using sysplex distributor to distribute connections across Telnet servers with CheckClientConn, you must use timed client affinity to ensure that the clients reconnect to the same Telnet server.

Tip: Be careful using the CheckClientConn parameter where proxy servers are being used and the Client Identifier is IP address rather than Host name or User ID. Telnet perceives all connections coming from the same IP address as coming from the same client. Depending on the number of connections, Telnet could send a large number of Timemarks every time a new emulator connects. A second parameter is available to limit the number of connections checked for a single client identifier.

Some end users require that the same LU be assigned when the new connection takes over the old connection. The takeover function fixes this problem. When takeover is active for a connection, Telnet LU lookup attempts LU takeover upon entry to the lookup function, whenever a single LU name can be associated with a connection. Any number of existing Specific requests from one client identifier can be associated with new Specific requests. A single existing Generic request from one client identifier can be associated with a new Generic request. If there are multiple existing Generic requests, only the first is taken over and the remaining connections continue to hang.

The TKOSPECLU and TKOSPECLURECON statements activate takeover for the connection and require that the end user specify the LU name. The statement name is derived from the function of connection takeover (TKO) for a Specific LU (SPECLU) connection request. Because the LU name is specified, LU lookup attempts to take over the original connection to which the LU was assigned. The Specific LU request allows an end user to move to any client to take over a connection that is lost and provides some level of security because it requires the end user to know the LU name.

The TKOGENLU and TKOGENLURECON statements activate takeover for a connection without the end user specifying an LU name. The statement name is derived from the function of connection takeover (TKO) for a Generic LU (GENLU) connection request. During the original connection LU lookup, Telnet saves the LU name by Client Identifier. If another connection request is received from the same Client Identifier, Telnet assumes takeover should be attempted using the original LU name. If multiple connections are made from a single client, all additional connection setups will be delayed by the time it takes to attempt takeover of the first connection. When the takeover attempt fails, Telnet resumes

normal Generic LU lookup for that connection. For Generic LU takeover to work, the Client Identifier must remain the same. The Client Identifier can be the client user ID derived from the client security certificate. If no user ID is available, the client hostname is used. If no hostname is available, the client IP address is used.

Rule: If you are using sysplex distributor to distribute connections across Telnet servers with TKOGENLU or TKOGENLURECON, you must use timed client affinity to ensure that the clients reconnect to the same Telnet server.

The TKOSPECLU and TKOGENLU statements cause the following events to occur. When the takeover connection request arrives, Telnet LU lookup discovers the LU name is in use and suspends the new request. Telnet sends a TIMEMARK request to the original client, which acts as an "are you there" message. The client is required to respond to the TIMEMARK. If no response is received by Telnet within the time specified on the takeover statement, Telnet drops the original session and connection. The original LU is reserved during the drop process. Once the original session and connection are dropped, Telnet resumes processing the new request. This time the LU is not in use, only reserved for takeover purposes, and is assigned to the new takeover session. The end user is essentially starting over. The original session has been dropped, allowing the end user to immediately log on to the same TSO user ID again.

When sysplex distributor is used to distribute connections across Telnet servers with the TKOSPECLU or TKOSPECLURECON statements, the series of events can be extended to include the LUNS and possibly the previous owning LUNR. When the takeover connection request arrives at a LUNR and Telnet LU lookup discovers that the LU name is shared and is not already allocated to itself, the new request is suspended, and verification and allocation is requested from the LUNS. If the LUNS determines that the LU name has been allocated to another LUNR, the LUNS sends a verification request to the other LUNR. That LUNR sends a TIMEMARK to its original client. If the client responds, the owning LUNR informs the LUNS that the LU name is still in use. If the client does not respond, the owning LUNR drops the original connection and tells the LUNS to deallocate the LU name. If the LUNS determines that the LU name is not in use, the name is allocated to the requesting LUNR. Depending on the response from the LUNS, the new LUNR then either accepts or rejects the takeover request.

The TKOSPECLURECON or TKOGENLURECON statements can be used to accomplish the same connection drop but avoid the session drop. When the original connection is dropped, the Telnet LU stays in session with the host application. The new connection is established and Telnet sends an LUSTAT to the host application indicating that Presentation Space Integrity was lost (X'082B'). Depending on the application, it will either end the session or resend the previous screen. By resending the previous screen, the end user is able save the original session and avoid the SNA session tear-down and restart process. At worst, if the application drops the session upon receipt of the LUSTAT, the end user is able to immediately log on again as if TKOSPECLU or TKOGENLU were coded.

In some cases, the original client TCP/IP stack may respond to the Timemark with a RESET. Telnet interprets this RESET as a client disconnect and assumes the end user disconnected the session. Telnet then drops the session. To keep the session in this case, add the KeepOnTmReset option to the TKOSPECLURECON or TKOGENLURECON statement. A security risk exists when using this parameter. An end user may actually disconnect just before the Timemark arrives due to an unauthorized takeover attempt. Telnet will interpret the disconnect as a response to the Timemark and allow the takeover without loss of the VTAM session.

Part of session initiation includes Telnet issuing a SETLOGON VTAM macro that contains control vectors. The control vectors include client information, such as IP address and host name if available. If the connection is capable of being taken over, a flag is set in the control vector. This information is passed to the application's logon exit for use by the application. If the connection is taken over, a second SETLOGON macro is issued. However, the control vector information does not go beyond the VTAM that processed the SETLOGON. The application's logon exit does not run again and is not aware of connection changes. Some applications require the IP address to remain constant. Since the application cannot be notified of changes, Telnet has the ability to only allow takeover by clients from the same IP address. Specify SAMEIPADDR on the TKOGENLURECON or TKOSPECLURECON statements to ensure takeover is done by a client from the same IP address.

TKOSPECLU, TKOSPECLURECON, TKOGENLU, and TKOGENLURECON can be coded at all three parameter block levels for different levels of granularity. Code NOTKO to turn off all takeover function at any of the three levels.

The new connection must have an equal or higher security level to take over the original connection. The order for connection security is:

1. Basic
2. Secure
3. Secure with CLIENTAUTH SSLCERT
4. Secure with CLIENTAUTH SAFCERT

If the original connection used SSL with CLIENTAUTH SAFCERT, either takeover method will verify that the new connection is using a client certificate that maps to the same user ID. Telnet verifies this by translating the new certificate to a user ID and comparing the new user ID to the user ID on the original connection.

Tip: If you are using TKOSPECLURECON or TKOGENLURECON, you can specify SAMECONNTYPE to force the same connection type between the taker and the target connections. CV64 information is not updated when a session takeover occurs, and if a secure connection takes over a basic connection, the application is not updated with the new connection level because no new CV64 is sent to the application. You can also consider using takeover without reconnect (TKOSPECLU or TKOGENLU).

Guideline: If you map multiple certificates to the same user ID, a client presenting any of those certificates will be able to take over the connection. If there is a chance the connection can be taken over by an unauthorized user, TKOSPECLURECON and TKOGENLURECON should not be used. Neither statement requires the end user to reverify user authenticity to the host application.

Tip: A time value of zero is permitted. In this case the server will always perform the takeover whether or not the original connection is still active. The zero value is intended for testing purposes rather than production use.

Sometimes a takeover attempt will not complete as expected. This might be due to one of the following factors:

- The profile of the original connection defines how the original connection can be taken over. Be sure the original connection supports the desired takeover method.

- The new connection is not of the same connection type as the original session, and SAMECONNTYPE was specified on the TKOSPECLURECON or TKOGENLURECON statement.
- The new connection request must specify the LU name of the connection being taken over if TKOSPECLU or TKOSPECLURECON is specified.
- TKOSPECLURECON and TKOGENLURECON do not preserve a session if the takeover is done from a different port. The ACB of the LU is associated with the original port and must be closed before it can be associated with the new port. The takeover will function as a TKOSPECLU and TKOGENLU takeover.
- TKOSPECLURECON and TKOGENLURECON do not preserve a session if the takeover is done for a shared Telnet LU name managed by a LUNS.
- TKOSPECLURECON and TKOGENLURECON might not preserve a session if the original client connection is ended before the TKOSPECLURECON or TKOGENLURECON timer expires. If the close reason is TIMEMARK or INACTIVE, the session will be preserved under the assumption that the inactivity is due to a lost connection. Any other close reason will cause the takeover to function as a TKOSPECLU or TKOGENLU takeover. This is done to protect users who disconnect their client as a means of logging off their session. These sessions will not be taken over. Instead, the end user will have to issue a new logon.

Takeover is also affected by where the new client resides and how the old client responds. There are several event scenarios and results will vary.

- Event 1

  New client connects from a different IP address or Port.

  Original client responds to TIMEMARK.

  Result - Takeover will not occur in this case because the original client is still responding. With a Specific LU request, the new client will receive an error indicating the LU is already in use. With a Generic LU request, Telnet assigns the next available LU to the connection.
- Event 2

  New client connects from a different IP address or Port.

  Original client does not respond to TIMEMARK.

  Result - Connection takeover will occur. If TKOSPECLURECON or TKOGENLURECON is mapped to the client, session takeover will occur. A likely scenario in this case is Telnet has lost connectivity to the old connection due to a failed router and the new connection is using a different route, the original machine lost power and has not reestablished connectivity, or the original machine lost power but reestablished connectivity with a different IP address.
- Event 3

  New client connects from a different IP address or Port.

  Original client stack responds with RESET.

  Result - Connection takeover will occur. However, even if TKOSPECLURECON or TKOGENLURECON is coded, session takeover will not occur because Telnet handles the RESET as a client disconnect. A likely scenario in this case is a PC lost power and then regained power. The takeover request is accepted from either a different PC or the same PC using a different port. After the new connection request is accepted, Telnet sends a TIMEMARK to the original client PC stack. The PC stack does not recognize the IP-port and responds with a RESET. If KeepOnTmReset is specified and the RESET is received by Telnet after the Timemark has been sent, Telnet will keep the session.

- Event 4

  New client connects from the same IP address and Port.

  Telnet stack rejects the request.

  Original client times out and sends a RESET.

  Result - The original session and connection are dropped. Takeover does not occur. The new client is able to connect on retry because the original connection and session were cleaned up. A likely scenario in this case is a PC has lost power and then regained power. The same PC is used to attempt takeover. The client is assigned the same port as before the power loss and has the same IP address.

Queueing sessions: Logon manager applications are very popular. Typically they are set up as a default application which sends a selection screen to the end user. Once the end user specifies the destination application choice, the logon manager typically issues a CLSDST macro with OPTCD=PASS to the destination application. A new session is started with the destination application. The logon manager session is closed with a special UNBIND sent to Telnet indicating that a new session BIND is forthcoming. Telnet receives that special UNBIND and then waits for the next BIND instead of cleaning up as it would when receiving a normal UNBIND. When the end user logs off the destination application, Telnet either goes through the initial database lookup process again (which will result in a session with the logon manager) or drops the connection, depending on whether LUSESSIONPEND is coded. Logoff of the original application will cause Telnet to perform normal close function instead of leaving the LU ACB open.

Many logon managers were written to support real terminals, not Telnet, and issue a SIMLOGON OPTCD=Q immediately after issuing the CLSDST-PASS. When SIMLOGON Q is coded, the logon request is added to a VTAM queue. The first application queued is the first application off the VTAM queue. Immediately after user logoff from the destination application, VTAM (on behalf of the logon manager) will request a session with the terminal LU (or Telnet LU representing the client). This works very well for real terminals, but causes timing problems for Telnet when the logon manager is a default application. In this case, Telnet and VTAM both end up requesting a session.

The QSESSION option on ALLOWAPPL or RESTRICTAPPL can be used to correct this timing problem. When coded for the logon manager, Telnet will *not* do normal close processing when the UNBIND from the destination application arrives. Telnet will leave the LU ACB open and wait for the BIND from the logon manager that is generated because of the Queued SIMLOGON. When the BIND does arrive, Telnet will verify that the application name is the original logon manager and finish session setup.

If QSESSION is specified for an application that does not queue a SIMLOGON, or the SIMLOGON is removed from the queue because the original application was recycled, Telnet will be waiting for a BIND that is never coming. The connection will appear to be hung. To safeguard against this hang condition, a timer can be started when the destination application UNBIND is received. Telnet will wait for the specified period of time for a BIND from the QSESSION application. If the timer expires and there is no session, Telnet will clean up the connection as if the QSESSION parameter had not been specified.

As an example of the QSESSION parameter, assume that APPL1, APPL2, and APPL3 are each defined in VTAM. APPL1 will issue a SIMLOGON-Q after

CLSDST-PASS. The following Telnet statements allow connections to access the applications and define which is a QSESSION application.

```
ALLOWAPPL APPL1 QSESSION,3
ALLOWAPPL APPL*
```

The client first logs on to APPL1. APPL1 issues a CLSDST-PASS to APPL2 and a SIMLOGON-Q. Finally, APPL2 issues a CLSDST-PASS to APPL3. When the APPL3 session is ended, VTAM sends an APPL1 BIND to Telnet. If the queued SIMLOGON had been removed, Telnet would have continued cleanup 3 seconds after receiving the UNBIND from APPL3. When the APPL1 session is ended, the ACB is closed and Telnet either goes through the initial database lookup again or closes the connection, depending on whether LUSESSIONPEND is coded.

As a second example, assume that APPL2 also issues a SIMLOGON-Q after it issues a CLSDST-PASS to APPL3. As in the previous example, when the APPL3 session is ended, VTAM sends an APPL1 BIND to Telnet. If the queued SIMLOGON had been removed, Telnet would have continued cleanup 3 seconds after receiving the UNBIND from APPL3. When the APPL1 session is ended, VTAM sends an APPL2 BIND to Telnet. The APPL2 SIMLOGON-Q was queued behind the APPL1 SIMLOGON-Q in VTAM.

Disconnect on session error: The DISCONNECTABLE option on either the ALLOWAPPL or RESTRICTAPPL statement determines what type of session termination to send to the host VTAM application when Telnet initiates session termination. If DISCONNECTABLE is coded, Telnet issues a TERMSESS UNBIND(0F). Otherwise, Telnet issues a TERMSESS UNCOND. For example, when DISCONNECTABLE is coded for the TSO application, an unexpected connection loss results in an UNBIND(0F) being sent to TSO putting it in a reconnectable state. The DISCONNECTABLE parameter has no effect on a session ended normally by the end user logging off the session. The QSESSION parameter can be coded with DISCONNECTABLE on either statement.

Bypass RESTRICTAPPL with CERTAUTH: CERTAUTH is an option on RESTRICTAPPL used in conjunction with client authenticated secure connections or Express Logon. In both cases the client certificate is used to derive a user ID. If the end user chooses an application that is a RESTRICTAPPL, the normal Telnet response is to request a valid user ID and password before allowing access to the application. However, if the end user has been authenticated with a client certificate it may not be necessary to require a user ID/password. With the CERTAUTH option on RESTRICTAPPL Telnet will use the derived user ID. If the user ID is valid (listed on the RESTRICTAPPL statement), Telnet will bypass the end user solicitation and immediately give access to the application. The derived user ID value depends on the type of connection. If Express Logon is being used, the user ID is derived from the latest Client Certificate/Applid combination received from the client. If Express Logon is not being used, the user ID is the Client Identifier user ID derived from the Client Certificate from the SSL handshake.

Allow printer sessions with RESTRICTAPPL: The ALLOWPRINTER option enables printers to establish a session with an application defined as a RESTRICTAPPL. Telnet verifies all session requests before finishing session setup, and if the application name is restricted by the RESTRICTAPPL statement, Telnet requires the user to enter a user ID and password before session initiation begins. The user of a printer emulator has no way to provide a user ID and password, and you might want to allow printer sessions without the user ID and password verification, mimicking the behavior of the ALLOWAPPL statement. The

ALLOWPRINTER option on RESTRICTAPPL gives you the flexibility to keep the terminal LU sessions restricted while allowing all printer LU sessions access to the application, without user ID and password. In most cases, printer sessions originate from the application and not the user, keeping security control in the application. However, use this option with care if you have coded PRTDEFAULTAPPL or PRTMAP-DEFAPPL. In this case, it is possible for users to originate a printer session.

Keeping the ACB open: Some host VTAM applications are set up to inquire whether a secondary LU is active. If the LU is active, the application initiates a session. The LUMAP option, KEEPOPEN, causes the LU to be activated when the LU is assigned to the connection, and to remain active for as long as the LU is assigned to the client by this mapping statement.

LU assignment is different for TN3270E and TN3270 connections. TN3270E connections have an LU assigned during connection negotiation. TN3270 connections do not have an LU assigned until the VTAM application name is known.

When the host VTAM application initiates a session with the secondary LU, the host must issue an INQUIRE to see if the LU is active with an OPEN ACB. This INQUIRE will fail for Telnet LUs because Telnet does not open the ACB until a session request is sent from Telnet to VTAM. When the end user gets the solicitor (or USSMSG10) panel, Telnet has not opened the ACB of the LU assigned to a TN3270E connection. TN3270 and LineMode connections do not have LUs assigned yet. If the KEEPOPEN parameter is coded on the LUMAP statement used by Telnet to assign an LU during Early Lookup for a terminal TN3270E connection, Telnet will open the ACB before sending the solicitor (or USSMSG10) panel. At that time an end user can either log on to an application as usual or wait for a host application to INQUIRE about the LU and initiate a session. TN3270 connections will not have an LU assigned until an application name is known. When the name is known, an LU is assigned to the connection, the ACB of the LU is opened, and a session request is issued. If the KEEPOPEN parameter is coded on the LUMAP statement used by Telnet to assign the LU, the LU stays assigned to the connection with the ACB open until the connection is dropped. If profile statements define LUs uniquely to different applications, a second logon to a different application might fail. When KEEPOPEN is mapped to a connection, the MSG07 and LUSESSIONPEND functions are in effect whether or not they were explicitly coded. When a session is ended, the connection remains and the ACB remains open. Only a client disconnect, a Telnet error, or the KEEPINACTIVE/INACTIVE timers will cause a KEEPOPEN connection to be dropped. The KEEPINACTIVE timer is used whenever the Telnet LU is not in session with a VTAM application. Otherwise, the INACTIVE timer is used. See “Connection persistence” on page 592 for information about ending idle KEEPOPEN connections.

Express Logon Feature: The Express Logon Feature (ELF) allows an end user to connect to an MVS host VTAM application without explicitly entering a user ID or password. Telnet uses the client certificate to resolve the user ID and RACF generates a temporary password, a PassTicket. ELF requires a secure connection with level 2 client authentication, a client that supports ELF, and RACF PassTicket setup.

The ELF function is activated by specifying the EXPRESSLOGON parameter. The function can be inactivated by specifying NOEXPRESSLOGON. Either parameter

can be coded in TELNETGLOBALS, TELNETPARMS or PARMSGROUP. For a detailed discussion of ELF, see Appendix C, “Express Logon Feature,” on page 1489.

Device types and logmode considerations

The VTAM logmode defines many characteristics of the session established between the Telnet LU representing the client and the host VTAM application. For example, the logmode defines response types, presentation style, and the type of LU Telnet is emulating. LU0 (non-SNA) and LU2 (SNA) represent terminal LU types. LU1 (SCS) and LU3 (3270 Data) represent printer LU types.

Telnet matches a VTAM logmode to each client as it connects based on the client device type, unless the end user specifies a logmode on the USSMSG10 screen or logmode is configured in the USS table mapped to the connection. See *z/OS Communications Server: IP Configuration Reference* for default device type and logmode table information. The default terminal logmodes are non-SNA for TN3270 connections and SNA for TN3270E connections. At session request time, Telnet indicates to VTAM the desired logmode based on device type. The host VTAM application usually honors the request and binds the session using the requested logmode. However, depending on VTAM statements, the application can override the requested logmode and bind the session using different characteristics than Telnet requested. For this reason, some screen sizes might not work correctly even though the logmode defined in Telnet is correct. If the KEEPOPEN function is used to allow session initiation by the host application, the desired logmode must be coded on the DLOGMOD parameter as part of the VTAM application definition statement that defines the Telnet LU. Otherwise, the application will choose its own logmode.

Telnet processes the ATTN KEY request differently for non-SNA and SNA sessions. For non-SNA sessions (BIND FM value 02), Telnet converts the ATTN KEY request to a '6C'x data byte and sends it to the application. For SNA sessions (BIND FM value 03), Telnet converts the ATTN KEY request into a SNA signal and sends it to the application as expedited data. Some clients send both an ATTN KEY function code and a '6C'x data byte to ensure the ATTN is seen by the application. Telnet converts the ATTN KEY function into either a '6C'x data byte or a SNA signal and also forwards the '6C'x data. Some applications give unexpected results or Telnet might appear to not support ATTN when two ATTNs are received. The SINGLEATTN parameter causes Telnet to drop the second ATTN if it immediately follows an ATTN. The SINGLEATTN and NOSINGLEATTN parameters can be coded at all three parameter block levels for different levels of granularity.

To change either the TN3270 or the TN3270E logmode for a device type, use the TELNETDEVICE parameter. Whenever Telnet initiates the session request, Telnet will request that the logmode specified on the TELNETDEVICE statement be used for the session. The application (the primary LU) does have the ability to override the requested logmode and use a completely different logmode. The TELNETDEVICE parameter can be coded in all three parameter block levels for different levels of granularity. Coding TELNETDEVICE in a PARMSGROUP that is mapped on the LUMAP-DEFAPPL-PMAP statement enables the logmode to be LU and application specific.

If the application initiates the session, the TELNETDEVICE logmode has no affect on the session. For example, printer sessions are initiated by the application unless a printer default application is specified. The LUMAP-KEEPOPEN parameter can be used to open a terminal ACB and wait for the primary application to initiate the session.

Transform Linemode connections can have a unique logmode by coding TELNETDEVICE with a device type of TRANSFORM. Any logmode used must not support extended graphics.

The special case logmode NONE can be specified indicating that Telnet should not send any logmode request when initiating the session.

In the examples that follow, the first line causes only the TN3270 logmode to change from the default to SNX32705. The second line causes both the TN3270 and TN3270E logmodes to change from their defaults to SNX32705 and SNX32702. The third line causes only the TN3270E logmode to change from the default to SNX32702.

```
TELNETDEVICE 3278-5-E SNX32705
TELNETDEVICE 3278-5-E SNX32705,SNX32702
TELNETDEVICE 3278-5-E ,SNX32702
```

Using the Telnet Solicitor or USS logon panel

This topic describes the Telnet Solicitor panel and Telnet Unformatted System Services (USS) support. All information needed to establish a session can be entered on the Telnet Solicitor panel. However, Telnet is often used as the primary method of connecting to the SNA mainframe environment. SNA end users are accustomed to entering abbreviated logon commands, specifying their own logmode, and entering user data from SNA terminals. The USS table itself can be used to customize information such as logmode before it is sent to VTAM. The logmode specified by the user or the USS table overrides the logmode specified by the TELNETDEVICE statement. For ease of migration, Telnet simulates SNA USS processing very closely. This simulation extends to being able to use the same assembled USS tables that are used by VTAM. VTAM-only character substitutions are ignored by Telnet and Telnet-only character substitutions are ignored by VTAM. Blanks are used in their place. To further extend the simulation of SNA terminals, Telnet also supports all of the INTERPRET table function.

Using the Telnet Solicitor logon panel: Telnet sends a Solicitor panel to the end user if one of the following is true:

- No DEFAULTAPPL, LINEMODEAPPL, USSTCP, or LUMAP-DEFAPPL mappings match the client's Client Identifier.
- The requested application is a RESTRICTAPPL.

Below is an example of the Telnet Solicitor panel:

```
Enter Your Userid:
Password:                          New Password:
Application:
```

Initial cursor placement can be specified. Where initial placement should be depends on client macros used and end user preferences. The OLDSOLICITOR parameter is used to implement this choice. The default cursor position is on the 'Application:' field. If OLDSOLICITOR is coded, the cursor is positioned on the 'Enter Your Userid:' field. The OLDSOLICITOR and NOOLDSOLICITOR parameters can be coded at all three parameter block levels for different levels of granularity.

In addition to satisfying RESTRICTAPPL, there are other times when an end user might want to use the user ID/Password fields. For example, the solicitor panel may also be used to change a password by entering the user ID, old password, and new password. The application field does not need to be filled in. If insufficient information was provided by the client (for example, a user ID but no

password), then the Telnet Solicitor panel is returned with a message prompting for the required field. A message is also returned if the security program encounters an error when attempting to change the password. Example messages include:

- Password required
- Password is not authorized

Using the Telnet USS and INTERPRET support: The Telnet USS function provides the end user with a USSMSG10 logon panel similar to the logon panel used by native SNA terminals. The Telnet USS function supports sending USSMSGs to the client, receiving and parsing USSCMDs from the client, and using a translation table defined in the USS table.

Telnet supports both 3270-format and SNA character stream (SCS)-format USS tables. The SCS USS table name is optional on the USSTCP mapping statement. If an SCS name is provided, the SCS USS table is used for all TN3270E connections.

The CLEAR key is handled differently by the client depending on whether a 3270-format or SCS-format USS table is used. The CLEAR key has a special function for 3270-format USSMSGs. Pressing the CLEAR key sends the CLEAR key data stream to Telnet. If REFRESHMSG10 is specified or used by default, pressing the CLEAR key refreshes the screen with USSMSG10 for any USSMSG other than USSMSG10. If you press the CLEAR key while at USSMSG10, the screen is cleared and the cursor is placed near the upper left corner (row 1, column 2). If you press the CLEAR key a second time, the screen refreshes with USSMSG10. If NOREFRESHMSG10 is specified, pressing the CLEAR key always clears the screen of any USSMSG and places the cursor in the upper left corner (row 1, column 1). For SCS-format USSMSGs, the CLEAR key does not provide the same special function. For SCS, the client processes the CLEAR key by clearing the screen and placing the cursor at the upper left corner (row 1, column 1) with no data sent to Telnet.

USS data traffic is also handled differently depending on whether a 3270-format or SCS-format USS table is used. If a 3270-format USS table is used with a TN3270E connection that has negotiated BIND-IMAGE, a Telnet-generated Bind/Unbind encapsulates the USS traffic. If the connection is TN3270, BIND-IMAGE is not negotiated, or the SCS-format USS table is used, Telnet does not encapsulate the USS traffic in a Bind/Unbind. If a 3270-format USS table is used, the Telnet data type for all traffic is 3270-DATA. If an SCS-format USS table is used, the Telnet data type for all traffic is SSCP-LU-DATA. Regardless of USS table format, if the SYSREQ function is supported on a TN3270E connection and SYSREQ is received by Telnet, Telnet will accept a LOGOFF command in SSCP-LU-DATA format. If the client sends any command other than LOGOFF, `COMMAND UNRECOGNIZED` is returned in SSCP-LU-DATA format. If the client sends a second SYSREQ, Telnet reverts back to whatever the session state was prior to receiving the first SYSREQ.

USSCMD parsing also includes checking for INTERPRET table entries that might provide more function than USS tables alone can provide. Sample USS tables are in TCP/IP data sets SEZAINST(EZBTPUST) and SEZAINST(EZBTPSCS). A sample INTERPRET table is in TCP/IP data set SEZAINST(EZBTPINT). The 3270 format USS sample has been assembled, linked, and loaded into the product data set. The tables can be used by coding the USSTCP and INTERPTCP mapping statements in BEGINVTAM. For example, the statements below will map the sample tables to the client at IP address 1.1.1.1. See “Mapping Objects to Client Identifiers” on page 595 for mapping details.

```
USSTCP      EZBTPUST,EZBTPSCS  1.1.1.1
INTERPTCP   EZBTPINT  1.1.1.1
```

A new table can be created at any time and link-edited. Customized USS and INTERPRET tables can be created to change messages, commands, and translation tables. For example, messages can be changed to have non-English text or to have different syntax. Commands can be changed to accept different syntax or to have different default values. A VARY TCPIP,*tnproc*,OBEYFILE command will cause Telnet to load the new table with the new profile being processed. Any new connection using the new profile will be assigned the new table. Telnet also supports dynamic updating of same-name USS or INTERPRET tables. The VARY TCPIP,*tnproc*,OBEYFILE command adds the new version of the table to the new profile. New connections use the new copy associated with the new profile while old connections continue to use the old copy associated with the old profile.

USS table customization: Customized USS tables are used by both VTAM and Telnet, with any product-specific character substitutions converted to blanks. For example, @@SSCPNM is blank for Telnet and @@PRT is blank for VTAM. Telnet USS processing also supports system symbolic substitution. VTAM does no substitution for system symbolics. The tables must reside in a data set that is in the system's linklist or is in the STEPLIB statement of the TCP/IP startup procedure. Any changes to a Telnet USS table should be made with supplementary user-defined USS tables. The IBM-supplied USS table should not be changed as it provides a good example of coding most commands and messages. Telnet loads the first table found with the name EZBTPUST and defines it as the default USS table. If this table is not found, there is no default USS table. Whether or not a default USS table should be included depends on the desired message output. When writing a USS Message, Telnet searches the USS table mapped to the client first. If the message does not exist in the mapped table, Telnet searches the default table. If the message does not exist in the default table, Telnet writes USSMSG14. If no default table exists, Telnet generates a USSMSG14. For 3270 format USSMSGs, the end user can get back to the USSMSG10 from any message by pressing the CLEAR key. The default table does not affect the USS commands. The command entered must be in the mapped table or it is not recognized. The sample SCS USS table found in SEZAINST(EZBTPSCS) is not assembled and linked, and it is not loaded into Telnet as a default SCS USS table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

Creating a USS table: The following macro instructions are used to create the USS table. Telnet USS function supports almost all VTAM session-level USS message and command definitions. See *z/OS Communications Server: IP Configuration Reference* for macro details.

- USSTAB indicates the beginning of the USS table.
- USSCMD defines commands accepted by Telnet.
- USSPARM defines each operand or positional parameter that can be specified on the USSCMD macro instruction. It also defines default values for the operand or positional parameter. Multiple USSPARM macro instructions can be associated with a USSCMD macro instruction. For each operand or positional parameter code a USSPARM macro instruction.
- USSMSG defines messages sent from Telnet.
- USSEND indicates the end of the USS table.

Following are some of the more common rules to consider when coding a new USS table. Also, see the samples found in SEZAINST(EZBTPUST) and

SEZAINST(EZBTPSCS) as a guide. “Considerations when using mixed-case passwords” discusses general table rules.

- If a DEFAULTAPPL application is mapped at the same Client Identifier level as a USS table, or an LUMAP-DEFAPPL application is mapped, the USS table is used only to return error messages and optionally after the first session logoff. FIRSTONLY or LOGAPPL options on DEFAULTAPPL will cause Telnet to send a USSMSG10 after the first session logoff. DEFAULTAPPL without the FIRSTONLY or LOGAPPL options will cause Telnet to request a session with the default application after every session logoff.
- Both the 3270 data stream and the SNA character stream (SCS) formats are supported. For more information, see *3270 Data Stream Programmer's Reference* and the table samples.
- If a user-defined table is coded as part of another module, code an assembler EXTRN definition statement for the table name in that module so the table will be known externally and can be accessed by other modules.

Below are message related rules.

- 3270 format USSMSGs must contain the 3270 data stream write control characters (WCCs).
- All character substitutions (@@'s) substitute the same number of characters. Any character substitution that is VTAM-specific will be translated to blanks. If the substituted value is smaller, the field is padded to the right with blanks. The parameter LUNAME or SCAN must be coded on the USSMSG macro instruction for Telnet to perform character substitutions. For a complete list of character substitutions, see *z/OS Communications Server: IP Configuration Reference* for Telnet and *z/OS Communications Server: SNA Resource Definition Reference* for VTAM. Telnet supports multiple USSPARMs with the DATA keyword. This method can be used to pass multiple data parameters to the host application. For example, two DATA USSPARMs allow the end user to type 'TSO USER1 PROC001' and have both the user ID and the Procname passed to TSO as data. Telnet also supports the system symbolics substitution, padding to the right when the substituted value is smaller than the symbolic. VTAM USS processing does not support system symbolic substitution.

Below are command related rules.

- LOGON command format

  PL1 - logon applid(tso) logmode(snx32702) data(user1)

  BAL - logon applid=tso,logmode=snx32702,data=user1
- Any application defined in a USSCMD macro instruction must also be specified on either an ALLOWAPPL or a RESTRICTAPPL statement in the Telnet profile.
- If the USS Command rules in *z/OS Communications Server: IP Configuration Reference* cannot be followed, use an interpret table to convert the character-coded command into a formatted SNA request.

Considerations when using mixed-case passwords: Mixed-case passwords can be used by applications if an SAF-compliant security product (such as RACF) has enabled this support. In some cases, the USS LOGON DATA parameter is used to send the password to the application. If a terminal user enters a mixed-case password on the USS LOGON command and it is translated to uppercase by the translation table, the logon will fail if the target application expects the password in mixed case.

The USS LOGON command is displayed on the terminal as it is typed, so the password is displayed unless the 3270 format is used and the password is entered

into a field with a non-display attribute. For additional security, inform the terminal user to stop entering the password as part of the USS LOGON. Instead, the application should prompt the terminal user for the password in a non-displayed field. If mixed-case passwords are used and the terminal user continues to enter the password as part of the USS LOGON command, the logon will fail when using TRANSLATE=YES (the default) on the USSPARM, because the password has been translated to uppercase.

If you want to continue allowing the terminal user to enter the password on the LOGON command, use one of the following methods to support mixed-case passwords:

- If the current USS translate table is used to set all characters to uppercase, the TRANSLATE=NO operand can be added to the USSPARM macros for the corresponding USSCMD, to prevent the specified DATA USSPARM containing the password from being translated to uppercase. For details, see *z/OS Communications Server: IP Configuration Reference*.
- Do not change the USS command and inform the terminal user to enter the DATA portion of the USS LOGON in single quotes. USS will not translate data within single quotes, and the quotes are removed before the data is passed to the application.
- If the terminal user is specifying only APPLID and DATA on the USS LOGON command, you can use an interpret table. The Telnet Interpret function passes all entered data without translation to the application. Specify REMOVE=Y on the LOGCHAR macro to remove the first non blank string from the entered data. Because the terminal user could enter the APPLID in lowercase, you should set up an interpret table that searches for both an uppercase and a lowercase APPLID.

With each of these methods, if the user ID is entered with the password, you must first verify whether the application supports translating the user ID to uppercase. A simple test is to enter the DATA portion of the USS LOGON in single quotes with the user ID specified in lowercase. USS will not translate data within single quotes and the quotes are removed before the data is passed to the application. If the logon fails, the application does not support translating the user ID to uppercase and the terminal user must enter the user ID in uppercase and the password in mixed case for the methods suggested.

INTERPRET table customization: The standard Telnet USS logon support should meet the needs of most installations. However, Telnet does support INTERPRET table function if special circumstances require accepting a sequence of characters outside the normal USS command format. For example, the end user might want to enter logon data that includes blanks. The INTERPRET table defines all entered data, including blanks, as a USSPARM DATA entry. The PL1 USSCMD format treats each blank as a parameter delimiter and cannot properly process a variable number of parameters. The INTERPRET table character sequences are scanned whenever the client is mapped to both a USS table and an INTERPRET table. Both must be mapped because the INTERPRET function is a subset of the USS function. INTERPRET is not a stand-alone function. The sample INTERPRET table found in SEZAINST(EZBTPINT) is not assembled and linked, and it is not loaded into Telnet as a default INTERPRET table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

Creating an INTERPRET table: Telnet INTERPRET function supports all functions provided by the VTAM INTERPRET definitions. See *z/OS Communications Server: IP Configuration Reference* for macro details. The following macro instructions are used to create an INTERPRET table:

- INTAB indicates the beginning of the INTERPRET table.
- LOGCHAR defines a single logon message and name of an application program.
- ENDINTAB indicates the end of the INTERPRET table.

Below are some of the more common rules to consider when coding a new INTERPRET table. Also, see the sample found in SEZAINST(EZBTPINT) as a guide.

- The LOGCHAR APPLID= supports APPLICID, ROUTINE and USERVAR.
- Code the most restrictive, or longest, LOGCHAR SEQNCE values first. Otherwise, unexpected matches can occur. The table is scanned from top to bottom until a match is found whether or not it is the most exact match. For example, assume sequence 'LOGA' is assigned APPL1 and any other 'LOG' sequence is assigned APPL2. If sequence 'LOG' is before 'LOGA', entry 'LOGA' will never be found even when the end user enters 'LOGA' because entry 'LOG' will be the first match. All sessions will go to APPL2. The problem is corrected by putting 'LOGA' before 'LOG' in the table.

Assemble, link, and load a table: Use the sample JCL in SEZAINST(EZBUSJCL). In the sample, the USS table is in USER1.TABLES(USSTEST). It must be assembled and link-edited into the system's linklist or into a library concatenated as a STEPLIB in the TCP/IP startup procedure. In the sample, the table is link-edited into USER1.LINKLIB(USSTEST). The same procedure can be used for the INTERPRET table. Simply change the name of the input file source and the link-edit target member. The VTAM USS and INTERPRET macros used for the assemble can be found in *hlq*.SISTMAC1.

SMF

SMF records are written when an end user establishes a session (SMF LOGN or Telnet SNA Session Initiation record) and when the session is ended (SMF LOGF or Telnet SNA Session Termination record). Optional SMF recording is controlled by using the SMFINIT and SMFTERM statements.

Two different record formats are available: SMF type 118 and 119. The type 119 records were first introduced in z/OS V1R2 Communications Server, and are controlled by use of the TYPE119/NOTYPE119 operands on the SMFINIT and SMFTERM statements. The subtypes cannot be changed for type 119 records and are set to the STD values. The use of the STD operand or the specification of a nonstandard subtype number on the SMFINIT and SMFTERM parameters control the usage of the older type 118 record processing. Data recorded includes the application name, Telnet LU name, client and host IP address and port, time of logon or logoff, and data count in and out. Combined with the SMF utility exit routine, SMF data can be used to track Telnet usage by a number of variables. If statements for both format types are coded then both record types are written. That capability should be used sparingly due to the additional processing costs involved in generating both types records. For more information about the layouts for type 118 and type 119 SMF records, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Connection monitoring mapping statement

Telnet collects monitoring data for any client connection that is mapped to a MONITORGROUP Object. The collected data can be retrieved several ways:

- Display the data for a single connection using the D TCPIP,*tnproc*,TELNET,CONN,CONN=*connid* command.
- A network management agent can request the data from the Telnet SNMP subagent, after the subagent is started by specifying the TNSACONFIG statement. TCPIPJOBNAME must be specified for the subagent to connect with the agent. For information about the TNSACONFIG statement and the parameters needed to start the subagent, see *z/OS Communications Server: IP Configuration Reference*. For details about configuring the SNMP agent, see Chapter 25, "Simple Network Management Protocol," on page 1325.
- The Network Management Interface (NMI) Application Programming Interface (API), EZBNMIFR, can be used instead of SNMP to retrieve the data. In this case, the TNSACONFIG statement is not needed. For details about configuring EZBNMIFR and the parameters needed to issue the call, see *z/OS Communications Server: IP Programmer's Guide and Reference*.
- The Telnet SMF119 session termination record contains two optional sections that can be used to retrieve life-of-session performance data. Life-of-session data is a subset of life-of-connection data. Sliding-window data is not available because data is reported only at the end of the session and not at periodic intervals. One optional section contains response time statistics (excluding sliding-window) and a second optional section contains response time counts by time bucket. For details on the Telnet server SNA session termination record, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Telnet is capable of collecting two types of response time data at the connection level.

- Response time statistics
  - Life-of-connection response time averages
  - Sliding-window response time averages
  - Sum of squares for variance and standard deviation calculations
- Response time counts by time bucket

The MONITORGROUP Object statement in BEGINVTAM is used to set the criteria for monitoring. Options allow the inclusion or exclusion of averages, counts by time bucket, and whether or not the IP network should be included in measurements. When a MONITORGROUP is mapped to Client Identifiers with the MONITORMAP mapping statement, the requested data will be collected for those connections.

Up to 255 MonitorGroups can be active at one time for all ports per Telnet instance. Once 255 MonitorGroups are active, no additional groups can be created until some groups are no longer in use by Telnet. A MonitorGroup is considered no longer in use when the group is not defined in a current profile and no connections are using the non-current profile where the MonitorGroup was defined. After being notified that no entries are available, it is up to the operator to manage the removal of some entries by ending connections to free a profile. The operator does not get a notification when an entry becomes available.

Each MonitorGroup entry in the table is assigned an index number. The index number coincides with one of the 255 slots available in the MonitorGroup table. Each Telnet connection entry saves the index number of the MonitorGroup mapped to the connection. When the management application queries a connection for data, it can also query the MonitorGroup table to get the group name and configuration values based on the index found in the connection entry. With the data from the connection and the MonitorGroup criteria from the MonitorGroup

table, a management application can generate several summary reports. If a management application is not being used to collect the connection monitoring data, the D TCPIP,*tnproc*,TELNET,CONN,CONN=*connid* command can be used to view all the collected data and MonitorGroup information for a single connection.

Collecting response time data: The typical Telnet data flow can be represented as shown in Figure 69.

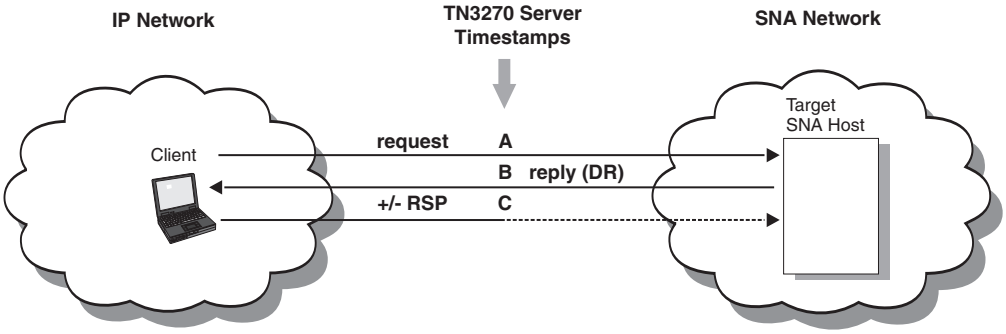

Figure 69. Typical Telnet data flow

Telnet saves timestamp A when it sends a client data request to VTAM, saves timestamp B when the target SNA host application returns data, and saves timestamp C when the client responds to the definite response request that flowed with the reply.

There are many clients, mostly those not supporting TN3270E negotiation, that do not support the Definite Response (DR) function. In this case, Telnet approximates IP response time by appending a TIMEMARK request immediately after the data. A Telnet TIMEMARK acts as a synchronization mark or simply an "are you there" function for almost all clients. Almost all clients respond to the TIMEMARK request. Timestamps B and C are set based on when the TIMEMARK request is sent and a TIMEMARK response is received. In rare cases, a client does not respond to a TIMEMARK request. If Telnet does not receive a response to the TIMEMARK, a flag in the connection data indicates that IP transit time measurements were not attempted.

Some installations might not want to incur the additional network traffic of DRs or TIMEMARKs to measure IP transit time, and are only interested in the SNA application side transit time. In this case, turn off IP response measurements by specifying NOINCLUDEIP within MonitorGroup. Total response times will be the SNA response time only.

Specify INCLUDEIP within the MonitorGroup to include IP response measurements when monitoring a connection. It does not matter whether the SNA host application requested a definite response on its reply. Many applications save processing time and IP transactions by not requesting Definite Response. If IP response time monitoring is desired and the client supports DR, specify DYNAMICDR within MonitorGroup to add the definite response request to ensure a response is received from the client. In this case, Telnet does not forward the response to the target SNA host application, as indicated by the dotted line in Figure 69. Specify NODYNAMICDR to turn off dynamic DR creation. If INCLUDEIP and NODYNAMICDR are specified and data from the application does not include a DR request, the TIMEMARK method is used.

If chained data is sent from the host application, Telnet collects the entire chain before sending the complete data stream to the client. Telnet will save timestamp B when the entire data chain is sent.

It should be pointed out that the measured response time might not be exactly what the end user sees. The first timestamp, A, is recorded when the data passes from Telnet to VTAM on its way to the SNA VTAM application. For various SNA reasons, Telnet might have received the data much earlier and had to queue it before it could be sent to VTAM. The most common reason for this is the application might not have given Telnet direction (the ability to send data). SNA applications often use a Change Direction Indicator (CDI) to manage which side can send data. The current sender can send data until it sends a CDI, which gives the other side permission to send. There might be scenarios where a client data request comes in, Telnet does not have direction, and must queue the data until the application sends a CDI. The measured response time will not include this queue time.

Average response time data collection: Specify AVERAGE within MonitorGroup to collect average response time data. Specify NOAVERAGE to turn off average response time data collection. If average response time data is requested, the following data is available on a per connection basis:

- Life-of-connection response time averages
- Sliding-window response time averages
- Variance and standard deviation of response time averages

Life-of-connection response time averages: These averages are based on data collected since the beginning of the connection. Data collected for this average includes:

- Total transaction count.
- Sum of the round-trip response times. Round-trip response time is the time difference between timestamp C and timestamp A.
- Sum of the IP response times. IP response time is the time difference between timestamp C and timestamp B. Sum of the SNA response times can be derived by subtracting the IP sum from the round-trip sum.

With this data collected, the average round-trip time, average IP time, and average SNA time can be calculated by dividing each sum by the transaction count. The data accumulation values might wrap. It is up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying averages.

Sliding-window response time averages: These averages give higher significance to more recent data without ever completely losing the impact of earlier data. The sliding-window methodology calculates an average over an interval of time instead of over the life of the connection. An interval is made up of a specified number of equal time periods. Use AVGSAMPMULTIPLIER to specify how many periods are in the interval. Use AVGSAMPPERIOD to specify the time length of a period. An interval should be long enough to have several data flows measured. Data collected during the period includes:

- Transaction count in the period (pTX).
- Sum of round-trip response times in the period (pRT).
- Sum of IP response times in the period (pIP). Sum of SNA response times can be derived.

In addition, there are three sliding-window variables that represent the interval and are used to calculate the sliding-window average. These variables are updated at the end of each period. They are:

- Sliding-window transaction count (swTX).
- Sliding-window sum of round-trip response times (swRT).
- Sliding-window sum of IP response times (swIP). Sliding-window sum of SNA response times can be derived.

When the interval has moved one period, subtracting the oldest period of collected data from the total and adding the newest period is one method for determining the new interval averages. However, this simple method loses all impact of earlier periods on the averages. Instead of dropping the collected data from the oldest period in the interval and completely losing its effect on the average, an average period of data is subtracted from the sliding-window totals. With this method, even the oldest period data continues to have a declining effect on the latest average calculations. And, by using an average period amount, the unique data for each period does not need to be retained. Only a total for the entire interval needs to be saved. Average period data is determined based on the fact that a period is a fraction of the total interval time. A period of data is $1/n$ of the current sliding-window totals, where n is the number of periods in the interval. The sliding-window average is derived from the new sliding-window values. At the end of each period the following calculations occur:

- Calculate the average period values:

```
avTX = swTX * (1/n)
avRT = swRT * (1/n)
avIP = swIP * (1/n)
```

- Remove an average period amount from the sliding-window totals and add the new period values:

```
swTX = swTX - avTX + pTX
swRT = swRT - avRT + pRT
swIP = swIP - avIP + pRT
```

- Calculate and report new sliding-window averages:

```
sliding-window round-trip average = swRT/swTX
sliding-window IP average = swIP/swTX
sliding-window SNA average = (swRT-swIP)/swTX
```

After the calculations are done, the period variables are reset and the next period of data collection begins. At the end of that period, the sliding-window variables are updated again with new information. The cycle continues for the life of the connection.

AVGSAMPMULTIPLIER 1 is a special case where 100% of the existing interval data is subtracted before the new period data is added. The result is an average for just that interval and the effect of older data is completely ignored.

AVGSAMPMULTIPLIER 0 is a special case that tells Telnet to include all data equally. The result is a life-of-connection average that is already available. A very large multiplier will have a similar effect.

A sliding-window round-trip average example follows. Assume an interval is made up of 5 periods. Each period is 2 minutes. Specify AVGSAMPMULTIPLIER 5 and AVGSAMPPERIOD 120. For illustrative purposes in this example, the average response time starts low and then increases to a steady state value. The data collected for each period is the sum of all response times in milliseconds (ms) and the number of transactions (tx).

Table 30. Sliding-window round-trip average example

Period	Sum of response times (ms)	Number of transactions (tx)	Average response time (ms/tx)
1	1000	10	100
2	1650	15	110
3	2800	20	140
4	3500	25	140
5	4200	30	140
6	4900	35	140
7	5600	40	140

The sliding-window average response time for period 1:
`1000ms/10tx = 1000ms/10tx = 100 ms/tx`

The sliding-window average response time for period 2:
`(1000-(1000*(1/5))+1650)ms/ (10-(10*(1/5))+15)tx = 2450ms/23tx = 106.5 ms/tx`

The sliding-window average response time for period 3:
`(2450-(2450*(1/5))+2800)ms/ (23-(23*(1/5))+20)tx = 4760ms/38.4tx = 124.0 ms/tx`

The sliding-window average response time for period 4:
`7308ms/55.7tx  = 131.2 ms/tx`

The sliding-window average response time for period 5:
`10046.4ms/74.6tx = 134.7 ms/tx`

The sliding-window average response time for period 6:
`12937.1ms/94.7tx = 136.6 ms/tx`

The sliding-window average response time for period 7:
`15949.7ms/115.7tx = 137.9 ms/tx`

The sliding-window method continues to include the effects of the earlier response time averages. The greater the number of periods (AVGSAMPMULTIPLIER), the longer older data will continue to impact new average calculations. Decreasing the number of periods (AVGSAMPMULTIPLIER) gives less emphasis to older data. The AVGSAMPMULTIPLIER gives the system administrator control over the emphasis placed on old data.

Each of the last five periods in the example had average response times of 140 ms/tx. Different multiplier values give the following results after seven periods. It is clear that the greater the number of periods in the interval, the greater the impact of the older data.

- 2 period interval - 139.7 ms/tx
- 5 period interval - 137.9 ms/tx
- 10 period interval - 136.6 ms/tx

Variance and standard deviation of response time averages: It is useful to know the dispersion of the response time data. The variance is a measure of how spread out

the data is. The square root of the variance is the standard deviation. Assuming the distribution is a normal distribution, you can have a confidence level of the following:

- 68% that a response time value will fall within the average, plus or minus 1 standard deviation
- 95% that a response time value will fall within the average, plus or minus 2 standard deviations
- 99% that a response time value will fall within the average, plus or minus 3 standard deviations

The data saved for variance and standard deviation includes the data saved for life-of-connection averages, and the sum of each response time squared for the following:

- Complete round-trip.
- IP portion of the transaction.
- SNA portion of the transaction. The sum of squares cannot be derived in this case and must be separately maintained.

These values might wrap. It is up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying these values or the standard deviation. The typical formula used for variance is:

```
VARIANCE = SUM((Xi-Xm)**2)/(n-1)
```

However, that would require keeping all the individual response times to calculate the sum of the squares. The same formula can be expanded and rewritten to not need individual response times. The formula used by Telnet is:

```
VARIANCE = [SUM(Xi**2) - (SUM(Xi))**2/n]/(n-1)
```

The values needed in this formula are saved by Telnet for each connection requesting average response time monitoring.

Time buckets: Five time buckets, each defined by a maximum response time, are used. Every transaction has a total response time, and that time fits into one of the five configurable time buckets. The bucket boundaries are created by specifying the maximum response time for the first four buckets. The fifth bucket has an open-ended maximum value. The minimum response time boundary for each bucket is the maximum of the previous bucket. The first bucket has a minimum value of 0. A bucket transaction count is incremented by one when a response time is greater than the minimum and less than or equal to the maximum. Figure 70 depicts the time buckets. For default values, see *z/OS Communications Server: IP Configuration Reference*.

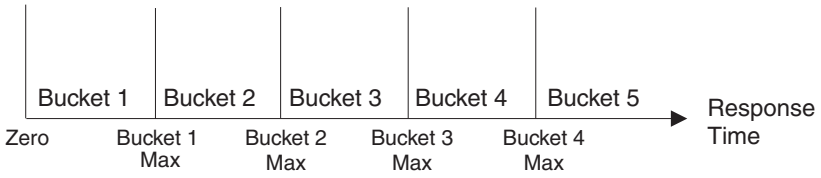

Figure 70. Time buckets

Reducing demand for ECSA storage

Telnet server configurations that support a large number of connections can place a high demand on ECSA storage. To reduce this demand, configure the Telnet server to enable multiple Telnet LUs to share an ACB.

To configure the Telnet server to enable LUs to share an ACB, specify SHAREACB in the TELNETGLOBALS statement block. Replace any predefined (static) VTAM APPL definitions that are being used to represent Telnet LUs with corresponding model application program definitions; the latter are required when using the SHAREACB function.

Configuring the z/OS UNIX Telnet server

The z/OS UNIX Telnet server (otelnetd) provides access to z/OS UNIX shell applications on the host using the Telnet protocol. The z/OS UNIX Telnet server lets hosts in an IP network log on to the z/OS shell environment directly, without going through TSO. The z/OS UNIX Telnet server supports AIX and UNIX full-screen applications such as the vi editor, so that AIX and UNIX users can use familiar Telnet commands. The z/OS UNIX Telnet server runs in both line mode and raw mode, but does not support TN3270 or TN3270E, as the TN3270E Telnet server does.

Installation information

The files used in the z/OS UNIX Telnet server and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here. For example:

```
otelnet xxxx/tcp
```

where *xxxx* is the port that inetd should listen on for otelnet.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file. otelnetd writes to syslog facility local1.

/etc/inetd.conf
The configuration parameters for all applications started by inetd are defined in this file.

/usr/sbin/otelnetd
This is a symbolic link to /usr/lpp/tcpip/sbin/otelnetd. /usr/lpp/tcpip/sbin/otelnetd is a sticky-bit file. The OTELNETD member of SEZALOAD contains the executable code for the Telnet server.

/etc/banner
This file contains a login message that is printed to the client's screen after the client logs in, unless the **-h** option is specified. Store the banner in this file.

/etc/otelnetd.banner
This file contains a message that is printed to the client's screen prior to the login prompt when the user connects to the server, unless the **-h** option is specified. Store the banner in this file.

/etc/utmpx
This file is updated by the call to fsumoclp. It contains a list of all the users who are logged in with their associated tty.

/dev/ptypXXXX and /dev/ttypXXXX
These special device files represent pseudoterminals (ptys); they are used by the z/OS UNIX Telnet server and other programs.

Note: For information on allocating more of these files for more connections, see *z/OS UNIX System Services Planning*.

/usr/share/lib/terminfo
The descriptions of supported terminals are stored here. For more information, see *z/OS UNIX System Services Planning*.

/usr/lib/nls/msg/C/tnmsgs.cat
The message catalog used by the z/OS UNIX Telnet server is stored here.

If the message catalog does not exist, the software will use the messages hard-coded within the software by default. These messages duplicate the English message catalog that is shipped with the product.

/usr/man/C/cat1/otelnetd.1
This file contains the associated manual (man) pages for the z/OS UNIX Telnet server. It provides online help for the user.

Environment variables

Table 31 provides a list of environment variables that can be explicitly set by z/OS UNIX Telnet.

Table 31. Environment variables for z/OS UNIX Telnet

Environment variable	Description
_BPX_SHAREAS	Controls whether a spawned child process is started in the same address space as the login shell.
KRB5_SERVER_KEYTAB	Specifies the location of the key table.
LC_ALL	Determines the values for all local categories.
LC_COLLATE	Determines the local category for character collation.
LC_CTYPE	Determines the local category for character handling functions, such as tolower(), toupper(), and isalpha(). Also determines the interpretation of sequences of bytes of text data as characters (for example, single as opposed to multibyte characters), the classification of characters (for example, alpha, digit, graph), and the behavior of character classes.
LC_MESSAGES	Determines the local category for processing affirmative and negative responses, and the language and cultural conventions in which messages should be written.
LC_NUMERIC	Determines the local category for numeric formatting information (for example, thousands separator and radix character) in various utilities, as well as the formatted I/O operations in printf() and scanf() and the string conversion functions in strtod().

Table 31. Environment variables for z/OS UNIX Telnet (continued)

Environment variable	Description
LC_TIME	Determines the local category for date and time formatting information. It affects the behavior of the time functions in strftime(). Additional semantics of this variable, if any, are implementation defined.
NLSPATH	Contains a sequence of templates that the catopen() function uses when attempting to locate message catalogs. Each template consists of an optional prefix, one or more conversion specifications, a file name, and an optional suffix.
TERMINFO	Specifies the path name for an unsupported terminal that has been added to the terminfo file. Use the TERMINFO variable in /etc/profile or /etc/.login.

Starting, stopping, and administration of z/OS UNIX Telnet

The z/OS UNIX Telnet server is started by inetd for each incoming Telnet connection. When the Telnet session is complete, the z/OS UNIX Telnet server will exit. Each active Telnet session will have a separate instance of the Telnet server which will communicate with the Telnet client.

The z/OS UNIX inetd daemon does not propagate environment variables other than PATH and TZ to its child processes, so the NLSPATH and LANG environment variables cannot be used to point to a different message catalog.

The following standards are supported:
- RFC 854 Telnet Protocol Specification
- RFC 855 Telnet Option Specification
- RFC 856 Telnet Binary Transmission
- RFC 857 Telnet Echo Option
- RFC 858 Telnet Suppress Go Ahead Option
- RFC 859 Telnet Status Option
- RFC 860 Telnet Timing Mark Option
- RFC 861 Telnet Extended Options - List Option
- RFC 885 Telnet End of Record Option
- RFC 1073 Telnet Window Size Option
- RFC 1079 Telnet Terminal Speed Option
- RFC 1091 Telnet Terminal type option
- RFC 1096 Telnet X Display Location Option
- RFC 1123 Requirements for Internet Hosts -- Application and Support
- RFC 1184 Telnet Linemode Option
- RFC 1372 Telnet Remote Flow Control Option
- RFC 1571 Telnet Environment Option Interoperability Issues
- RFC 1572 Telnet Environment Option
- RFC 2941 Telnet Authentication Option
- RFC 2942 Telnet Authentication: Kerberos Version 5
- RFC 2946 Telnet Data Encryption Option
- RFC 2952 Telnet Encryption: DES 64 bit Cipher Feedback
- RFC 2953 Telnet Encryption: DES 64 bit Output Feedback

When a z/OS UNIX Telnet session is started up, otelnetd sends Telnet options to the client side indicating a willingness to do the following:

- WILL ENCRYPT
- DO ENCRYPT
- DO TERMINAL TYPE
- DO TSPEED
- DO XDISPLOC
- DO NEW-ENVIRON
- DO ENVIRON
- WILL SUPPRESS GO AHEAD
- DO ECHO
- DO LINEMODE
- DO NAWS
- WILL STATUS
- DO LFLOW
- DO TIMING-MARK

The z/OS UNIX Telnet server can enable the following options locally.

- WILL BINARY

  This option indicates that the client is willing to send 8 bits of data, rather than the normal 7 bits of network virtual terminal data.
- WILL ECHO

  When the LINEMODE option is enabled, a WILL ECHO or WONT ECHO will be sent to the client to indicate the current state of terminal echoing. When terminal echo is not desired, a WILL ECHO is sent to indicate that Telnet will take care of echoing any data that needs to be echoed to the terminal, and then nothing is echoed. When terminal echo is desired, a WONT ECHO is sent to indicate that Telnet will not be doing any terminal echoing, so the client should do any terminal echoing that is needed.
- WILL LOGOUT

  When a DO LOGOUT is received, a WILL LOGOUT is sent in response and the Telnet session is shut down.
- WILL SGA

  This option indicates that it will not be sending IAC GA, the go ahead command.
- WILL STATUS

  Indicates a willingness to send the client, upon request, the current status of all Telnet options.
- WILL TIMING-MARK

  Whenever a DO TIMING-MARK is received, a WILL TIMING-MARK is the response. It is only used in kludge linemode support.
- WILL ENCRYPT

  Indicates a willingness to encrypt the data stream.

The z/OS UNIX Telnet server can enable the following options remotely.

- DO BINARY

  Sent to indicate that Telnet is willing to receive an 8-bit data stream.
- DO ECHO

  If a WILL ECHO is received, a DONT ECHO will be sent in response.
- DO ENVIRON

Indicates a desire to be able to request environment variable information. (See RFC 1408.)

- DO LFLOW

  Requests that the client handle flow control characters remotely.
- DO LINEMODE

  Supports requests that the client do line-by-line processing.
- DO NAWS

  Requests that the client inform the server when the window size changes.
- DO NEW-ENVIRON

  Indicates a desire to be able to request environment variable information. (See RFC 1572.)
- DO SGA

  Indicates that it does not need to receive IAC GA, the go ahead command.
- DO TERMINAL-TYPE

  Indicates a desire to be able to request the name of the type of terminal that is attached to the client side of the connection.
- DO TERMINAL-SPEED

  Indicates a desire to be able to request information about the speed of the serial line to which the client is attached.
- DO TIMING-MARK

  Only supported if the client responded with WONT LINEMODE. If the client responds with WILL TM, then it is assumed that the client will support kludge linemode. It is not used for any other purposes.
- DO XDISPLOC

  Indicates a desire to be able to request the name of the X Window System display that is associated with the Telnet client.
- DO AUTHENTICATION

  Indicates a willingness to receive authentication information for automatic login.
- DO ENCRYPT

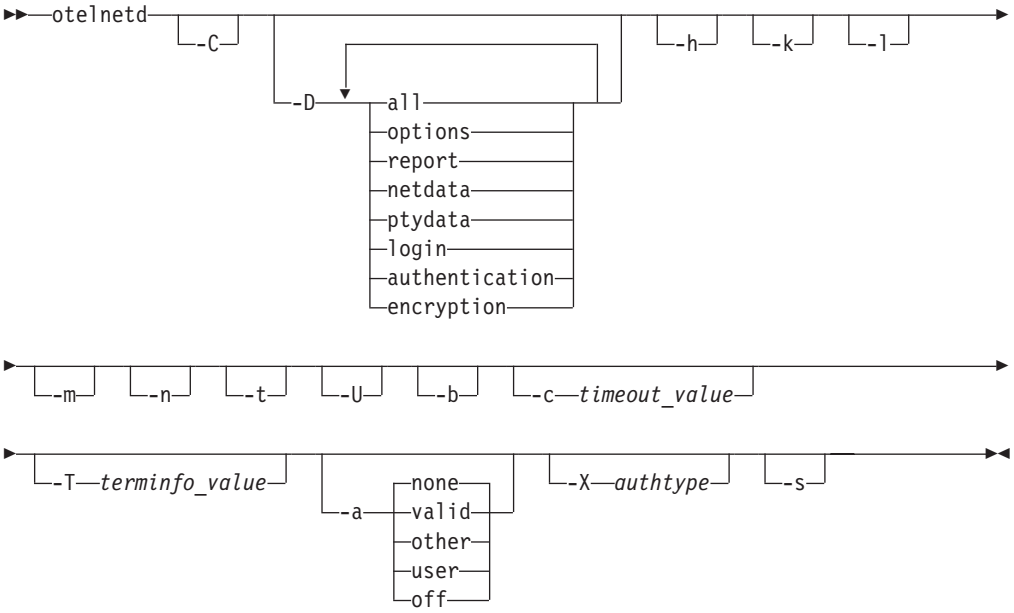
  Indicates a willingness to decrypt the data stream.

otelnetd

Note: The user ID associated with the daemon in /etc/inetd.conf requires superuser authority. See *z/OS UNIX System Services Planning* for a description of the types of authority defined for daemons.

The following syntax is used in the /etc/inetd.conf file to define the arguments used to invoke otelnetd.

Syntax



Parameters

-C

Prints user messages in uppercase. There are several exceptions. Messages issued at startup are not affected by the -C option because the -C option is not processed during the startup. Also, data transmittal messages will not be uppercase. Data transmittal messages are generated from the -D netdata option or the -D ptydata option.

-D The following suboptions apply to -D:

options

Prints information about the negotiation of Telnet options. This information is used for debugging purposes. This suboption allows telnetd to generate debugging information to the connection, which allows the user to view telnetd activity.

report Prints the options information and additional information about processing. This information also includes print information designated for suboption=options. This can be used for debugging purposes. This suboption telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

netdata

Displays the data stream received by telnetd. This information is used

for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

ptydata
Displays the data stream written to the pty. This information is used for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

all Enables options, report, netdata, ptydata, login, authentication and encryption.

login Records login and logout activity to syslogd facility auth using message EZYTU36I.

authentication
Turns on authentication debugging code.

encryption
Turns on encryption debugging code.

-h Disables the display of the /etc/banner and /etc/otelnetd.banner files at the terminal of the client.

-k Disables kludge linemode. The server normally attempts to use kludge linemode when the **-l** option was specified, but the client does not support line mode. Use the **-k** option when there are remote clients that do not support kludge linemode, but pass the heuristic for kludge line mode support (for example, if they respond with WILL TIMING-MARK in response to a DO TIMING-MARK). This option does not disable kludge line mode when the client requests it. This is accomplished by the client sending DONT SUPPRESS-GO-AHEAD and DONT ECHO.

-l Specifies linemode, which tries to force clients to use linemode. If the LINEMODE option is not supported and the **-k** option was not specified, it will attempt to use kludge linemode.

Notes:

1. Many clients decline the server's request to operate in linemode.
2. Linemode is not appropriate for full-screen applications like the z/OS UNIX vi editor.

-m Enables the creation of a forked or spawned process to coexist in the same address space. This option can improve performance because the user's login shell runs in the same address space as otelnetd.

-n Disables TCP keep-alives. Normally, telnetd enables the TCP keep-alive mechanism to probe connections that have been idle for some time to determine if the client is still there. In this way, idle connections from machines that have crashed or can no longer be reached can be cleaned up. The cleanup of disabled connections is controlled by the presence of the INTERVAL parameter on the TCPCONFIG statement in the TCPIP profile.

-t Specifies internal tracing. It also activates the REPORT option, as if the user also specified -D Report.

-U Causes telnetd to drop connections from any IP address that cannot be mapped back into a symbolic name by the gethostbyaddr or getnameinfo routines.

-b Forces the server to DO BINARY in the first pass during negotiations with the client.

-c *timeout_value*
Specifies the number of seconds to wait before terminating the Telnet session for inactive connections. The *timeout_value* is a value between 1 and 86400 seconds.

-T *terminfo_value*
Sets the TERMINFO environment variable to the specified values at startup. This option is needed when terminfo definitions are located in nonstandard directories.

-a This option may be used for specifying what mode should be used for authentication. There are several valid suboptions for authentication mode:

valid
Only allow connections when the remote user can provide valid authentication information to identify the remote user. Thus, for otelnetd, Kerberos authentication will be required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID that was mapped from the name in the Kerberos principal using the SAF R_usermap function, then no password will be requested. This is the most secure authentication mode.

other
Only allow connections that supply some authentication information. This option is currently not supported by any of the existing authentication mechanisms, and is thus the same as specifying **-a valid**.

user
Only allow connections when the remote user can provide valid authentication information to identify the remote user, and is allowed access to the specified account without providing a password. Thus, for otelnetd, Kerberos authentication is required. The NAME received during AUTHENTICATION option negotiation must match the name in the Kerberos principal, and the Kerberos principal must map to a valid TSO user ID on the host using the SAF R_usermap function. No user verification will occur through the login or password prompt.

none
This is the default state. Authentication information is not required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID that was mapped from the name in the Kerberos principal using the SAF R_usermap function, then no password will be requested.

off
This disables the authentication code. All user verification happens through the login and password prompt. During option negotiation, otelnetd will not send DO AUTHENTICATION and, if necessary, will send DONT AUTHENTICATION.

Note: Authentication is not supported for IPv6 connections. If tcp6 is specified in inetd.conf, **-a** should not be used as a start option. If tcp6 and **-a** are both specified, the suboption will be overridden and forced to OFF.

-X *authtype*
This option disables the use of authtype authentication. Currently the only valid value for authtype is KERBEROS_V5. Thus, if otelnetd sends the

AUTHENTICATION option SEND command, the authentication-type-pair-list will not contain any KERBEROS_V5 entries and will be empty.

-s Used to set the KRB5_SERVER_KEYTAB environment variable. If this environment variable is set, security runtime uses a local instance of the Kerberos security server to decrypt service tickets instead of obtaining the key from a key table. To use this capability, the otelnetd application must have at least READ access to the IRR.RUSERMAP resource in the FACILITY class. For more information, see *z/OS Integrated Security Services Network Authentication Service Administration*.

SMF record handling

The SMF records generated are the typical set of records that MVS generates for start of job (login) and end of job (logoff). Additionally, interval records might be issued during the life of the user login. These records are SMF type 30 and type 72 and not the type 118 or type 119 in the current z/OS UNIX Telnet server. The process of issuing these records is external to the specific daemons.

BPX.DAEMON considerations

If the BPX.DAEMON FACILITY class profile is defined, perform the following additional configuration steps:

1. Provide read access to BPX.DAEMON for the user ID specified in /etc/inetd.conf for otelnetd.
2. Define SEZALOAD to program control.
3. Define the C run-time library, *hlq*.SCEERUN to program control.

See *z/OS UNIX System Services Planning* for more information about the BPX.DAEMON FACILITY class profile, the security product commands used to perform the required configuration, and the diagnosis procedure for resolving related problems.

Kerberos

otelnetd supports Kerberos Version 5 for authentication on IPv4 connections. Authentication is not supported on IPv6 connections (that is, if tcp6 is specified for otelnetd in inetd.conf). On z/OS, Kerberos is implemented by Security Server. See *z/OS Integrated Security Services Network Authentication Service Administration* for more information.

The Kerberos principal used by otelnetd will generally be of the form "host/<*hostname*>@*realm*". That is, the first component of the Kerberos principal is "host"; the second component is the fully qualified lowercase hostname of the server; and the realm is the Kerberos realm to which the server belongs.

otelnetd will not accept forwarded credentials from the client.

Successful AUTHENTICATION option negotiation is required for successful ENCRYPT option negotiation. The ENCRYPT option must be negotiated in both directions.

Chapter 12. Transferring files using FTP

The File Transfer Protocol (FTP) allows a user to copy files from one machine to another. The protocol allows for data transfer between the client (the end user) and the server in either direction. In addition to copying files, the client can issue FTP commands to the server to manipulate the underlying file system of the server (for example, to create or delete directories, delete files, rename existing files, and so on.) FTP is the most frequently used TCP/IP application for moving files between computers.

Copying files from one machine to another is one of the most frequently used operations. The data transfer between client and server can be in either direction. The client can send a file to the server machine. It can also request a file from this server.

To access remote files, the user must identify himself or herself to the server. At this point the server is responsible for authenticating the client before it allows the file transfer.

From an FTP user's point of view, the link is connection-oriented. FTP uses TCP as a transport protocol to provide reliable end-to-end connections. Both hosts must run TCP/IP to establish file transfer.

The z/OS model for the FTP server includes a daemon process and a server process. The daemon process starts when you start your cataloged procedure (for example, START FTPD) and it listens for connection requests on a specific port. The port is the well-known port 21 unless otherwise specified. For methods of choosing a different port number, see “Configuring ETC.SERVICES” on page 661 and “Configuring the FTPD cataloged procedure” on page 662. When the daemon accepts an incoming connection, it creates a new process (server's address space) for the FTP server, which handles the connection for the rest of the FTP login session. Each login session has its own server process.

The server process inherits the accepted connection from the daemon process. This connection is called the control connection. The server receives commands from the client and sends replies to the client using the control connection. The control connection port is the same as the daemon's listening port.

The client and server use a different connection for transferring data; this connection is called the data connection. By default, the data port is one less than the control connection port. For example, if the control connection port is 21, the data port is 20. An FTP client can override the default data port by directing the server to run in passive mode. In passive mode, the server uses an ephemeral port for the data port. Passive mode is requested by firewall friendly clients and by clients initiating three-way data transfers.

Notes:

1. This topic discusses RACF configuration required for FTP. References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.
2. If you use the environment variable _BPX_JOBNAME when you start FTPD, the server's address space is known as the job name specified in the

_BPX_JOBNAME variable. You might need to have a common naming convention for your installation's FTP address spaces if your installation uses syslogd isolation or has other workload management requirements.

If you do not use the _BPX_JOBNAME environment variable, the server's address space assumes the name of the user. For example, if a user logs into an FTP server with the user ID TCP0001, the FTP server address space servicing the request is also known as TCP0001.

If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are not using the _BPX_JOBNAME environment variable, the server's address space name is a name derived from the FTP server job name. The name is in the form *jobnamex*, where the *jobname* value is the job name, and the *x* value is a number in the range 1 – 9. If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are using the _BPX_JOBNAME environment variable, the server's address space name is a name derived from the _BPX_JOBNAME environment variable. The name is in the form *bpxjobnamex*, where the *bpxjobname* value is the value specified for the _BPX_JOBNAME environment variable, and the *x* value is a number in the range 1-9.

Configuring PROFILE.TCPIP for FTP

If you have configured the FTP server to have affinity to a specific stack, or you have configured the FTP server to be a generic server in a single stack environment, the FTP server can be started automatically when the TCP/IP address space is started by specifying the name of the FTP server cataloged procedure in the AUTOLOG statement. If you have configured the FTP server as a generic server in a multiple stack environment, you should not use the AUTOLOG statement to automatically start the server. Instead, use some other automation outside of AUTOLOG to automatically start the server.

In the following example, if your procedure is called FTPD, the following statement allows TCP/IP to issue the MVS START command for procedure FTPD. The job name of FTPD1 will be used on the port statement shown below. If the daemon job name is fewer than eight characters, the FTP daemon forks a process that has the job name of the original daemon appended with the numeral 1.

```
AUTOLOG
  FTPD JOBNAME FTPD1
ENDAUTOLOG
```

To reserve ports 21 and 20 for the FTP server, add the following:

```
 PORT
   21 TCP FTPD1             ; FTP server control port
   20 TCP OMVS NOAUTOLOG    ; FTP server data port
```

Specifying FTPD1 on the PORT and AUTOLOG statements directs TCP/IP to restart FTPD if it shound end.

To allow FTP to detect data connection errors when there has been no activity on the data connection for a certain amount of time, set the INTERVAL parameter on the TCPCONFIG statement to a relatively low value. The keepalive packets that the stack sends as specified on the INTERVAL parameter enable the stack to detect errors, such as a reset or terminated peer connection, instead of waiting indefinitely. Be careful when choosing an INTERVAL value on the TCPCONFIG statement because this value will affect all TCP connections at the host for which the interval has been activated, not just FTP connections.

The control connection can also benefit from keepalive packets. Many firewalls require periodic activity on any connection that is made and the control connection can appear idle during a long data transfer. Coding the INTERVAL parameter on the TCPCONFIG statement will, of course, cause keepalive packets to be sent on the control connection as well as the data connection. You can override the keepalive interval that you have configured in the stack for the FTP control connection and data connection with the FTPKEEPALIVE (control connection) and DATAKEEPALIVE (data connection) statements in the FTP.DATA file or data set.

Optimally, FTP needs a buffer size of 180K for data connections. Setting TCPMAXRCVBUFRSIZE below 180K is not recommended. The default value for the parameter is 256K. IBM Health Checker for z/OS can be used to check whether the TCPMAXRCVBUFRSIZE value is sufficient to provide optimal support to the z/OS Communications Server FTP server. For more details about IBM Health Checker for z/OS, see *z/OS Communications Server: IP Diagnosis Guide* and *IBM Health Checker for z/OS: User's Guide*.

For more information about the AUTOLOG, PORT, and TCPCONFIG statements, see *z/OS Communications Server: IP Configuration Reference*.

If your FTP server accepts connections on a distributed Dynamic VIPA (DVIPA), SYSPLEXPORTS must be specified for the distributed DVIPA if either of the following are true:

- The DVIPA is an IPv6 address.
- Passive mode FTP is used.

For more information about the VIPADYNAMIC statement and specifying the SYSPLEXPORTS option on the VIPADISTRIBUTE parameter, see *z/OS Communications Server: IP Configuration Reference*.

Configuring ETC.SERVICES

The ETC.SERVICES file contains the relationship between service names (servers) and port numbers in the z/OS UNIX environment. If necessary, update your ETC.SERVICES file to include the control port that the FTP server is to use. For the search order used to locate the ETC.SERVICES file, see "Configuration files for TCP/IP applications" on page 30. For example, add the following:

```
ftp 21/tcp
```

Notes:

1. In the ETC.SERVICES file, only one port (the one for the control connection) is listed.
2. If the ETC.SERVICES file is changed such that a port other than 21 is specified, that port will become the FTP port for that z/OS host.
3. The port specified for FTP in the ETC.SERVICES file can be overridden by the FTP start parameter, PORT *nnnn*. In either case, the port that is specified should match the port specified for FTP on the PORT statement in PROFILE.TCPIP.

Configuring /etc/syslog.conf

Note: For FTP syslog, you should consider the fact that FTP writes log messages to the system console if syslogd is not running. If you enable FTP server traces without syslogd active, large amounts of data might be written to the system console.

The daemon.*priority* entries in /etc/syslog.conf determine where FTP messages and trace entries are written. The FTP server issues info, warning, and error messages. All trace entries are written with debug priority. To direct trace entries (and all messages) to /tmp/daemon.trace, include the following in /etc/syslog.conf:

```
*.*.daemon.debug   /tmp/daemon.trace
```

Log messages can be isolated within syslogd. For FTP, an installation might want FTP log messages to be written to different files depending on the user ID, or separately for the FTP daemon. If FTP messages are to be isolated for user1, use the first statement below. If FTP messages are to be logged for all the FTP applications, use the second statement below.

```
user1.*.daemon.debug /tmp/daemon.trace
*.FTPD*.daemon.debug /tmp/daemon.trace
```

In this statement, it is assumed that _BPX_JOBNAME is set to FTPD.

Configuring the FTPD cataloged procedure

The FTPD catalogued procedure is sample JCL that you can use to start the FTP server. To use the sample, you must modify it to suit your needs.

Before you begin: You must configure TCP/IP and your security product. You will modify the configuration of your security product for use with your FTP server.

Perform the following steps to configure the FTPD catalogued procedure:

1. Copy the sample in SEZAINST(FTPD) to your system or recognized PROCLIB.
2. Update the SYSFTPD DD and SYSTCPD statements.

   See "Configuring FTP.DATA" on page 671 to configure SYSFTPD DD and "Configuring TCPIP.DATA for FTP" on page 671 to configure SYSTCPD DD.
3. Decide whether you will pass start parameters in the FTPD catalogued procedure.
   - If you are not going to pass start parameters, add your parameters to the FTP.DATA file.
   - If you are going to pass start parameters, add your parameters to the PARMS parameter in the PROC statement of the FTPD cataloged procedure.

     Any parameters that you modify in the PROC statement override parameters that are set in the FTP.DATA file. Separate each parameter with a blank and enter all parameters in uppercase.

     The system parameters required by the FTP server are passed by the PARM parameter on the EXEC statement of the FTPD cataloged procedure. For example, the entry `//FTPD PROC MODULE='FTPD',PARMS='TRACE ANONYMOUS PORT 21'` starts FTP with tracing active, anonymous support enabled, and using control port 21.

   For more information about the FTPD parameters, see *z/OS Communications Server: IP Configuration Reference*.
4. Define the FTPD catalogued procedure to the security program.

   Add the FTPD catalogued procedure to the RACF STARTED class facility or to the started procedures table.

The user ID that is associated with the FTP server STARTED class must have UID 0. If the FACILITY class is active and the BPX.DAEMON or BPX.POE profiles are defined, the user ID that is associated with the FTP server must have READ access to them.

5. (Optional) If the daemon address space will be configured to run as nonswappable, provide at least READ access to the FACILITY class resource BPX.STOR.SWAP.
6. Set up security for the FTP server.

   See "Security for the FTP server" for information about setting up security.
7. (Optional) Define environment variables.

   See "Defining environment variables for the FTP server (optional)" on page 669 for information about defining environment variables for the FTP server.

When you are done, you should be able to start the FTPD catalogued procedure with no errors. If you receive errors, then ensure that you have completed all the steps correctly.

See SEZAINST(EZARACF) for more information about SAF resource requirements needed for FTP.

Restriction: The Language Environment runtime option NATLANG(JPN) is not supported. If you specified NATLANG(JPN) as a Language Environment runtime option, then you need to specify PARM='NATLANG(ENU)' in the FTPD cataloged procedure to override the runtime option for FTP.

Security for the FTP server

To provide security for the FTP server, you must perform the following tasks:

1. (Optional) Activate and define the SERVAUTH class [see "(Optional) Steps for activating and defining the SERVAUTH class" on page 664].
2. Set up security for the FTP server (see "Steps for setting up security for your FTP server" on page 664).
3. Provide and control user access to the FTP server (see "Steps for controlling user access to the FTP server" on page 665).
4. Set up a port of entry for users of the FTP server (see "Steps for setting up a port of entry for users of the FTP server" on page 666).
5. Provide and control user access to the z/OS UNIX file system (see "(Optional) Steps for controlling user access to the z/OS UNIX file system" on page 667).
6. Prevent exploitation of your FTP server (see "Preventing exploitation of your FTP server" on page 668).

FTP uses resource profiles in the System Authorization Facility (SAF) SERVAUTH class to control access to certain facilities and servers. When access to a resource is controlled by a profile in the SERVAUTH class, you must activate and RACLIST the SERVAUTH class. You do not have to use the SERVAUTH class, but when a profile is defined in that class, all FTP users who require access to it must be permitted to it.

For more information, see *z/OS UNIX System Services Planning* and *z/OS Security Server RACF Security Administrator's Guide*. For more information about network access security zones, see "Network access control" on page 120. If you are

planning to implement a multilevel security environment on your z/OS system, see Chapter 4, "Preparing for TCP/IP networking in a multilevel secure environment," on page 153.

(Optional) Steps for activating and defining the SERVAUTH class

Before you begin: You need to know which resource profiles you want to define. You need to install and start your security product.

Perform the following steps to activate and RACLIST the SERVAUTH class, if you have not already done so:

1. Issue the following command from a RACF special user to activate the SERVAUTH class:

   ```
   SETROPTS CLASSACT (SERVAUTH)
   ```

   Requirement: If you change the SERVAUTH class after you activate it, you must refresh the class. Changes include, but are not limited to, adding a resource profile to the SERVAUTH class or changing access to a profile in the SERVAUTH class. To refresh the class, issue the following command from a RACF special user:

   ```
   SETROPTS RACLIST (SERVAUTH) REFRESH
   ```

2. Issue the following command from a RACF special user to RACLIST the SERVAUTH class:

   ```
   SETROPTS RACLIST (SERVAUTH)
   ```

Steps for setting up security for your FTP server

Before you begin: You need to know the user ID that is associated with the FTP daemon and how TCP/IP is configured for security. You should also know the resource profiles that are in the SAF classes.

To set up security for your FTP server, perform one or more of the following tasks:

- If the SERVAUTH class is activated and a profile is defined for the EZB.STACKACCESS.*mvsname.tcpname* resource, you must grant the user ID that is associated with the FTP daemon READ access to the profile.
- If the SAF class APPL is activated and the OMVSAPPL resource profile is defined, grant the user ID that is associated with the FTP daemon READ access to the OMVSAPPL resource profile. For more information on defining the OMVSAPPL profile, see *z/OS UNIX System Services Planning*.
- If the SAF class APPL is activated and you have a resource profile defined in that class that matches the job name of the address space that the FTP server starts when a user logs into FTP, a user ID should have READ access to that resource profile.
- The FTP daemon listening port should be reserved for the FTPD job by a PORT statement in the TCPIP PROFILE. If the PORT statement for the FTPD port is protected with the SAF keyword, you must define a SERVAUTH profile for the EZB.PORTACCESS.*sysname.tcpname*.SAFkeyword resource. The user ID associated with the FTP daemon must have READ access to that resource.
- If your IP network is configured to use named security zones, grant the user ID that is associated with the FTP daemon READ access to the security zone that maps its bind address (0.0.0.0/32 for INADDR_ANY or ::/128 for the IPv6 unspecified address, in6addr_any), unless these addresses are overridden by the PORT statement in the TCP/IP profile.

You know you are done when you can start the FTP server without receiving an error.

Steps for controlling user access to the FTP server

Every user who logs in to your FTP server requires access to that server. Perform the following steps to provide and control user access to your server.

Before you begin: You need to know which users you want to allow to log in to your FTP server. You need to know whether your IP network is configured to use named security zones.

Perform the following steps to control user access to the FTP server:

1. Provide each user who is going to log in to the FTP server with a z/OS UNIX UID.

   You can either provide a UID to the user, or the user can use the default UNIX UID.

2. If your IP network is configured to use named security zones, each defined security zone has a SERVAUTH profile for the resource named EZB.NETACCESS.*sysname*.*tcpname*.*zonename*. If the client IP address is mapped into a network access security zone, grant each login user ID READ access to the SERVAUTH profile that corresponds to the security zone.

   For more information about security zones, see "Network access control" on page 120.

3. Do one or more of the following to allow only certain users to log in to the FTP server:

   - Code an FTCHKPWD user exit routine to allow or deny access to users, based on user ID.

     For more information about user exits, see FTP server user exits in *z/OS Communications Server: IP Configuration Reference* and "Configuring the optional FTP user exits" on page 706.

   - Use the SERVAUTH resource profile that FTP uses for TLS level 3 authentication to control which users can log in to FTP:

     a. Define a profile in the SERVAUTH class for the FTP port.

        For information about how to define the profile, see "Add user IDs to the SERVAUTH profile access list" on page 1478.

     b. Grant at least READ access to the profile to the users that you want to permit to log in to FTP.

        For example, if your security product is RACF, your FTP port is port 21, and the profile that you defined is EZB.FTP.*.*.PORT21, issue the following command to grant the user ID FTPUSER access to the profile:

        ```
        PERMIT EZB.FTP.*.*.PORT21 CL(SERVAUTH) ID(FTPUSER)
        ```

        See *z/OS Security Server RACF Command Language Reference*, *z/OS Security Server RACF Security Administrator's Guide*, or the documentation for your SAF-compliant security product for more information.

     c. Code VERIFYUSER TRUE in the server's FTP.DATA file.

        FTP verifies the user's access to the profile for every session, whether or not that session is secured. TLS-secured sessions are also verified, even when level 3 authentification has not been requested.

4. (Optional) Set up transport layer security (TLS) support or Kerberos support for the FTP server.

   The FTP server supports TLS. TLS enables secure file transfer by providing data privacy, message authentication, and message integrity services for data sent and received using the FTP control and data connections. For information

about setting up TLS support for the FTP server, see "Customizing Transport Layer Security and Kerberos security" on page 681.

You can use the Generic Security Service Application Programming Interface (GSSAPI) to authenticate FTP clients to FTP servers. For more information about setting up GSS support for the FTP server, see "Customizing Transport Layer Security and Kerberos security" on page 681.

When you are finished, only certain users will be able to log in to your FTP server.

Steps for setting up a port of entry for users of the FTP server

The *port of entry* is the origin of work for the FTP server. You must establish a port of entry for each user who logs in to your FTP server. For IPv4 connection partners, you can establish either terminal access or servauth access. IPv6 connection partners must use servauth access, which is established automatically for them.

Before you begin: You need to know the following:

- The IP addresses of the clients who will be logging in to your FTP server
- Whether your connection partners are in a network access security zone
- Whether your RACF SETROPTS options are TERMINAL(READ) or TERMINAL(NONE)

Perform the following steps to set up the port of entry for IPv4 and IPv6 users of the FTP server.

- To establish terminal access for IPv4 connection partners, do one of the following:
  - If your RACF SETROPTS options are TERMINAL(NONE):
    1. Define profiles for the IP addresses that you want to permit to your system in the TERMINAL class.

       Translate all the IP addresses of any clients that connect to the FTP server to an 8-byte hexadecimal character strings that contain an IPv4 address. Add the strings to the TERMINAL class.

       For example, the IP address 163.97.227.17 is translated to A361E311. To allow all addresses in the 163.97.227.17 subnet, code the following:

       ```
       RDEFINE TERMINAL A361E3* UACC(READ)
       ```

    2. Ensure that login user IDs have READ access to the TERMINAL profile that includes their client system IP address.
  - If your RACF SETROPTS options are TERMINAL(READ), then all terminals are allowed access to your system and you do not need to add extra resource definitions to your RACF database.
- To establish servauth access, instead of terminal access, for IPv4 connection partners, specify PORTOFENTRY4 SERVAUTH in the FTP.DATA file. The FTP server will use the UNIX System Services _poe() service to identify the control socket as the port of entry.
- To establish servauth access for IPv6 connection partners, you do not need to do anything; IPv6 connection partners automatically establish servauth access. If the IPv6 connection partner is not in a network access security zone, the _poe() service does not pass a port of entry resource name and the port of entry is not checked. For information about network access security zones, see "Network access control" on page 120.

For IPv4 and IPv6 users with either terminal or servauth access, you can optionally restrict access to DATASET resources during the login session by adding WHEN(TERMINAL=...) or WHEN(SERVAUTH=...) conditions to DATASET resource profiles in RACF.

When you are finished, access to the FTP server is controlled based on the client's port of entry.

(Optional) Steps for controlling user access to the z/OS UNIX file system

FTP uses the resource profile EZB.FTP.*sysname*.*ftpdaemonname*.ACCESS.HFS in the SAF SERVAUTH class to control access to the z/OS UNIX file system. If you do not control access to this profile, then all users will be able to access your z/OS UNIX file system. If the FTP.DATA file for the server specifies STARTDIRECTORY HFS and the user is not permitted to the SERVAUTH class profile, FTP makes the TSO user ID the starting directory.

Before you begin: You must have the authority to issue the necessary RACF commands.

Perform the following steps to control access to the z/OS UNIX file system:

1. Define the profile for the FTP user access to the z/OS UNIX file system.

   The profile has the following form:

   ```
   RDEFINE  SERVAUTH   EZB.FTP.sysname.ftpdaemonname.ACCESS.HFS
   ```

   For example, the profile name for FTP daemon FTPD running on system MVSA is the following:

   ```
   EZB.FTP.MVSA.FTPD1.ACCESS.HFS
   ```

   Tip: The profile name can contain wildcard values as allowed by the security product. All security-product rules (for example wildcards, PROTECTALL, and so on) apply. For example, if all systems will use the same access list and RACF generic profile checking is active for the SERVAUTH class, you could use the following profile name:

   ```
   EZB.FTP.*.FTPD.ACCESS.HFS
   ```

2. Permit the user IDs that require access to the z/OS UNIX file system to the profile:

   ```
   PERMIT EZB.FTP.sysname.ftpdaemonname.ACCESS.HFS CL(SERVAUTH)
          ID(ftpuser)
   ```

3. Issue the following command to activate the RACF SERVAUTH class, if it is not already activated:

   ```
   SETROPTS CLASSACT (SERVAUTH)
   ```

4. Do one of the following:

   - RACLIST the SERVAUTH class, if this is a new profile:

     ```
     SETROPTS RACLIST (SERVAUTH)
     ```

   - Refresh the SERVAUTH class, if you have changed an existing profile:

     ```
     SETROPTS RACLIST (SERVAUTH) REFRESH
     ```

When you are finished, only certain users will be able to access the z/OS UNIX file system.

Preventing exploitation of your FTP server

Your FTP server can be used by a client for disruptive purposes. A client can use your server to send random data to other servers, or a client can request that your server be the passive server in a three-way transfer.

Any FTP client that is in PROXY mode with your FTP server can establish a data connection to any server that is listening to a port. This situation could be very disruptive to that server, because the client could then send a very large amount of unexpected data to it. Any malicious FTP client can attack or disrupt the server in a normal server-to-client connection by making the FTP server send a large amount of data to another application server that is listening to a specific port. Because the client itself is not sending the disruptive data, it is difficult to identify the client that is causing the problem. Use the PORTCOMMAND, PORTCOMMANDPORT and PORTCOMMANDIPADDR statements in FTP.DATA to prevent your server from being used in this way.

Table 32. PORTCOMMAND scenarios

When you want your server to...	Code the following statements in the server's FTP.DATA	Comments
Reject all PORT or EPRT commands	PORTCOMMAND REJECT	If you disable the PORT or EPRT commands, then you prevent your server from being used to send random data to other servers. However, your server loses some ability to transfer data in PROXY mode. If a client sends a PORT or EPRT command to your server to set up a proxy transfer, your server will reject the command and the proxy transfer will fail. If your client is not firewall friendly, and it does not implement the default port number and IP address for data transfer, that client cannot transfer files to and from your server.
Reject all PORT or EPRT commands that specify well-known ports (port numbers less than 1024)	PORTCOMMANDPORT NOLOWPORTS	When you specify this combination, your server cannot be used to send random data to servers listening on well-known ports. However, a rogue client can use your server to send random data to servers listening on other ports. The server still supports data transfer in PROXY mode.
Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address.	PORTCOMMANDIPADDR NOREDIRECT	When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server on its own IP address. Transfers between client and server are not affected.
Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address or port numbers that are well known.	PORTCOMMANDPORT NOLOWPORTS PORTCOMMANDIPADDR NOREDIRECT	When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server that is on its own IP address; the port numbers cannot be well known. The client cannot use PROXY mode to send random data to a server that is on its own IP address and listening to a well-known port.

Your FTP server can also be used as a passive server in a three-way transfer. When a client sends a PASV or EPSV command to the server, the server opens a listening data socket. This socket is similar to the listening socket associated with the well-known port, in the sense that any application that knows its IP address and port number can connect to it (not just the client that sent the PASV or EPSV command). The client can exploit this situation to initiate a three-way data transfer, which is a data transfer between two servers. The client sends PASV to one server followed by PORT to the other. The client sets the PORT command IP address and port number to the information it gets from the PASV reply, and the second server connects to the IP address and port number specified in the PORT command, connecting the two servers. The next data transfer command causes data to move directly between the two servers. The client can also use the EPSV and EPRT commands to set up the three-way data transfer.

Three-way transfers are supported functions in the FTP protocol, but you might not want to allow your server to participate in three-way transfers. To prevent your server from being the passive server (the server that receives the PASV or EPSV command) in a three-way data transfer, code PASSIVEDATACONN NOREDIRECT in the server's FTP.DATA file. This directs the server to verify that the data connection comes from the IP address where the original FTP client resides (the client that sent the PASV or EPSV command). If that is not where the data connection originates, the server closes the data socket and the next data transfer command fails.

To completely disallow the use of your FTP server in three-way transfers, code the PASSIVEDATACONN statement as described in the preceding paragraph, and the PORTCOMMANDIPADDR NOREDIRECT statement or PORTCOMMAND REJECT statement described in Table 32 on page 668.

Defining environment variables for the FTP server (optional)

The FTP server optionally uses environment variables to identify the translate table data sets to be used for the control and data connections. These environment variables are used to override a default naming convention as described below. CCXLATE and XLATE statements will be ignored if EXTENSIONS UTF8 is specified in FTP.DATA.

_FTPXLATE_name used for translation

In your FTP.DATA file, you can use the CCXLATE or XLATE statements to specify a name that corresponds to a particular data set that is to be used for the initial translate tables for the control or data connections.

FTP will look for an environment variable defined as *_FTPXLATE_name=fully_qualified_dsn*, where *name* must be one to eight uppercase characters or numbers, and *fully_qualified_dsn* can be a fully qualified MVS data set name or z/OS UNIX file name.

If the environment variable exists, FTP will use the data set name defined by the environment variable. If no such environment variable is defined, FTP will use the data set name *hlq.name*.TCPXLBIN.

Similarly, from any client you can issue SITE XLATE= to set the translate tables for the data connection for that particular FTP session. The FTP server will look for an environment variable called *_FTPXLATE_name*. If the environment variable does not exist, the server will look for a data set called *hlq.name*.TCPXLBIN.

Note: The CCXLATE and XLATE statements and SITE XLATE command are not case-sensitive, but the name of the optional environment variable is case-sensitive and must be in uppercase or FTP will not recognize it.

TZ and other UNIX environment variables

You can use the ENVAR runtime option in your FTPD start procedure to set environment variables for the FTP server. For information on using the ENVAR runtime option to set environment variables, see *z/OS XL C/C++ Programming Guide*. The following example shows how to specify environment variables in your FTPD started procedure:

```
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//           'ENVAR("TZ=EST")/&PARMS')
```

_BPX_JOBNAME

An installation that wants all FTP forked tasks to have similar job names needs to set the _BPX_JOBNAME environment variable. WorkLoad Manager (WLM), accounting, and isolation of syslogd messages are reasons an installation might not want to have each FTP logged-in user to have a job name of its user ID.

The following example sets all FTP forked() tasks to have the job name of FTPD:

```
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//           'ENVAR("_BPX_JOBNAME=FTPD"',
//           '"TZ=EST")/&PARMS')
```

Requirement: If you activate the SAF class APPL, and you have defined a resource profile in that class that matches the job name that you specify with the _BPX_JOBNAME environment variable, you must grant user IDs that log into FTP at least READ access to the resource profile.

_BPXK_SETIBMOPT_TRANSPORT for affinity to a specific stack

As discussed in "Generic server versus server with affinity for a specific transport provider" on page 51, if an installation wants to ensure that FTP has an affinity to a TCP/IP stack, the _BPXK_SETIBMOPT_TRANSPORT keyword should be used.

The example below sets the FTP server to have an affinity to TCPIPOE.

```
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//           'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE"',
//           '"TZ=EST")/&PARMS')
```

Configuring FTP with multiple TCP/IP stacks

Prior to configuring the FTP server with multiple TCP/IP stacks, review "Considerations for multiple instances of TCP/IP" on page 50.

The FTP server can be configured as a server with affinity to a specific transport provider or as a generic server.

To configure the FTP server to have affinity to a specific transport provider, do the following:

- Code the _BPXK_SETIBMOPT_TRANSPORT keyword in the FTP cataloged procedure. The example below sets the FTP server to have an affinity to TCPIPOE.

```
//FTPD   PROC MODULE='FTPD',PARMS=''
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//           'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE"',
//           '"TZ=EST")/&PARMS')
```

- Reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP as follows:

```
PORT
    21 TCP FTPD1          ; FTP server control port
    20 TCP OMVS NOAUTOLOG ; FTP server data port
```

To configure the FTP server as a generic server, reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP on all transport providers. The FTP server will detect when new transport providers are activated and attempt to bind to port 21. If this port is not reserved for the FTP server, the FTP server will end with the following message:

```
EZYFT13E bind error : EDC5111I Permission denied
```

Configuring TCPIP.DATA for FTP

The following five statements are used by the FTP server:

DATASETPREFIX
Specifies HLQ for dynamic allocation

DOMAINORIGIN
Specifies the domain name to be appended to host name

HOSTNAME
Specifies the TCP host name

LOADDBCSTABLES
Specifies the DBCS tables used by the client and server

MESSAGECASE
Specifies the case that messages should be displayed in

See Chapter 2, "IP configuration overview," on page 11 for information about TCPIP.DATA or see *z/OS Communications Server: IP Configuration Reference* for information about these statements.

Configuring FTP.DATA

The FTP.DATA data set is optional. The FTP daemon looks for this data set during initialization, using the first file it finds in the following search order:

1. A data set specified by the //SYSFTPD DD statement
2. *ftpserve_job_name*.FTP.DATA
3. /etc/ftp.data
4. SYS1.TCPPARMS(FTPDATA)
5. *hlq*.FTP.DATA data set

It is not necessary to include all statements in the FTP.DATA data set. Only include the statements if the default value is not what you want, because the default will be used for any statement not included in the FTP.DATA data set.

To pick up changes made in the FTP.DATA data set, the FTP server must be stopped and restarted. Some FTP server parameters can be changed during an FTP

session by the client issuing the SITE subcommand. See *z/OS Communications Server: IP User's Guide and Commands* for more information. The FTP client has an FTP.DATA data set which can also be used to change the defaults for the FTP client local site parameters. See the *z/OS Communications Server: IP User's Guide and Commands* for more information about using the FTP.DATA data set for the FTP client local site parameters.

Optionally configuring user-level server options using FTPS.RC

The default values for the site parameters are coded in the server FTP.DATA. These SITE defaults apply to all login sessions to the server. You can customize settings for a specific user or group of users by creating an FTPS.RC configuration data set containing FTP commands specific to that login session. This file may contain a series of CWD and SITE commands. See *z/OS Communications Server: IP User's Guide and Commands* for information about these commands.

The FTP server uses the following search order to find the MVS data set or z/OS UNIX file:

1. tso_prefix.FTPS.RC
2. userid.FTPS.RC
3. $HOME/ftps.rc

Data set attributes

Data set attributes play a significant role in FTP performance. If your environment permits, tune both BLOCKSIZE and LRECL according to the following recommendations:

- Use half a track as the block size.
- For IBM 3380 DASD, use 23424 as the block size with an LRECL of 64 bytes.
- For IBM 3390 DASD or IBM9334, use 27968 as the block size with an LRECL of 64 bytes.
- Use FB as the data set allocation format.
- Use cached DASD controllers.
- If your environment permits, use a preallocated data set for FTP transfers into MVS.

The following configuration data statements apply to FTP server's allocation of data sets.

- AUTOMOUNT
- AUTORECALL
- BLKSIZE
- BUFNO
- CONDDISP
- DATACLASS
- DCBDSN
- DIRECTORY
- LRECL
- MGMTCLASS
- MIGRATEVOL
- PDSTYPE
- PRIMARY

- RECFM
- RETPD
- SECONDARY
- SPACETYPE
- STORCLASS
- UCOUNT
- UMASK
- UNITNAME
- VCOUNT
- VOLUME

See *z/OS Communications Server: IP Configuration Reference* for more detailed information about these keywords.

Some of these allocation variables might provide duplicate information. FTP passes all variables that are specified to z/OS's dynamic allocation function and lets it determine which of the specifications take precedence. The only exceptions to this are the following:

- If the data set organization is physical sequential, directory blocks are not sent.
- If neither primary nor secondary space quantities are specified, the allocation units value is not sent.

For example, the model DCB (DCBDSN) might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. The order of precedence for dynamic allocation variables are as follows:

1. Any FTP.DATA statements or SITE parameters explicitly specified or in effect by default.
2. Any attributes picked up from the model DCB and not otherwise explicitly specified.
3. Any attributes picked up from the data class and not previously derived from 1 and 2 above.
4. Any system allocation defaults.

Specifying attributes for new MVS data sets

When allocating new data sets, there are two methods you can use to specify the data set attributes. You can customize the data set attributes for your login session using the SITE command, or you can configure the data set attributes for logging in to your server using statements in FTP.DATA. Or, if your system programmer has used the Storage Management System to group together default attributes into named classes, you can specify those class names on the DATACLASS, STORCLASS, and MGMTCLASS statements.

Dynamic allocation

The FTP server allows a client program to dynamically allocate a new physical sequential data set, a partitioned data set (PDS), or a partitioned data set extended (PDSE), for the purpose of transferring data to be written to that data set. The following optional allocation variables can be used to override and turn off the defaults that affect the allocation of the data set.

Variable	**FTP.DATA statement**
allocation units	SPACETYPE

blocksize	BLKSIZE
data class	DATACLASS
directory blocks	DIRECTORY
logical record length	LRECL
management class	MGMTCLASS
model DCB values	DCBDSN
PDS type	PDSTYPE
primary space	PRIMARY
secondary space	SECONDARY
unit count	UCOUNT
volume count	VCOUNT
record format	RECFM
retention period	RETPD
storage class	STORCLASS
unit	UNITNAME
volume serial number or list	VOLUME

Some of these allocation variables might provide duplicate information. For example, the model DCB might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. FTP passes all variables that are specified to dynamic allocation and lets it determine which of the specifications take precedence. The following list describes the exceptions to that policy:

- If neither the primary nor secondary space quantity is specified, the allocation units value is not sent.
- If the data set organization is physical sequential, directory blocks specification is not sent.
- Otherwise, all variables are sent to dynamic allocation where the order of precedence is:
  1. Any FTP.DATA statements or SITE parameters explicitly specified or specified by default
  2. Any attributes picked up from the model DCB and not otherwise explicitly specified
  3. Any attributes picked up from the data class and not previously derived from 1 or 2
  4. Any allocation defaults

Storage Management Subsystem

You can specify one or more of the following Storage Management Subsystem (SMS) classes to manage characteristics that are associated with or assigned to data sets.

- Data class is an SMS construct that an installation can define to control data set allocation attributes used by SMS for the creation of data sets. An installation can override all or part of an SMS DATA CLASS definition by using FTP.DATA statements. Note that there is an order of precedence for dynamic allocation. (See "Data set attributes" on page 672 for more information on the precedence.) The fields listed are available attributes that serve as a template for allocation. Each is *optional* and is overridden by any explicit specification of FTP allocation variables or by a model DCB (DCBDSN).

Variable	**FTP.DATA statement**
directory blocks	DIRECTORY
logical record length	LRECL
primary space	PRIMARY
record format	RECFM

retention period	RETPD
secondary space	SECONDARY
pds type	PDSTYPE

Note: If either primary or secondary space is explicitly specified, the primary and secondary values from data class are not used.

- Management class (MGMTCLASS) is an SMS construct that determines DFHSM action for data set retention, migration, backup, and release of allocated but unused space. Management class replaces and expands attributes that otherwise would be specified. That is, management class might override any other specification of retention period.
- Storage class (STORCLASS) is a list of storage performance and availability services requests for an SMS-managed data set that SMS attempts to honor when selecting a volume or volumes for the data set. It might conflict with an explicit specification of volume and unit. If storage class is used, volume and unit should not be specified.

Translation of data

Selecting an appropriate translate table for conversion of data from host to network format, and from network to host format, will ensure that data read from or written to the z/OS system are in correct format. The following statements apply to translation of data for the FTP server. See *z/OS Communications Server: IP Configuration Reference* for more information on these statements. The statements are:

- ASATRANS
- CTRLCONN
- DBSUB
- ENCODING
- EXTENSIONS UTF8
- MBDATACONN
- MBSENDEOL
- MBREQUIRELASTEOL
- SBDATACONN
- SBSENDEOL
- SBSUB
- SBSUBCHAR
- UCSHOSTCS
- UCSSUB
- UCSTRUNC
- UNICODEFILESYSTEMBOM

z/OS UNIX named pipes

FTP can transfer data to and from z/OS UNIX System Services named pipes. The following statements apply to the creation of named pipes:

- UMASK
- UNIXFILETYPE

The following statements apply to the transfer of data to and from named pipes:

- CONDDISP

- FIFOIOTIME
- FIFOOPENTIME

For more information about these FTP.DATA data set statements, see *z/OS Communications Server: IP Configuration Reference*. For information about using z/OS UNIX System Services named pipes, see *z/OS Communications Server: IP User's Guide and Commands*.

FTP code page conversion

Code page conversion must be performed for:

- FTP commands and replies sent over the control connection
- Data transferred over the data connection

FTP uses the *iconv* function to establish ASCII-to-EBCDIC and EBCDIC-to-ASCII translate tables for the control connection. The default network transfer code page for the control connection is 7-bit ASCII. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility. After an end user has logged in, a SITE subcommand can be used to change the code page being used on the control connection.

FTP uses the *iconv* function to establish network transfer to file system and file system to network transfer translate tables for the data connection. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility.

Note: Using iconv conversion to retrieve EBCDIC data that was created with CONVXLAT-generated conversion tables could result in data corruption due to possible conversion table differences.

After an end user has logged in, SITE and LOCSITE subcommands can be issued to change the translation tables being used for single-byte translation.

Code page conversions for the control connection

For the control connection, FTP generally uses ASCII for the network code page, as specified in the FTP RFCs. For the host/ASCII conversion for the control connection, FTP uses either iconv() or the support for single-byte translation tables. However, when EXTENSIONS UTF8 is coded in FTP.DATA, FTP starts the connection in 7-bit ASCII and negotiates a switch to UTF-8 encoding of the control connection, as described in RFC 2640. FTP uses iconv() for the host/UTF-8 conversion.

Priority: The priority for establishing the conversion tables used for the control connection is:

1. FTP start parameter (FTP client only)
2. EXTENSIONS UTF8 coded in FTP.DATA
3. CTRLCONN or CCXLATE keyword in FTP.DATA
4. Search order used to locate a TCPXLBIN data set:
   a. Original jobname.SRVRFTP.TCPXLBIN
   b. *hlq*.SRVRFTP.TCPXLBIN
   c. Original jobname.STANDARD.TCPXLBIN
   d. *hlq*.STANDARD.TCPXLBIN
5. 7–bit ASCII
6. Internal (hard-coded) 7–bit tables

Code page conversions for the data connection

For the transfer of data on the data connection, FTP supports:

- All single-byte conversions available through iconv. For example, iconv supports conversions between IBM-1047 and IBM-850, so conversions between IBM-1047 and IBM-850 are available for data transfer.
- UNICODE conversions available through iconv: UTF-8, UTF-16, UTF-16BE, and UTF-16LE for network transfer, and UTF-8 and UTF-16 for file storage.
- Multibyte conversions for the Chinese standard GB18030 using code page IBM-5488 with code page IBM-1388 or UTF-8, as well as certain double-byte character set (DBCS) code page pairs that are equivalent to supported DBCS languages.
- Both single-byte and double-byte data conversions are supported with the translate tables provided with TCP/IP or generated by the CONVXLAT utility.

Priority for single-byte conversions: The priority that determines how to build single-byte translate tables for converting network transfer data and file system data is the following:

- SYSFTSX DD statement in the startup procedure, where the named data connection is CONVXLAT-generated translate tables. The data set can be an MVS data set or a z/OS UNIX file.
- SBDATACONN or XLATE keyword in FTP.DATA.
- Search order to locate a TCPXLBIN data set, where the MVS data set contains CONVXLAT-generated translate tables:
  1. Original jobname.SRVRFTP.TCPXLBIN
  2. *hlq*.SRVRFTP.TCPXLBIN
  3. Original jobname.STANDARD.TCPXLBIN
  4. *hlq*.STANDARD.TCPXLBIN
- The same conversions established for the control connection.

Multibyte character sets (MBCS) support: MBCS support in the FTP server is provided for the following code page pairs:

Support for:	TYPE command	File system code page	Network transfer code page
Chinese standard GB18030	Not applicable	IBM-1388 or UTF-8	IBM-5488
BIG5	TYPE B 8	IBM-937	IBM-950 or BIG5
EUCKANJI	TYPE B 2	IBM-930	IBM-eucJP
JIS78KJ (JISROMAN	TYPE B 4 R	IBM-930	IBM-5053
JIS78KJ (ASCII	TYPE B 4 A	IBM-939	IBM-5055
JIS83KJ (JISROMAN	TYPE B 3 R	IBM-930	IBM-5052
JIS83KJ (ASCII	TYPE B 3 A	IBM-939	IBM-5054
KSC5601	TYPE B 6	IBM-933	IBM-949
SCHINESE	TYPE B 9	IBM-935	IBM-1381
SJISKANJI	TYPE B 1	IBM-930 or IBM-939	IBM-932 or IBM-eucJC
TCHINESE	TYPE B 7	IBM-937	IBM-948

Support for:	TYPE command	File system code page	Network transfer code page
UNICODE	Not applicable	UTF-8, UTF-16	UTF-8, UTF-16, UTF-16BE, and UTF-16LE

Guidelines: The following restrictions and limitations exist::

- ENCODING must be specified as MBCS, either in FTP.DATA or on a SITE command.
- The data type must be ASCII.
- The file structure must be FILE (not RECORD), and the transfer mode must be STREAM (not BLOCK or COMPRESS).
- The FTP file type must be SEQ (not JES or SQL).
- If the file is transferred to or from an MVS data set, the record format of the data set must be V, VB, or U.
- If a file is transferred outbound and is an MVS data set with record format V or VB, the request for RDWs is not allowed.
- Translation of ASA or machine control characters is not allowed.
- MBCS can be used as a migration path for the DBCS languages listed that have an associated TYPE B *x* command.

  Restriction: The DBCS languages can be migrated to the MBCS support only if they do not use the following parameters on the TYPE B *x* command:

  S A SOSI ASCII characters X'1E' and X'1F' in the ASCII data stream

  S E SOSI EBCDIC characters X'0E' and X'0F' in the ASCII data stream

  S S SOSI SPACE characters X'20' and X'20' in the ASCII data stream

  N No SOSI characters in the ASCII data stream and none written to the file system

Master catalog access

FTP uses the IGGCSI00 function to request catalog processing. This accesses both the user and master catalog. Users require READ access to the master catalog as well as their own user catalog.

Customizing FTP message catalogs

FTP messages and replies are contained in two z/OS UNIX message catalogs as follows:

- ftpdmsg.cat

  Contains messages that the FTP daemon, server, and client issue.
- ftpdrply.cat

  Contains replies that the server sends to the client.

If messages in either of these catalogs need to be modified, the timestamp that is contained in the shipped level of the FTP catalog must be preserved in the modified catalog.

This timestamp is included within and is unique to each catalog. When FTP (client or daemon) is started, FTP verifies that this timestamp matches the timestamp that

it expects. This prevents FTP from presenting the wrong message when the z/OS UNIX message catalogs and FTP are not synchronized.

When you apply a service update to FTP load modules that requires a service update to a catalog, you must install both at the same time. Otherwise, FTP will report an error and use default messages instead of messages from the catalog.

If you are using a modified FTP catalog, the catalog that matches the service level of FTP load modules needs to be updated with your local modifications, and the timestamp of the catalog must be preserved.

Steps for creating a message catalog from the shipped catalog and preserving its timestamp

Before you begin: This example assumes that the FTP code and catalog are at the correct levels and that only local customization to the catalog is to be performed. Also, if you customize a catalog, IBM Service personnel might require that you use the shipped level of the catalog to recreate and diagnose a reported problem.

Perform the following steps to create a file from the shipped catalog and preserve its timestamp. You can then update this file with your local modifications, and create a new FTP catalog with the preserved timestamp. Perform all of these steps from the z/OS UNIX shell; the commands indicated are z/OS UNIX commands.

1. Copy the official z/OS UNIX catalog that is shipped with the release or service to a backup file.

   ```
   cp  /usr/lpp/tcpip/lib/nls/msg/C/ftpdmsg.cat  /tmp/ftpdmsg.cat.backup
   ```

2. Using the **dspcat** command, convert a copy of the backup catalog that you just copied to a copy that you can edit. This is the file that you need to update to preserve the timestamp, and that you will update to support any local user message changes.

   ```
   dspcat -t -g  /tmp/ftpdmsg.cat.backup  >/tmp/ftpdmsg.cat.copy
   ```

3. Change the first line in the catalog from a comment to a z/OS UNIX **gencat** command, which enables the timestamp to be imbedded in the catalog when it is rebuilt.

   a. Edit the file to be updated.

      ```
      oedit /tmp/ftpdmsg.cat.copy
      ```

   b. Change the first line comment to add a **gencat** command to preserve the timestamp when the directory is built. The first line in the file will be similar to the following line:

      ```
      The time stamp of catalog /tmp/ftpdmsg.cat.backup is: 2006 095 20:30 UTC
      ```

      Replace the leading text on the line with the **gencat** subcommand **$timestamp** as follows:

      ```
      $timestamp 2006 095 20:30 UTC
      ```

      If this step is omitted and the original line is left in the catalog, when an attempt is made to generate a catalog from this file, you will see a message similar to the following:

      ```
      FSUM5108 gencat: Invalid message number.
      ```

   c. Save the file.

4. Update the catalog (/tmp/ftpdmsg.cat.copy) with any local modifications and save the file.

5. Build a new and customized catalog using the z/OS UNIX **gencat** command, and save a copy of the shipped level of the catalog.

   ```
   gencat   /tmp/ftpdmsg.cat   /tmp/ftpdmsg.cat.copy
   ```

   The correct response is:

   ```
   FSUM5105 gencat: Message catalog generated normally.
   ```

6. Browse the new catalog and verify that the timestamp from step 3 on page 679 matches what is in the file.

   ```
   obrowse /tmp/ftpdmsg.cat
   ```

   The first record contains the time stamp (*yyyy ddd hh:mm* UTC). For example:

   ```
   ...2006 095 20:30 UTC
   ```

7. Replace the official z/OS UNIX catalog that is shipped with the release with the updated catalog that you created in step 5.

You know you are done when you test the catalogs to verify correct synchronization by performing the following:

1. Start the FTP server and inspect the syslog output (console if no syslog is running). Message EZYFS30W should not appear.
2. Using the FTP client, connect to the FTP server and inspect the SYSPRINT output. Message EZYFS31W should not appear.

For more information on the **dspcat** and **gencat** utilities, see *z/OS UNIX System Services Command Reference*.

Accounting

The following parameters apply to SMF data:

- SMF
- SMFAPPE
- SMFDEL
- SMFEXIT
- SMFJES
- SMFLOGN
- SMFREN
- SMFRETR
- SMFSQL
- SMFSTOR

See *z/OS Communications Server: IP Configuration Reference* for more information on these statements.

Configure the FTP server for SMF (optional)

The FTP server can write SMF type 118 (X'76') or type 119 (X'77') records to record transactions made by the FTP server. SMF records can be written for the following commands:

- APPE (append)
- DELE (delete)
- RNTO (rename)
- RETR (retrieve)

- STOR (store)
- STOU (store unique)

Information about the previous commands can be recorded for:

- FTP server running in normal data transfer mode (FILETYPE=SEQ)
- FTP server running remote job submission (FILETYPE=JES)
- FTP server running Structured Query Language (SQL) queries (FILETYPE=SQL)
- Any combination of SEQ, JES, and SQL

For commands involving data transfer (APPEND, RETR, STOU or STOR) an SMF record will be written for both successfully and unsuccessfully completed data transfer commands which have begun data transfer. For data transfer commands which have completed unsuccessfully, the byte count of transmission field will contain the number of bytes transferred before the failure, and the recent server reply field will contain the 3-digit error reply code sent to the client. See the information about type 118 records and type 119 records in *z/OS Communications Server: IP Programmer's Guide and Reference* to find the particular offsets for the record type being used.

The FTP server can also write SMF records when a login attempt fails.

The capability also exists for a user-written exit routine to get control before the SMF records are written. See "Configuring the optional FTP user exits" on page 706 for more information.

If you want the FTP server to write SMF type 118 (X'76') or type 119 (X'77') SMF records, you must include at least one of the SMF subtype statements (SMF, SMFAPPE, SMFDEL, SMFLOGN, SMFREN, SMFRETR, or SMFSTOR) in the FTP.DATA data set.

If SMF subtype statements are not coded in the FTP.DATA data set, no SMF records are written by the FTP server.

Customizing Transport Layer Security and Kerberos security

The following terms apply to Transport Layer Security (TLS) and Kerberos.

Integrity protected, data integrity, or data authentication
Indicates an algorithm is applied to the data being transferred, which modifies the data such that the receiving program can verify the data was not modified or changed during the transfer.

Privacy protected
Indicates an algorithm is applied to the data being transferred, which encrypts or scrambles the data such that only the receiving program can use a special key to decrypt or unscramble the data to its original format. The original data cannot be seen or interpreted while the data is in transit.

Raw Indicates data is transmitted without being modified by any encryption or data integrity algorithms.

Encipher or cipher algorithm
Data being transferred is encrypted, integrity protected, or both. This term does not imply which algorithm is used and does not imply the data is encrypted.

Steps for customizing the FTP server for TLS

Before you begin: You should understand the following:

- The FTP server can be enabled to support both TLS and Kerberos. Some of the configuration statement settings apply to both TLS and Kerberos and affect the behavior of both.
- To support TLS, the FTP server always provides server certificate authentication to all the clients to validate that the server is what it says it is. Therefore, a server key ring database is required to contain at least the FTP server's digital certificate and private key. For more information about key ring databases, see Appendix B, “TLS/SSL security,” on page 1461.
- The FTP server can implement TLS security by itself, or the FTP server can be configured to use Application Transparent Transport Layer Security (AT-TLS) as a controlling application. For more information about AT-TLS, see Chapter 22, “Application Transparent Transport Layer Security data protection,” on page 1193.

  Guideline: Using AT-TLS is the better way to implement TLS security. With AT-TLS, for example, you can do the following:

  – Specify the label of the certificate to be used for authentication instead of using the default certificate
  – Support SSL Session Key Refresh
  – Support SSL Sysplex Session ID Caching
  – Trace decrypted SSL data for FTP in a data trace
  – Receive more detailed diagnostic messages in syslogd

  Requirement: AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see “Configuring the server system” on page 1199.

Perform the following steps to customize the FTP server for TLS:

1. Decide what level of RFC 4217, *On Securing FTP with TLS*, that you want the server to support.
   - To have the server support *On Securing FTP with TLS* at the Internet draft level, code the following statement in the server's FTP.DATA configuration file:

     ```
     TLSRFCLEVEL DRAFT
     ```

     This is the default. The z/OS FTP server has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.
   - To have the server support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the server's FTP.DATA configuration file:

     ```
     TLSRFCLEVEL RFC4217
     ```

     The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. RFC 4217 is less restrictive than the Internet draft regarding when the AUTH and CCC commands can be sent to the server, and more explicit about the details of the server REIN implementation. For more information, see RFC 4217.

2. Code the following statement in the server's FTP.DATA configuration file to enable the server for TLS:

   ```
   EXTENSIONS AUTH_TLS
   ```

---

3. Decide what level of authentication you will use for TLS sessions:
   - Server authentication only
   - Client authentication level 1
   - Client authentication level 2
   - Client authentication level 3

   For more information about server authentication and client authentication, see "Secure Socket Layer overview" on page 1461.

---

4. Create the server key ring database and add the certificates you will need to the server key ring database.

   For information on how to create a key ring database and add certificates to that database, see "Creating and managing keys and certificates at the server" on page 1467.

   Every TLS session handshake includes server authentication, so you must always add a certificate for this server to the server key ring database. If a server certificate is self signed, you must also export that certificate to the key ring databases of those clients that will log in using TLS. If a server certificate is signed by a certificate authority (CA), the CA certificate used to sign the server certificate needs to be in the client key ring databases, rather than the server certificate. For more information about server authentication, see "Server authentication" on page 1462 and "Creating and managing keys and certificates at the server" on page 1467.

   If you are using client authentication and self-signed certificates, you must import the client certificates into the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate. For more information, see "Client authentication" on page 1463 and "Creating and managing keys and certificates at the server" on page 1467.

---

5. Decide whether FTP will implement TLS security or AT-TLS will implement TLS security. The default is to have FTP implement TLS security. This setting is customized using the TLSMECHANISM configuration statement.
   - To configure the FTP server to use AT-TLS for TLS security, code the following statement in FTP.DATA:

     ```
     TLSMECHANISM ATTLS
     ```
   - To configure the FTP server to implement TLS security by itself, code the following statement in FTP.DATA:

     ```
     TLSMECHANISM FTP
     ```

     This is the default setting.

---

6. If using TLSMECHANISM FTP, you must configure the FTP server with a key ring database. To configure the FTP server with the name of the key ring database, code the following statement in FTP.DATA:

KEYRING *server-keyring-database*

For information about the KEYRING statement, see *z/OS Communications Server: IP Configuration Reference*.

---

7. Decide whether clients logging in to this server should be required to use the TLS protocol. The default is to allow the client to decide whether to use TLS. This setting is customized using the SECURE_FTP configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

   To allow the client to decide whether to use TLS, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP ALLOWED
   ```

   This is the default setting, and indicates the following:

   - If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
   - If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
   - If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

   To require that clients log in using a security mechanism, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP REQUIRED
   ```

   This setting indicates:

   - If the server is enabled for TLS only, clients must log in using TLS.
   - If the server is enabled for Kerberos only, clients must log in using Kerberos.
   - If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.

---

8. If you do not want to use client authentication, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_LOGIN NO_CLIENT_AUTH
   ```

   This is the default.

   If you do want to use client authentication, the following levels of client authentication are possible:

   - Level 1 authentication is performed by system SSL. The client passes an X.509 certificate to the server. To pass authentication, the Certificate Authority that signed the client certificate must be considered trusted by the server. To use level 1 client authentication, code the following statement in the server's FTP.DATA configuration file:

     ```
     SECURE_LOGIN REQUIRED
     ```

   - Level 2 authentication provides level 1 authentication, and additionally requires that the client certificate be registered with RACF (or another SAF compliant security product) and mapped to a user ID. The client certificate received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system prior

to connection negotiation. To use level 2 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN VERIFY_USER
```

- Level 3 authentication provides level 1 and 2 authentication. In addition, it provides the capability to restrict access to the server based on the user ID returned from RACF. If the SERVAUTH class of RACF is active and the server's port profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is defined in the server's port profile. To use level 3 client authentication, code the following statement in the server's FTP.DATA configuration file:

  ```
  SECURE_LOGIN VERIFY_USER
  ```

  Also, define the server's port profile in the SERVAUTH class of RACF. For more information on the FTP server's port profile, see "Add user IDs to the SERVAUTH profile access list" on page 1478.

If you choose to use client authentication, you can also use the client certificate authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session. The certificate received from the client must be registered in the security product and must be associated with the login user ID. You can use the RACDCERT ADD command to register and associate the certificate. If either the certificate is not registered or is not associated with the user ID, you will be prompted for a password.

If you do not want to use the client authentication process to eliminate the client password prompt, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD REQUIRED
```

This is the default.

If you want to use the client authentication process to eliminate the client password prompt, along with your client authentication statement (either SECURE_LOGIN REQUIRED or SECURE_LOGIN VERIFY_USER), code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD OPTIONAL
```

---

9. If you specified TLSMECHANISM ATTLS, configure the AT-TLS policy for the FTP server. To configure AT-TLS, see "Configuring the server system" on page 1199.

   Requirements:

   - The FTP server is a controlling application. For more information about controlling applications, see "Advanced application considerations" on page 1216.

     Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicatonControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.
   - The FTP server requires that the HandshakeRole parameter with the value Server or ServerWithClientAuth be coded on the TTLSEnvironmentAction statement. If the SECURE_LOGIN statement is coded in FTP.DATA with

the parameters REQUIRED or VERIFY_USER, the HandshakeRole parameter value must be ServerWithClientAuth.

- The TTLSRule statement for the FTP server requires the Direction parameter with the value Inbound.

A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for AT-TLS is as follows:

```
   TTLSGroupAction  secure_ftp_server_group
   {
      TTLSEnabled On
   }
   TTLSEnvironmentAction secure_ftp_server_env
   {
      TTLSKeyringParms
      {
         Keyring server-keyring-database
      }
      HandshakeRole Server       # When Secure_Login NO_CLIENT_AUTH is coded
      #HandshakeRole ServerWithClientAuth     # When Secure_Login Required or Verify_User is coded
      TTLSEnvironmentAdvancedParms
      {
         ApplicationControlled On
         SecondaryMap  On
      }
      TTLSCipherParmsRef   ftp_server_ciphers        # Used to customize ciphersuites for the FTP
                                                     # server
   }
TTLSCipherParms ftp_server_ciphers
{
   # Sample ciphers.  Should be customized!
   V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_NULL_SHA
}

   TTLSRule secure_ftp_server_rule
   {
      LocalPortRange 21                  # This should be set to the port the FTP server is
                                         #  listening on
      Direction Inbound
      TTLSGroupActionRef secure_ftp_server_group
      TTLSEnvironmentActionRef secure_ftp_server_env
   }
```

Tip: You can enable additional security settings with AT-TLS, such as LDAP servers and handshake timeout values. The configuration used in the example is the minimum required to allow the FTP server to use AT-TLS. You can add additional configuration statements.

10. Decide which cipher algorithms the server should use to encipher data transfers and to encipher control information.

    FTP and AT-TLS support TLS through the system SSL cryptographic services base element of z/OS. System SSL supports multiple cipher algorithms that provide both encryption and data authentication (that is, data integrity). Encryption scrambles the data so it is transferred confidentially and cannot be interpreted without a special key. Data authentication algorithms ensure the data was not modified during transfer. Some of the supplied cipher algorithms provide only data authentication, and some provide both encryption and authentication. Be aware that the actual cipher algorithm used for the session is determined by a negotiation between the server and client. For example, if you configure an FTP server to use the Triple DES encryption, SHA authentication algorithm, but the client does not support that cipher algorithm, Triple DES encryption, SHA authentication will not be used for sessions between the server and that client.

    If using TLSMECHANISM FTP, select which cipher algorithms you prefer to use by coding a CIPHERSUITE configuration statement in the FTP.DATA file for each cipher algorithm the server can use. For a list of the cipher algorithms you can specify on the CIPHERSUITE statement, see *z/OS Communications Server: IP Configuration Reference*. List the CIPHERSUITE

statements in FTP.DATA in the order of preference, your most preferred cipher algorithm being first. System SSL will negotiate a cipher algorithm with the server on behalf of the client using the same order of preference as is indicated by the order of CIPHERSUITE statements in FTP.DATA.

If you specify TLSMECHANISM ATTLS, select which cipher algorithms you want to use by coding a TTLSCipherParms configuration statement to specify the cipher algorithms that the server can use. For a list of the cipher algorithms you can specify with the TTLSCipherParms statement, see *z/OS Communications Server: IP Configuration Reference*. List the ciphers in the order of preference, your most preferred cipher algorithm first. The cipher algorithm is negotiated with the server on behalf of the client using the same order of preference as indicated by the order of the TTLSCipherParms statement.

Restrictions:

- Only RSA key exchange is supported.
- The following algorithms are subject to export regulations and might not be available to your system:
  - Triple DES encryption, SHA authentication
  - RC4 (128-bit) encryption, SHA authentication
  - RC4 (128-bit) encryption, MD5 authentication
  - AES (128-bit and 256-bit) encryption, SHA authentication

Guideline: The default ciphers used by System SSL support a null cipher, which has no encryption or authentication. A TTLSCipherParms statement or CIPHERSUITE statement should be coded to remove the null cipher from the list of acceptable ciphers.

---

11. Decide the level of security for the data connection. You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

    This setting is customized using the SECURE_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

    If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server's FTP.DATA configuration file:

    ```
    SECURE_DATACONN NEVER
    ```

    If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

    ```
    SECURE_DATACONN CLEAR
    ```

    This is the default.

    For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred enciphered and that clients attempting to send raw data are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the data must be transferred using both integrity and privacy protection. Clients attempting to send data that is only integrity protected are rejected.

---

12. For information about configuring your security product for TLS, see Appendix B, "TLS/SSL security," on page 1461.

Steps for customizing the FTP server for Kerberos

Before you begin: You should understand that the FTP server can be enabled to support both TLS and Kerberos. Some of the configuration statement settings apply to both TLS and Kerberos and will affect the behavior of both.

Decide which RACF ID the service principal will be associated with. This will help determine whether or not a keytab file is required. If the service principal is associated to the FTP startup procedure ID, a keytab file will not be required. Decide whether or not a keytab file is required. If a keytab file is not required and will not be used, decide how the FTP startup procedure will be updated to identify the environment variable (ENVAR) KRB5_SERVER_KEYTAB.

Perform the following steps to customize the FTP server for Kerberos:

1. Code the following statement in the server's FTP.DATA configuration file to enable the server for Kerberos:

   ```
   EXTENSIONS AUTH_GSSAPI
   ```

   ---

2. Decide whether clients should be required to use the Kerberos protocol. The default is to allow the client to decide whether to use Kerberos.

   This setting is customized using the SECURE_FTP configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

   To allow the client to decide whether to use Kerberos, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP ALLOWED
   ```

   This is the default setting, and indicates the following:

   - If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
   - If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
   - If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

   To require that clients log in using Kerberos, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_FTP REQUIRED
   ```

This setting indicates:

- If the server is enabled for TLS only, clients must log in using TLS.
- If the server is enabled for Kerberos only, clients must log in using Kerberos.
- If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.

---

3. Decide whether to use the client authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session.

   The Kerberos principal that is received from the client is used to query the security product (either RACF or another SAF-compliant security product) to determine whether the Kerberos principal maps to a user ID that is known to the system. If the Kerberos principal maps to a user ID, and that user ID matches the user name passed from the client on the USER command, you can eliminate the password prompt.

   If the client principal is for the same realm as the FTP server, the principal is correlated to the user ID using the KERBNAME option of the ADDUSER or ALTUSER commands. If the client principal is a cross-realm principal, it is correlated to the user ID using the RDEFINE KERBLINK command.

   If you want to require the client to provide a password even when the client authentication process does not require it, code the following statement in the server's FTP.DATA configuration file. This is the default.

   ```
   SECURE_PASSWORD_KERBEROS REQUIRED
   ```

   If you want to use the client authentication process to eliminate the client password prompt, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_PASSWORD_KERBEROS OPTIONAL
   ```

---

4. Decide the level of security for the data connection. You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

   This setting is customized using the SECURE_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

   If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_DATACONN NEVER
   ```

   If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_DATACONN CLEAR
   ```

   This is the default.

   For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols, and clients attempting to send raw data are rejected. For Kerberos, the data must be transferred using both integrity and privacy protection, and clients attempting to send raw data or data that is only integrity protected are rejected.

If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN SAFE
```

For TLS, specifying this option is identical to specifying SECURE_DATACONN PRIVATE. For Kerberos, specifying this option indicates the data can be transferred integrity protected only, or both integrity and privacy protected. Clients attempting to send raw data are rejected.

---

5. Decide the level of security for the control connection (that is, for FTP commands and replies). You can choose to require enciphered control connection data, or to allow the client to decide the level of security. The default is to allow the clients to decide the level of security.

   This setting is customized using the SECURE_CTRLCONN configuration statement. This setting applies only to Kerberos. For TLS, the control connection is required to be enciphered and this setting has no effect on TLS behavior.

   If you want the client to decide whether control data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN CLEAR
   ```

   This is the default.

   The client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

   If you want the server to require that control data is transferred both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN PRIVATE
   ```

   Clients attempting to send raw data or data that is only integrity protected are rejected.

   If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN SAFE
   ```

   Clients attempting to send raw data are rejected.

---

6. Create the service principal against a RACF ID for use with a keytab (see step 7 for using Kerberos with no keytab).

   a. Create a RACF user ID to associate with the FTP service principal.

```
adduser FTP NOPASSWORD DFLTGRP(SYS1) omvs(autouid home('/u/ftp') prog('/bin/sh'))
```

b. After the FTP RACF user ID is created, add the Kerberos principal to it.

```
ALTUSER FTP KERB(KERBNAME(ftp/<hostname>))
```

c. To ensure the Kerberos segment was added, use the following command to display the ID.

```
LU FTP NORACF KERB
```

Result:

```
USER=FTP

KERB INFORMATION
----------------
KERBNAME= ftp/<hostname>
KEY VERSION= 001
KEY ENCRYPTION TYPE= DES DES3 DESD
```

d. To add the FTP service principal to the keytab file, do the following:

1) The keytab file is located in the /etc/skrb directory. Switch to that directory using the following command:

```
cd /etc/skrb
```

2) Use the following command to see what is currently in the keytab file:

```
keytab list
```

If nothing is currently in the keytab file, the following is returned:

```
Key table: /etc/skrb/krb5.keytab
```

3) Add the FTP service principle using the following command:

```
keytab add ftp/<hostname>
```

You will be prompted for the principals' password. For this example, that password is FTP. The password must be entered in uppercase. This password was assigned with the RACF ALTUSER command when the FTP service principal was created.

4) Issue the keytab list command again.

The following should be displayed when the FTP service principal is present:

```
Key table: /etc/skrb/krb5.keytab

Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 56-bit DES
  Entry timestamp: 2005/02/04-16:21:10

Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 56-bit DES using key derivation
  Entry timestamp: 2005/02/04-16:21:10

Principal: ftp/<hostname>@<realm>
  Key version: 1
  Key type: 168-bit DES using key derivation
  Entry timestamp: 2005/02/04-16:21:10
```

---

7. An alternate way to run without a keytab file is to associate the FTP service principal to the ID under which the FTP started task runs. If the ID that the FTP started task runs under is FTPD, issue the following command to create the FTP service principal and have it associated to that ID.

```
ALTUSER FTPD PASSWORD(ftpd) NOEXPIRED KERB(KERBNAME(ftp/<hostname>))
```

Rule: In this setup, you must set the KRB5_SERVER_KEYTAB environment variable. Specify it directly in the FTP startup procedure as follows:

```
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//        'ENVAR("KRB5_SERVER_KEYTAB=1")/&PARMS')
```

Another way of specifying the environment variable directly in the startup procedure is to specify a file where the environment variables are listed.

```
//FTPD   EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//        'ENVAR("_CEE_ENVFILE=/etc/ftp.envvars")/&PARMS')
```

Then, within the /etc/ftp.envvars file, add the following:

```
KRB5_SERVER_KEYTAB=1
```

You know you are done when a client is able to successfully log in to the FTP server using Kerberos. An example of the login is as follows:

1. Obtain the Kerberos credentials by issuing the following command:

   ```
   kinit joe
   ```

2. You will be prompted for the password. Enter it.
3. Issue the **ftp** command:

   ```
   ftp <hostname>
   ```

   You should see the following:

   ```
   Using /u/JOE/ftp.data for local site configuration parameters.
   IBM FTP CS V1R9
   FTP: using TCPIP
   Connecting to: <hostname><ip address> port:  <port number>.
   220-FTPD1 IBM FTP CS V1R9 at <hostname>, 21:51:51 on 2007-04-04.
   220 Connection will close if idle for more than 5 minutes.
   >>> AUTH GSSAPI
   334 Using authentication mechanism GSSAPI
   >>> ADAT
   235 ADAT=YGgGCSqGSIb3EgECAgIAb1kwV6ADAgEFoQMCAQ+iSzBJoAMC7moS==
   Authentication negotiation succeeded
   NAME (<hostname>:USER):
   JOE
   >>> USER JOE
   331 Send password please.
   PASSWORD:

   >>> PASS
   230 JOE is logged on.  Working directory is "JOE".
   Command:
   ```

   Tip: The password prompt is skipped if the server is configured with SECURE_PASSWORD_KERBEROS OPTIONAL and the client's Kerberos ticket principal name matches the logon user ID.

Steps for customizing the FTP client for TLS

Before you begin: You should understand the following:

- The FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.
- To support TLS, the FTP server always provides server certificate authentication to all the clients to validate that the server is what it says it is. Therefore, a client key ring database is required to contain at least the certificate for the CA that

signed the server certificate (or the server certificate if the server certificate is self-signed). For more information about key ring databases, see Appendix B, "TLS/SSL security," on page 1461.

- The FTP client can implement TLS security by itself, or the FTP client can be configured to use Application Transparent Transport Layer Security (AT-TLS) as a controlling application. For more information on AT-TLS, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

  Guideline: Using AT-TLS is the best way to implement TLS security. With AT-TLS, for example, you can do the following:

  – Specify the label of the certificate to be used for authentication instead of using the default certificate
  – Support SSL Session Key Refresh
  – Support SSL Sysplex Session ID Caching
  – Trace decrypted SSL data for FTP in a data trace
  – Receive more detailed diagnostic messages in syslogd

  Requirement: AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see "Configuring the client systems" on page 1201.

Perform the following steps to customize the FTP client for TLS:

1. Decide what level of RFC 4217, *On Securing FTP with TLS*, that you want the client to support.
   - To have the client support *On Securing FTP with TLS* at the Internet draft level, code the following statement in the client's FTP.DATA configuration file:

     ```
     TLSRFCLEVEL DRAFT
     ```

     This is the default. The z/OS FTP client has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.
   - To have the client support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the client's FTP.DATA configuration file:

     ```
     TLSRFCLEVEL RFC4217
     ```

     The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. This has implications for client subcommands such as AUTH and CCC. Generally, RFC 4217 is less restrictive than the Internet draft. For more information, see RFC 4217. For more information on RFC 4217 and using security mechanisms, see *z/OS Communications Server: IP User's Guide and Commands*.

---

2. Code the following statement in the client's FTP.DATA configuration file to enable the client for TLS:

   ```
   SECURE_MECHANISM TLS
   ```

---

3. Decide what level of authentication you will use for TLS sessions:
   - Server authentication only
   - Client authentication level 1

- Client authentication level 2
- Client authentication level 3

For more information about server authentication and client authentication, see "Secure Socket Layer overview" on page 1461.

---

4. Use a CERTAUTH virtual key ring, or create a client key ring database and add the certificates that you need to that database.

   If you are using server authentication only and the FTP server certificate is signed by a certificate authority (CA), the FTP client can use a CERTAUTH virtual key ring and you do not need to create a client key ring database. To use a CERTAUTH virtual key ring, use the key ring name `*AUTH*/*` .

   If you cannot use a virtual key ring, create the client key ring database and add the certificates that you need to that database. For information about how to create a key ring database and add certificates to that database, see "Creating and managing keys and certificates at the server" on page 1467.

   Every TLS session handshake includes server authentication. If a server certificate is self-signed, you must import that certificate to the key ring database of any client that will log in using TLS. If the server certificate is signed by a CA, the CA certificate used to sign the server certificate (rather than the server certificate itself) needs to be in the client key ring database. For more information, see "Server authentication" on page 1462 and "Creating and managing keys and certificates at the server" on page 1467.

   If you are using client authentication, you must add a certificate for the client to the client key ring database.

   If you are using client authentication and self-signed client certificates, you must add a certificate for the client to the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate.

   For information about the client certificates you must create, see "Client authentication" on page 1463 and "Creating and managing keys and certificates at the server" on page 1467.

---

5. Decide whether FTP will implement TLS security or AT-TLS will implement TLS security. The default is to have FTP implement TLS security. This setting is customized using the TLSMECHANISM configuration statement.
   - To configure the FTP client to use AT-TLS for TLS security, code the following statement in FTP.DATA:

     ```
     TLSMECHANISM ATTLS
     ```
   - To configure the FTP client to implement TLS security by itself, code the following statement in FTP.DATA:

     ```
     TLSMECHANISM FTP
     ```

     This is the default setting.

---

6. If using TLSMECHANISM FTP, you must configure the FTP client with the name of the key ring database. Code the following statement in FTP.DATA:

   `KEYRING` *`client-keyring-database`*

   For information about the KEYRING statement, see *z/OS Communications Server: IP Configuration Reference*.

7. If you specified TLSMECHANISM ATTLS, configure the AT-TLS policy for the FTP client. To configure AT-TLS, see "Configuring the client systems" on page 1201.

   Requirements:

   - The FTP server and client are controlling applications. For more information about controlling applications, see "Advanced application considerations" on page 1216.

     Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicatonControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.
   - The FTP client requires the HandshakeRole parameter with the value Client to be coded on the TTLSEnvironmentAction statement.
   - The TTLSRule statement for the FTP client requires the Direction parameter with the value Outbound.

   A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for AT-TLS is as follows:

```
   TTLSGroupAction  secure_ftp_client_group
   {
      TTLSEnabled On
   }
   TTLSEnvironmentAction secure_ftp_client_env
   {
      TTLSKeyringParms
      {
         Keyring client-keyring-database
      }
      HandshakeRole Client
      TTLSEnvironmentAdvancedParms
      {
         ApplicationControlled On
         SecondaryMap  On
      }
      TTLSCipherParmsRef   ftp_client_ciphers        # Used to customize ciphersuites
   }
TTLSCipherParms ftp_client_ciphers
{
   # Sample ciphers.  Should be customized!
   V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_NULL_SHA
}

   TTLSRule secure_ftp_client_rule
   {
      RemotePortRange 21                  # This should be set to the port the FTP server is
                                          #  listening on
      Direction Outbound
      TTLSGroupActionRef secure_ftp_client_group
      TTLSEnvironmentActionRef secure_ftp_client_env
   }
```

   Tip: You can enable additional security settings with AT-TLS, such as LDAP servers and handshake timeout values. The sample configuration is only the minimum required to allow the FTP client to use AT-TLS. You can add additional configuration statements.

8. Decide which cipher algorithms the client should use to encipher data transfers and control information.

   FTP and AT-TLS support TLS through the system SSL cryptographic services base element of z/OS. System SSL supports multiple cipher algorithms that

provide both encryption and data authentication (that is, data integrity). Encryption scrambles the data so it is transferred confidentially and cannot be interpreted without a special key. Data authentication algorithms ensure that the data was not modified during transfer. Some of the supplied cipher algorithms provide only data authentication, and some provide both encryption and authentication. Be aware that the actual cipher algorithm used for the session is determined by a negotiation between the server and client. For example, if you configure an FTP client to use the Triple DES encryption, SHA authentication algorithm, but the server does not support that cipher algorithm, Triple DES encryption, SHA authentication will not be used for sessions between the client and that server.

If using TLSMECHANISM FTP, select which cipher algorithms you prefer to use by coding a CIPHERSUITE configuration statement in the FTP.DATA file for each cipher algorithm the client can use. For a list of the cipher algorithms you can specify on the CIPHERSUITE statement, see *z/OS Communications Server: IP Configuration Reference*.

If you specify TLSMECHANISM ATTLS, select which cipher algorithms you want to use by coding a TTLSCipherParms configuration statement to specify the cipher algorithms the client can use. For a list of the cipher algorithms you can specify with the TTLSCipherParms statement, see *z/OS Communications Server: IP Configuration Reference*. List the ciphers in the order of preference, your most preferred cipher algorithm first. The cipher algorithm is negotiated with the server on behalf of the client using the same order of preference as is indicated by the order of the TTLSCipherParms statement.

Restrictions:

- Only RSA key exchange is supported.
- The following algorithms are subject to export regulations and might not be available to your system:
  - Triple DES encryption, SHA authentication
  - RC4 (128-bit) encryption, SHA authentication
  - RC4 (128-bit) encryption, MD5 authentication
  - AES (128-bit and 256-bit) encryption, SHA authentication

Guideline: The default ciphers used by System SSL support a null cipher, which has no encryption or authentication. A TTLSCipherParms statement or CIPHERSUITE statement should be coded to remove the null cipher from the list of acceptable ciphers.

---

9. Decide whether the client should be required to use the TLS protocol. If the FTP server does not support TLS, you can choose to allow the client to log in without using the TLS security, or require the client to use a secure session, thus failing the login. The default is to not require the client to use TLS. This setting is customized using the SECURE_FTP configuration statement.

   To have the client log in using the TLS protocol when the server supports TLS, and log in without TLS when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

   ```
   SECURE_FTP ALLOWED
   ```

   This is the default.

   To have the client log in using the TLS protocol, but close the server connection and prevent logging in when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

10. Decide the level of security for the data connection. You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

    Note that the level of security for data connections is determined by both the SECURE_DATACONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

    The following subcommands can be issued by the user:

    clear Resets the security level so that data is transferred raw.

    private Resets the security level so that data is transferred enciphered. The cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

    If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

    ```
    SECURE_DATACONN NEVER
    ```

    To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

    ```
    SECURE_DATACONN CLEAR
    ```

    This is the default.

    By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred enciphered. The user can also issue the `clear` subcommand to reset the data connection security level back, so that data is transferred raw again. For TLS, if the `private` subcommand is issued, the cipher algorithm is negotiated between the server and the client using TLS protocols.

    If you want to require that data is transferred enciphered, code the following statement in the client's FTP.DATA configuration file:

    ```
    SECURE_DATACONN PRIVATE
    ```

    For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols.

Steps for customizing the FTP client for Kerberos

Before you begin: You should understand that the FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.

Perform the following steps to customize the FTP client for Kerberos:

1. Code the following statement in the client's FTP.DATA configuration file to enable the client for Kerberos:

   ```
   SECURE_MECHANISM GSSAPI
   ```

2. Decide whether the client should be required to use the Kerberos protocol. If the FTP server does not support Kerberos, you can choose to allow the client to log in without using Kerberos security, or require the client to use a secure

session, thus failing the login. The default is to not require the client to use Kerberos. This setting is customized using the SECURE_FTP configuration statement.

To have the client log in using the Kerberos protocol, but if the server does not support Kerberos allow the client to complete the login without using it, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP ALLOWED
```

This is the default.

To have the client log in using the Kerberos protocol, but if the server does not support Kerberos have the login fail and not allow the client to log in, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

---

3. Decide the level of security for the data connection. You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

   Note that the level of security for data connections is determined by both the SECURE_DATACONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

   The following subcommands can be issued by the user:

   clear Resets the security level so that data is transferred raw.

   private Resets the security level so that data is transferred enciphered. If the client is using the Kerberos security mechanism, the data is transferred both integrity protected and privacy protected. If the client is using the TLS security mechanism, the cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

   safe Resets the security level so that data is transferred integrity protected only.

   If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

   ```
   SECURE_DATACONN NEVER
   ```

   To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

   ```
   SECURE_DATACONN CLEAR
   ```

   This is the default.

   By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to change the data connection security level so that data is transferred integrity protected only, or the `clear` subcommand to reset the data connection security level back so that data is transferred raw again.

   If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN SAFE
```

By default, data is transferred integrity protected only. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to reset the data connection security level back, so that data is transferred integrity protected only.

---

4. Decide the level of security for the control connection (that is, for FTP commands and replies). You can choose to require enciphered data, or to allow the FTP user to decide the level of security. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

   Note that the level of security for data connections is determined by both the SECURE_CTRLCONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

   The following subcommands can be issued by the user:

   cprotect clear
   : Resets the security level so that data is transferred raw.

   cprotect private
   : Resets the security level so that data is transferred both integrity protected and privacy protected.

   cprotect safe
   : Resets the security level so that data is transferred integrity protected only.

   To indicate the data can be transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN CLEAR
   ```

   This is the default.

   By default, data is transferred raw. However, the user can issue the `cprotect private` subcommand during the FTP session to change the security level so that data is transferred both integrity and privacy protected. The user can also issue the `cprotect safe` subcommand to change the security level so that data is transferred integrity protected only, and the `cprotect clear` subcommand to reset the security level back so that data is transferred raw again.

   If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN PRIVATE
   ```

   If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

   ```
   SECURE_CTRLCONN SAFE
   ```

   By default, data is transferred integrity protected only. However, the user can issue the `cprotect private` subcommand during the FTP session to change the

data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the `cprotect safe` subcommand to reset the data connection security level, so that data is transferred integrity protected only.

Port 990

The use of port 990 to implicitly protect FTP sessions was included in the early drafts of the IETF documents that describe how to use TLS with FTP, but has been removed from later drafts and from RFC 4217. For more information, see Information APAR II13516.

Port 990 is known as the protected port, or the TLSPORT. You can disable implicit security for port 990, or reassign the protected port, by coding the TLSPORT statement in the server's FTP.DATA configuration file.

Rule: If you start the FTP server on the protected port, you should code a SECUREIMPLICITZOS statement in the server's FTP.DATA file to specify when the server should expect the client to negotiate TLS security.

The FTP server can provide explicit TLS security on a different port by specifying the following in FTP.DATA:

```
EXTENSIONS AUTH_TLS
SECURE_FTP REQUIRED
SECURE_CTRLCONN PRIVATE
SECURE_DATACONN PRIVATE
```

Steps for migrating the FTP server and client to use AT-TLS

Before you begin: Application Transparent Transport Layer Security (AT-TLS) is the best way to implement TLS security for the FTP server and client. AT-TLS provides additional functionality and performance for TLS secured connections.

Perform the following steps to migrate from an existing configuration using TLS security for the FTP server and client to a configuration using AT-TLS:

1. Configure AT-TLS and Policy Agent.

   For details about AT-TLS setup, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193. For Policy Agent setup and AT-TLS policy statements, see *z/OS Communications Server: IP Configuration Reference*.

   Requirements:

   - The FTP server and client are controlling applications. For more information about controlling applications, see "Advanced application considerations" on page 1216.

     Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicatonControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.
   - The FTP server requires the HandshakeRole parameter with the value Server or ServerWithClientAuth to be coded on the TTLSEnvironmentAction

statement. If the SECURE_LOGIN statement is coded in FTP.DATA with the parameters REQUIRED or VERIFY_USER, the HandshakeRole parameter value must be ServerWithClientAuth.

- The TTLSRule statement for the FTP server requires the Direction parameter with the value Inbound.
- The FTP client requires the HandshakeRole parameter with the value Client to be coded on the TTLSEnvironmentAction statement.
- The TTLSRule statement for the FTP client requires the Direction parameter with the value Outbound.

Guideline: The FTP server and client do not support SSLv2 when using TLSMECHANISM TLS. By default, AT-TLS does not enable SSLv2. SSLv2 should not be enabled in AT-TLS unless explicitly required by a remote system. If SSLv2 is required by a remote system, use a specific TTLSRule statement for the remote system that points to a TTLSConnectionAction statement enabling SSLv2.

---

2. Configure the FTP server and client to use AT-TLS by coding TLSMECHANISM ATTLS in FTP.DATA.
3. Use Table 33 to migrate the existing FTP server and client configuration to AT-TLS. Remove the statements from FTP.DATA and code the AT-TLS equivalent statement.

Table 33. Migrating existing FTP server and client configuration

FTP.DATA statement	AT-TLS equivalent statement	AT-TLS policy statement
KEYRING	Keyring	TTLSKeyRingParms -> TTLSEnvironmentAction
CIPHERSUITE	V3CipherSuites	TTLSCipherParms -> TTLSEnvironmentAction
TLSTIMEOUT	GSK_V3_SESSION_TIMEOUT	TTLSGskAdvancedParms -> TTLSEnvironmentAction

4. Use Table 34 to migrate existing ciphers coded on CIPHERSUITE statements in FTP.DATA to AT-TLS TTLSCipherParms statements.

Table 34. Migrating existing ciphers

CIPHERSUITE cipher	V3CipherSuites cipher	Hexadecimal value
SSL_DES_SHA	TLS_RSA_WITH_DES_CBC_SHA	09
SSL_3DES_SHA	TLS_RSA_WITH_3DES_EDE_CBC_SHA	0A
SSL_NULL_MD5	TLS_RSA_WITH_NULL_MD5	01
SSL_NULL_SHA	TLS_RSA_WITH_NULL_SHA	02
SSL_RC2_MD5_EX	TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5	06
SSL_RC4_MD5	TLS_RSA_WITH_RC4_128_MD5	04
SSL_RC4_MD5_EX	TLS_RSA_EXPORT_WITH_RC4_40_MD5	03
SSL_AES_128_SHA	TLS_RSA_WITH_AES_128_CBC_SHA	2F
SSL_AES_256_SHA	TLS_RSA_WITH_AES_256_CBC_SHA	35

For example, for an FTP.DATA file containing the following:

```
CIPHERSUITE SSL_AES_256_SHA
CIPHERSUITE SSL_3DES_SHA
CIPHERSUITE SSL_NUL_SHA
```

The equivalent TTLSCipherParms statement is:

```
TTLSCipherParms
{
   V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites TLS_RSA_WITH_NULL_SHA
}
```

Traversing firewalls with SSL/TLS secure FTP

This topic describes functions in FTP that enable you to use FTP sessions that are secured by SSL/TLS using both network address translation (NAT) and filtering firewalls.

FTP requires the following TCP connections to transfer a file:

- Control connection
- Data connection

The control connection is established from the FTP client to the FTP server (default port 21). The data connection is established either from the FTP client to the FTP server, or from the FTP server to the FTP client; the direction is based on whether the client selects active mode or passive mode FTP.

- Active mode

  With active mode FTP, the data connection is established from the FTP server to the FTP client, which is the opposite direction of the control connection. The active mode data connection is established from a well-known port on the server host (default port 20) to an ephemeral port on the client host.

- Passive mode

  With passive mode FTP, the data connection is established from the FTP client to the FTP server, which is the same direction as the control connection. The data connection is established from an ephemeral port on the server host to an ephemeral port on the client host.

  Passive mode is also referred to as firewall-friendly FTP. An intranet FTP client connecting to an Internet FTP server can establish connections outbound through the company firewall, but not inbound through the firewall. With passive mode, both the control and data connections are established outbound through the firewall to the Internet.

The FTP client user decides which mode to use. Active mode is the default, but the user can usually change to passive mode. The z/OS FTP client user can switch between active and passive modes by issuing the LOCSITE subcommand with the NOFWFRIENDLY and FWFRIENDLY parameters.

Both active mode and passive mode FTP require the exchange of IP address and port information over the control connection. For active mode, the FTP client sends a PORT command specifying the IP address and port number to which the server must connect to establish the data connection. For passive mode, the FTP client sends a PASV command to the server, and the server replies with the IP address and port number to which the client should connect to establish the data connection.

Firewalls are often aware of FTP; they monitor the exchanges over the FTP control connection to learn the IP address and port number to which the data connection is to be established. NAT firewalls change the IP addresses on the PORT command or in the PASV reply. Filtering firewalls install dynamic filters based on the IP addresses and port information to enable the data connection to be established.

When you use SSL/TLS for FTP, the control connection is typically encrypted, so firewalls between the FTP client and server cannot see the data that is exchanged on the PORT command and the PASV reply. The firewalls cannot perform NAT successfully and they cannot install dynamic filters for the data connection, so the result is that your data connection very likely fails.

z/OS FTP includes the following support for functions that are specifically aimed at enabling FTP sessions through such firewalls:

- Extended passive mode (EPSV)

  Extended passive mode works very much like passive mode. Instead of sending a PASV command to the server, the client sends an EPSV command to the server. The server EPSV reply includes only a port number. The client always uses the same IP address for the data connection that it used for the control connection. A z/OS FTP client user switches to extended passive mode for IPv4 connections by issuing the LOCSITE subcommand with the EPSV4 and FWFRIENDLY parameters. These options can also be configured in the z/OS FTP client FTP.DATA file.

  EPSV allows sessions secured by SSL/TLS through NAT firewalls, but EPSV alone does not allow FTP sessions that are secured by SSL/TLS through firewalls that also implement dynamic filters.
- The PASSIVEIGNOREADDR configuration option

  This z/OS FTP client option directs the z/OS FTP client to ignore the IP address in the PASV reply and use only the port number when FTP is in passive mode. The client uses the same IP address that it used to log into the FTP server for the data connection. A z/OS FTP client user enables this support by issuing a LOCSITE subcommand with the PASSIVEIGNOREADDR option. You can also configure this option in the z/OS FTP client FTP.DATA file.

  The PASSIVEIGNOREADDR configuration enables sessions secured by SSL/TLS through NAT firewalls in the same way that extended passive mode enables them, subject to the same limitations. You can use the PASSIVEIGNOREADDR option when the server does not support the EPSV command.
- The PASSIVEDATAPORTS statement in FTP.DATA

  This z/OS FTP server option enables you to define a range of port numbers that the z/OS FTP server can use in PASV and EPSV replies for passive mode data connections. If the PASSIVEDATAPORTS statement on the z/OS FTP server is used in combination with EPSV from the FTP client, the two techniques together allow FTP sessions secured with SSL/TLS through NAT firewalls that also implement static IP filters, assuming that the firewall administrators add static filter rules that allow FTP data connections access to one or more of the ports in the PASSIVEDATAPORTS range.
- The clear command channel (CCC) command

  The CCC command can be used on a control connection secured by SSL/TLS to disable SSL/TLS security. The control connection starts out as secured by SSL/TLS, and stays that way until a user ID and password have been exchanged with the server. At that point, the FTP client can send a CCC command to the server, which disables SSL/TLS for the control connection and enables PORT commands and replies to PASV and EPSV commands to flow in the clear on the

control connection. When these exchanges occur in the clear, firewalls between the FTP client and FTP server can perform NAT processing and dynamic filter processing as if the connection is not secured with SSL/TLS. The CCC command does not turn off security for the data connection.

To enable the z/OS FTP server to accept the CCC command, configure TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY at the FTP server.

To enable the z/OS FTP client to support the CCC command, configure TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY at the FTP client, matching the client TLSRFCLEVEL value to the server TLSRFCLEVEL value. You can use the LOCSITE subcommand to change the TLSRFCLEVEL value. When TLSRFCLEVEL RFC4217 or TLSRFCLEVEL CCCNONOTIFY is configured at the z/OS FTP client, use the CCC subcommand after logging in to the FTP server to send a CCC command to the FTP server.

The support you use depends on your network topology. Following are a few selected scenarios to consider for making sure that FTP sessions secured by SSL/TLS can get through your network. The scenarios assume that z/OS is at least one of the endpoints of the secure FTP session. The partner endpoint can be z/OS or any secure FTP product on the market that supports the same RFC levels as z/OS (primarily RFC 4217).

- Your firewall performs NAT only (minimal or no filtering), your FTP client is in a private network behind the NAT firewall, and the FTP server is in a public network such as the Internet, as shown in Figure 71.

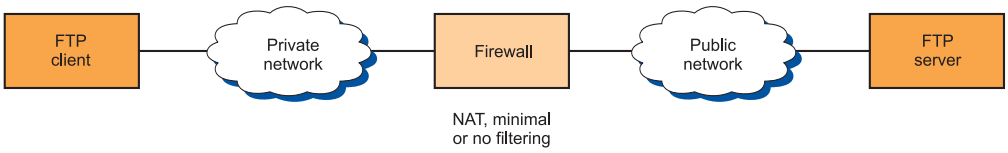


Figure 71. SSL/TLS-secured FTP session scenario 1

Normal passive mode (PASV) usually works in such a scenario. Extended passive mode (EPSV) also works, but is generally not required.

- Your firewalls perform NAT only (minimal or no filtering), your FTP client is in one private network, your FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in Figure 72.

Figure 72. SSL/TLS-secured FTP session scenario 2

If your partner's secure FTP product supports extended passive mode, use extended passive mode (EPSV) from the FTP client. If the FTP client is the z/OS FTP client and the partner's secure FTP server product does not support EPSV, configure the PASSIVEIGNOREADDR option at your z/OS FTP client to simulate EPSV processing.

- Your firewall performs NAT and static filtering (predefined filter rules). Your FTP client is in a private network behind the NAT firewall, with a z/OS FTP server residing in a public network such as the Internet, as shown in Figure 73 on page 705.

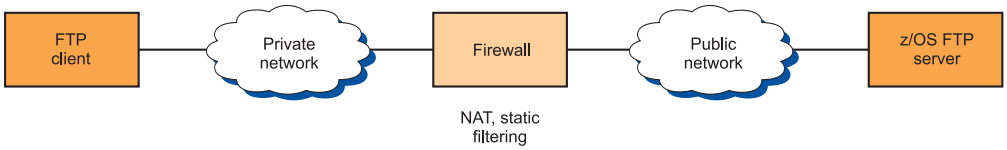

Figure 73. SSL/TLS-secured FTP session scenario 3

Use the PASSIVEDATAPORTS statement in the z/OS FTP server's FTP.DATA file to predefine a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs to add static filter rules for the passive data port range. Normal passive mode (PASV) usually works in such a scenario, but extended passive mode (EPSV) can also be used if supported by the FTP client.

- Your firewalls perform NAT and static filtering (predefined filter rules). Your FTP client is in one private network, your z/OS FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in Figure 74.

Figure 74. SSL/TLS-secured FTP session scenario 4

Use the PASSIVEDATAPORTS statement in the z/OS FTP server's FTP.DATA file to predefine a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs to add static filter rules for the passive data port range. In this case, you must use extended passive mode. If the FTP client does not support extended passive mode, this scenario is not likely to work.

- Your firewalls perform dynamic filtering (with or without NAT) and your partner's secure FTP product supports the CCC command, as shown in Figure 75.

Figure 75. SSL/TLS-secured FTP session scenario 5

Use the CCC command from the FTP client. This scenario is not likely to work without CCC command support.

- You do not know what your firewalls do and your partner's secure FTP product does support the CCC command, as shown in Figure 76.

Figure 76. SSL/TLS-secured FTP session scenario 6

Use the CCC command from the FTP client. This scenario is not likely to work without CCC command support.

Firewalls reject FTP sessions secured by SSL/TLS in the following additional scenarios:

- Some firewalls are known to apply various validity checks on the FTP control connection data stream. One known check verifies that all interactions on the FTP control connection are terminated with an ASCII newline (NL) character. Most of these checks fail when the control connection is secured with SSL/TLS, because the data is encrypted. If you use the information in this topic and still run into problems establishing FTP sessions secured by SSL/TLS through firewalls, verify with your firewall administrators whether your firewalls implement such validity checks on the FTP control connection, and consider disabling those validity checks.
- Some firewalls are known to disable active mode data connections by default, and block all active mode data connections. Use passive mode or extended passive mode FTP instead.
- Many firewalls monitor activity on TCP connections and terminate connections that are idle for a certain period of time. During a large data transfer over an FTP data connection, the FTP control connection is idle. To avoid having firewalls terminate idle FTP connections, consider coding the FTPKEEPALIVE statement in the z/OS FTP.DATA file for the client or the server. For more information about the FTPKEEPALIVE statement, see "Configuring PROFILE.TCPIP for FTP" on page 660.

DB2 and JES

The following statements are used when FTP interfaces with DB2 and JES, respectively. For more information, see *z/OS Communications Server: IP Configuration Reference* and the optional steps in this information.

- DB2
- DB2PLAN
- JESGETBYDSN
- JESINTERFACELEVEL
- JESLRECL
- JESPUTGETTO
- JESRECFM
- SPREAD and SQLCOL

Configuring the optional FTP user exits

The following describes exit routines you can code and install. For detailed information regarding these exit routines, see *z/OS Communications Server: IP Configuration Reference*.

The FTPSMFEX user exit

Note the FTP server SMF user exit is called before an SMF type 118 record that contains information about an FTP server session is written to the SYS1.MANx data set. The user exit allows site specific modifications to the record and controls whether the record is written to the SYS1.MANx data set.

Note that the exit is called only for type 118 records. SMF type 119 FTP records must use the system-wide SMF user exits (IEFU83, IEFU84, and IEFU85) to obtain this same functionality. For information on these SMF user exits, see *z/OS MVS System Management Facilities (SMF)*.

The FTCHKIP user exit

The FTCHKIP user exit is called when a user attempts to log in to the FTP server or when a user issues the OPEN subcommand to establish a new connection. The following information is passed to the exit:

- Client IP address *
- Client port number *
- Server IP address *
- Server port number *
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier

Note: Fields above marked with an asterisk (*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.

An installation can use this exit to determine if a particular IP address or port number is allowed to access the FTP site. If the connection is denied by the user exit, the following message is sent to the user:

```
421 User Exit rejects open for connection
```

The FTCHKPWD user exit

The FTCHKPWD user exit is called immediately after the user enters the password or e-mail address during login to the FTP server. The following information is passed to the exit:

- The user ID
- The user password or an asterisk (*) if an e-mail address is entered instead of a password
- A userdata buffer

  If an e-mail address is entered to log in, the userdata buffer contains the e-mail address.
- The number of bad passwords entering during this login attempt
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier

The exit can be used to restrict access to a site based on user ID, password, number of bad passwords, or anything in the socket address information for the client or server. If the login is denied by the user exit, the following reply is sent to the user:

```
530 PASS command failed
```

Note: If ACCESSERRORMSGS TRUE is coded in FTP.DATA, an additional 530 reply with information about why the PASS command failed might precede the reply above.

The FTCHKCMD user exit

The FTCHKCMD user exit is called whenever the user enters an FTP command. The following information is passed to the user exit:

- The user ID
- The FTP command to be issued

- The command's arguments
- The directory type (MVS or HFS)
- The FILETYPE (SEQ, JES, or SQL)
- The current working directory
- A buffer to hold a modified argument string
- A buffer to hold a 500 reply extension to explain why the exit denied the request
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The user exit allows an installation to modify the arguments of an FTP command or to deny a user from issuing the command. For example, if a user issues a DIR * ftp command, the exit can either deny the command or modify it to DIR 'USER1.*'. If the user exit denies the request by this user to issue this command, one or both of the following replies will be sent to the user. The first reply is optional and is sent only if the user exit returns a string in the 500 reply extension buffer.

```
500-UX-buffercontents
500 User Exit denies Userid userid from using Command command
```

The FTCHKJES user exit

FTCHKJES is called if the server is in FILETYPE=JES mode and the client tries to submit a job. The following information is passed to the exit:

- The user ID
- A buffer containing the current JCL statement
- Size of statement in the buffer
- JESLrecl value
- Number of this buffer in current series
- Bytes transferred so far (including this buffer)
- Client identifier (see also session instance identifier)
- JESRecfm value
- FTCHKJES exit-specific workarea (4 bytes)
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The exit can allow or refuse the job to be submitted to the JES internal reader based on any information passed to the exit. For example, the exit can look for a USER= parameter on the JOB statement and check it against the client's user ID. If the remote job submission is denied, the exit sends the user the following reply:

```
550 User Exit refuses this job to be submitted by userid
```

The FTPOSTPR user exit

FTPOSTPR is called after execution of the FTP commands RETR, STOR, STOU, APPE, DELE, and RNTO. The following information is passed to the exit:

- The user ID
- Client IP address *
- Client port number *

- The directory type (MVS or HFS)
- The current working directory
- The FILETYPE (SEQ, JES, or SQL)
- Most recent reply code number
- Most recent reply text string
- Current FTP command
- Current CONDDISP setting
- Close reason code
- Name of data set or z/OS UNIX file retrieved or stored
- Bytes transferred
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer
- The 1-byte description of the confidence-of-successful-completion level assigned to this file transfer

Notes:

1. Fields above marked with an asterisk (*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.
2. The directory type reflects the current working directory. The MVS data set or z/OS UNIX file that is retrieved or stored can be located in a different type of directory.

The exit allows for post processing at the termination of data transfer functions within the server.

Customizing the FTP-to-JES interface for JESINTERFACELevel 2 (optional)

If FTP.DATA does not change the JESINTERFACELEVEL to 2, the FTP server uses the JES interface provided in releases prior to CS for OS/390 V2R10. At this level, the FTP user is allowed to submit jobs to JES, retrieve held output matching their logged-in user ID plus one character, and delete held jobs matching their logged-in user ID plus one character.

If JESINTERFACELevel is set to 2, FTP users have the ability to retrieve and delete any job in the system permitted by the System Authorization Facility (SAF) resource class JESSPOOL. For that reason, JESINTERFACELevel=2 should only be specified if the proper JES and SDSF security measures are in place to protect access to JES output. The SAF controls used for JESINTERFACELevel=2 are essentially a subset of those used by SDSF. Therefore, if an installation has customized SAF facilities for SDSF, they are configured for FTP JES level 2.

Before customizing the FTP-to-JES interface, complete JES customization. For example, JESJOBS is an SAF class that controls which users can submit jobs to JES. JESSPOOL is the SAF class that controls which users can access output jobs. Customize these SAF classes before beginning customization of the FTP-to-JES interface.

JESSPOOL defines resource names as <nodeid>.<userid>.<jobname>.<Dsid>.<dsname>. An FTP user can delete an

output job if they have UPDATE access to the resource that matches their nodeid, userid, and job name. If the FTP user has READ access to the resource, they can list, retrieve, or GET the job output. For more information on JES security, see *z/OS JES2 Initialization and Tuning Guide*. For more information on the SAPI interface, see *z/OS MVS Using the Subsystem Interface*.

There are three filters used by the FTP server to control the display of jobs:

- JESSTATUS
- JESOWNER
- JESJOBNAME

SDSF resources are employed for this.

JESSTATUS can be changed by an FTP user with the SITE command to filter jobs in INPUT, ACTIVE, or OUTPUT state. The SDSF resources checked for these states are ISFCMD.DSP.INPUT.jesx, ISFCMD.DSP.ACTIVE.jesx, and ISFCMD.DSP.OUTPUT.jesx, respectively. At login time (USER command), the default value is set to ALL if READ access is allowed to all three classes. Otherwise it attempts to set it to OUTPUT, ACTIVE, and then INPUT if the appropriate READ access is allowed. If no READ access is allowed to any of the classes, JESSTATUS is set to OUTPUT but JESOWNER and JESJOBNAME cannot be changed from the default. In this way, SAF controls can be put in place to limit FTP users to whatever status of jobs an installation requires.

At login time, JESOWNER will have the value of the logged-in user ID. Authority to change JESOWNER is obtained through READ access to RACF profile ISFCMD.FILTER.OWNER. An FTP user who has READ access to ISFCMD.FILTER.OWNER will be allowed to change the JESOWNER parameter with the SITE command.

At login time, JESJOBNAME will have the value of the logged-in user ID plus an asterisk (*). Authority to change JESJOBNAME is obtained through READ access to RACF profile ISFCMD.FILTER.PREFIX. An FTP user who has READ access to ISFCMD.FILTER.PREFIX will be allowed to change the JESJOBNAME parameter with the SITE command.

For example, to allow all users except USER1 to be allowed to change JESOWNER enter the following:

```
SETROPTS CLASSACT(SDSF) REFRESH
RDEFINE SDSF (ISFCMD.FILTER.OWNER) UACC(READ)
PERMIT ISFCMD.FILTER.OWNER ACCESS(NONE) CLASS(SDSF) ID(USER1)
SETROPTS CLASSACT(SDSF) REFRESH
```

For more information on SDSF security, see *z/OS SDSF Operation and Customization*.

Configuring the FTP server for anonymous logins (optional)

You can configure the FTP server to accept anonymous logins. A login is anonymous when the remote user specifies USER ANONYMOUS instead of an FTP user ID. To enable anonymous logins, add the ANONYMOUS statement to the server FTP.DATA data set.

You can specify three levels of anonymous support via the ANONYMOUSLEVEL keyword. ANONYMOUSLEVEL 1 is the default, and is equivalent to anonymous login support provided by releases prior to OS/390 V2R10. That is, the

ANONYMOUS statement is supported. If no operands are specified on the ANONYMOUS statement, the anonymous user needs no password and has unrestricted access to MVS data sets and the z/OS UNIX file system.

You can specify ANONYMOUSLEVEL 2, but this is not recommended. ANONYMOUSLEVEL 2 is provided for migration purposes only. Consider ANONYMOUSLEVEL 3 if ANONYMOUSLEVEL 1 does not meet your anonymous login security requirements.

If you specify ANONYMOUSLEVEL 3, the anonymous user cannot issue the USER command to leave anonymous mode, nor can another user issue USER anonymous to enter anonymous login mode. If you specify ANONYMOUSLEVEL 3 and STARTDIRECTORY HFS in FTP.DATA, the anonymous user's z/OS UNIX file system access is restricted to the anonymous user's home directory and home directory subtrees.

The ANONYMOUSLEVEL 3 server recognizes additional keywords that restrict the anonymous user's access to FTP resources. These keywords are ignored when ANONYMOUSLEVEL is less than three:

- ANONYMOUSFILEACCESS allows the system programmer to preclude access to either the z/OS UNIX file system or MVS data sets.
- ANONYMOUSFILETYPEJES, ANONYMOUSFILETYPESQL, and ANONYMOUSFILETYPESEQ control whether the anonymous user can set filetype JES, SQL, or SEQ, respectively.
- ANONYMOUSHFSFILEMODE defines the mode bits used for files written to the z/OS UNIX file system.
- ANONYMOUSHFSDIRMODE defines the mode bits used for directories created in the z/OS UNIX file system.

Finally, when ANONYMOUSLEVEL is set to three, the user's e-mail address is requested in lieu of a password when:

- ANONYMOUS is specified without any parameters.
- ANONYMOUS is specified with user ID/password.
- ANONYMOUS is specified with user ID/SURROGATE.

Control the degree of verification of the e-mail address an anonymous user enters as password by using the EMAILADDRCHECK keyword in FTP.DATA. See *z/OS Communications Server: IP Configuration Reference* for details about the EMAILADDRCHECK keyword. The e-mail address entered is logged to the syslog daemon and is also passed to a user exit routine, FTCHKPWD, for user processing.

The FTP server can be defined to process users without passwords by using the ANONYMOUS SURROGATE support. In order to support this, ANONYMOUSLEVEL must be set to 3 in FTP.DATA on the server and BPX.SRV surrogate must be defined in RACF.

z/OS UNIX uses profiles defined to the RACF SURROGAT class to authorize the server to act as a surrogate of a client. Profiles defined to the SURROGAT class are of the form:

```
BPX.SRV.<userid>
```

in which <userid> is the MVS user ID of the user that the server will support without a password.

The steps below are for a sample userid of the FTP daemon (the userid associated with the FTP started task procedure) called FTPD with the ability to support user ID GUEST without a password. As you add more servers, you will need to follow similar procedures.

1. Activate the SURROGAT class support in RACF:

   ```
   SETROPTS CLASSACT(SURROGAT)
   ```

   This has to be done only once on the system. The SURROGAT class may already have been set up on your system. If a daemon or server you are running will be using the SURROGAT support heavily, consider using the RACLIST command to keep the SURROGAT profiles in storage. The following example shows how to cache the SURROGAT profiles in storage:

   ```
   SETROPTS RACLIST(SURROGAT)
   ```

2. If the SURROGAT profile is in the RACLIST, any changes to the SURROGAT profiles must be followed by a REFRESH command. To create the SURROGAT class profile for user ID GUEST, issue:

   ```
   RDEFINE SURROGAT BPX.SRV.GUEST UACC(NONE)
   SETROPTS RACLIST(SURROGAT) REFRESH
   ```

   A similar SURROGAT profile is required for each user ID that a server must support without a password.

3. To permit the userid of the FTP daemon (the userid associated with the FTP started task procedure), FTPD, to create a security environment for user ID GUEST, issue the PERMIT command:

   ```
   PERMIT BPX.SRV.GUEST CLASS(SURROGAT) ID(FTPD) ACCESS(READ)
   SETROPTS RACLIST(SURROGAT) REFRESH
   ```

If you choose ANONYMOUSLEVEL greater than one and you choose STARTDIRECTORY HFS, you must create an anonymous directory structure in the z/OS UNIX file system.

Creating an anonymous directory structure in the z/OS UNIX file system

The sample shell script, ftpandir.scp, will create an anonymous directory structure for you, containing required and optional structures. Or, a superuser can create the anonymous directory structure. In this topic, the steps a superuser would follow to create an anonymous directory structure are outlined.

For the following steps, assume that the RACF user ID that is used when an anonymous user logs in is called GUEST, that the HOME directory in that user's OMVS segment in RACF is /u/guest, and that FTP.DATA contains a statement similar to this: ANONYMOUS GUEST

1. Create a bin subdirectory in the anonymous root containing the executable files *ls* and *sh*. This is a required directory. *ls* can be copied from the standard directory. *sh* is part of the standard MVS search order, so you need only create an empty file with the sticky bit.

   The following example shows how to create ls and sh in the user GUEST's home directory:

   ```
   ===> cd /u/guest
   ===> mkdir bin
   ===> chmod 711 bin
   ===> cd bin

   ===> cp /bin/ls ls
   ```

```
===> chmod 711 ls
===> touch sh
===> chmod 711 sh
===> chmod +t sh
```

An **ls -al** command should give the following results. Owner and group attributes may be different in your system.

```
# ls -al
total 280
drwx--x--x   2 USER22   0  8192 Sep 21 17:39 .
drwx--x--x   7 USER22   0  8192 Nov  1 14:44 ..
-rwx--x--x   1 USER22   0  126976 Sep 21 17:39 ls
-rwx--x--t   1 USER22   0  0 Sep 21 17:39 sh
```

2. Create a usr/sbin sudirectory of the anonymous root containing the executable file ftpdns. This is a required subdirectory. The file ftpdns can be empty with the sticky bin on.

   The following example is for anonymous user GUEST:

   ```
   ===> cd /u/guest
   ===> mkdir usr
   ===> chmod 711 usr

   ===> cd usr
   ===> mkdir sbin
   ===> chmod 711 sbin
   ===> cd sbin
   ===> touch ftpdns
   ===> chmod 711 ftpdns
   ===> chmod +t ftpdns
   ```

   If you do not configure the subdirectories, bin and usr/sbin, and their contents correctly, the FTP server will not be able to accept anonymous logins and message EZYFT731 will be displayed.

3. Create a dev subdirectory within the anonymous root. This is a required subdirectory. A null file is created in this directory and used during the open of syslog.

   The following example is for anonymous user GUEST:

   ```
   ===> cd /u/guest
   ===> mkdir dev
   ===> chmod 711 usr
   ```

   If you do not have the dev subdirectory, syslog might not open correctly. Messages such as EZA2830I will not be logged out correctly.

4. Set up the public directory structure. This is a required directory.

   This is the directory structure into which you place files that can be downloaded by the anonymous FTP user. It does not have to be named pub; it can be any name you choose. A general convention for anonymous FTP sites is to call it pub:

   ```
    ===> cd /u/guest
   ===> mkdir pub
   ===> cd pub
   ```

   If you want to structure the files you allow to be accessed, you can create multiple subdirectories underneath this directory.

   For simplicity, assume a single level directory, the pub directory. Into this directory you copy the files you want to allow the anonymous user to download:

```
===> cp /x/y/z/prodinfo1.txt prodinfo1.txt
===> cp /x/y/z/prodinfo2.txt prodinfo2.txt
===> cd ..
```

Make sure that the permission bits are set correctly by using the following shell command when executed in the /u/guest directory. This will set the permission bits of all files in the pub directory and its subdirectories to 755:

```
===> chmod -R 755 pub
```

If your system does not require an incoming or extract directory, the system is configured for anonymous FTP. An **ls -al** command of the pub directory should give the following results:

```
drwxr-xr-x   3 IBMUSER  SYS1  8192 May 13 21:15 .
drwxr-xr-x   6 IBMUSER  SYS1  8192 May 20 14:51 ..
-rwxr-xr-x   1 IBMUSER  SYS1  12 May 11 12:41 prodinfo1.txt
-rwxr-xr-x   1 IBMUSER  SYS1  12 May 11 12:41 prodinfo2.txt
```

5. Set up an incoming directory (optional).

   If you want anonymous users to be able to upload files to your FTP server, you need some additional setup. The objective is to allow an anonymous user to upload a file, but not to allow another anonymous user to download or even be aware of the existence of the file until after an administrative user has verified that the content of the file is acceptable. You do not want your FTP server site to become a store-and-forward site for files of questionable ethical content.

   Positioned at the /u/guest directory, a superuser issues the following shell command:

   ```
   ===> cd /u/guest
   ===> mkdir incoming
   ===> chmod 733 incoming
   ```

   It does not have to be named incoming; it can be any name you choose. A general convention for anonymous FTP sites is to call it incoming.

   The 733 permission bits means that a non-superuser cannot list the content of the incoming directory, but can write a file to it. Because the FTP server enforces a UMASK of 777 when an anonymous user logs in, these files will be written with permission bits 000, which means that they cannot be accessed by the anonymous user or by any other user except a superuser.

   An FTP client user can normally change the UMASK via a SITE UMASK command or the user can change the permission bits of files they own through a SITE CHMOD command.

   If you define ANONYMOUSLEVEL 3, you can use the ANONYMOUSHFSDIRMODE keyword to set the permission bits of any directory created by an anonymous user, and the ANONYMOUSHFSFILEMODE to set the permission bits of any file created by an anonymous user.

   If you do allow anonymous users to store files on your FTP server, you should ensure that the directory into which these files are stored is a separate z/OS UNIX file system that can fill up without impacting other work on your z/OS system. The best way to do that is to allocate the /u/guest/incoming directory in its own zSeries File System, HFS data set, or Network File System. If an anonymous user uploads large amounts of data to the incoming directory, only this separate z/OS UNIX file system will be filled up. Filling this separate z/OS UNIX file system prevents other anonymous users from storing new files on the server, but will not affect other functions on your system. At a minimum, you should make sure that the incoming directory is not located on the same physical device as your /tmp directory.

6. Set up the extract directory (optional).

If you need to make files available to certain anonymous users, but not to everyone, you can create a directory that cannot be listed, but files in it can be downloaded if the anonymous user knows the name of the file.

Positioned at the /u/guest directory, a superuser issues the following shell commands:

```
===> cd /u/guest
===> mkdir extract
===> chmod 711 extract
```

It does not have to be named extract; it can be any name you choose. A general convention for anonymous FTP sites is to call it extract.

A superuser can then copy files into this directory, ensure they have permissions of 755, inform the intended anonymous user of the file name, and that user can then log on as anonymous and retrieve the file.

An **ls -al** command at the /u/guest location should give the following result, if you created all four subdirectories:

```
drwxr-xr-x   6 IBMUSER  SYS1 8192 May 20 14:51 .
dr-xr-xr-x   6 IBMUSER  SYS1  0 Jun 10 15:43 ..
drwx--x--x   2 IBMUSER  SYS1  8192 May 11 12:44 bin
drwx--x--x   3 IBMUSER  SYS1  8192 May 11 13:39 extract
drwx-wx-wx   3 IBMUSER  SYS1  8192 May 25 09:35 incoming
drwxr-xr-x   3 IBMUSER  SYS1  8192 May 13 21:15 pub
```

Configure the welcome banner page, login, and directory message (optional)

The FTP server provides support to enable FTP administrators to provide useful information about the site to FTP users. The following FTP.DATA statements are available:

- BANNER
- LOGINMSG
- ANONYMOUSLOGINMSG
- MVSINFO
- ANONYMOUSMVSINFO
- HFSINFO
- ANONYMOUSHFSINFO

You can use the LOGINMSG statement in FTP.DATA to point to a set of messages displayed when a known user logs in to FTP. Similarly, ANONYMOUSLOGINMSG can point to a set of messages displayed when an anonymous user logs in to FTP.

You can use the MVSINFO statement to point to a set of messages displayed when a known user changes the working directory to a particular MVS data set path. Likewise, use the ANONYMOUSMVSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular MVS data set path.

You can use the HFSINFO statement to point to a set of messages displayed when a client changes the working directory to a particular z/OS UNIX directory. Likewise, use the ANONYMOUSHFSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular z/OS UNIX directory.

Using magic cookies to represent information

The content of all the informational messages may include a predefined set of magic cookies, which are substituted by the FTP server before the data is sent to the FTP client. The following magic cookies are supported:

- %T — Local time
- %C — Current working directory
- %E — The FTP server administrators e-mail address
- %R — Remote host name
- %L — Local host name
- %U — Username (logged in user)

If %R is used, a long delay in login processing might occur as the FTP server will issue a DNS query to resolve the remote host IP address. In order to use %E, the ADMINEMAILADDR keyword must be specified in the server FTP.DATA configuration file.

Configuring the FTP server to log session (user ID) activity

You can configure the FTP server to write log messages for trace activity related to individual sessions by coding the FTPLOGGING or ANONYMOUSFTPLOGGING statements in FTP.DATA. If you have configured syslogd for FTP, the log messages appear in syslog.

Table 35 shows the FTP log message written for various activities. You can identify an FTP log message by the ID=*sessionID* parameter in the message. Each login session is assigned a session ID that can be used to identify all log messages related to that session. For more information about EZYF*xxxx* messages, see *z/OS Communications Server: IP Messages Volume 3 (EZY)*.

Table 35. EZYFxxxx messages

FTP log message	Activity
EZYFS50I	A client connected to the FTP daemon.
EZYFS51I	A client connection to the FTP daemon failed.
EZYFS52I	An FTP session ended.
EZYFS54I	The server accepted the security mechanism. The connection with the client is now protected.
EZYFS55I	The server rejected the security mechanism. The connection with the client is not protected.
EZYFS56I	A client logged into the server.
EZYFS57I	A client login to the server failed.
EZYFS58I	The server denied the client access to an MVS data set.
EZYFS59I	The server denied the client access to a z/OS UNIX file.
EZYFS60I, EZYFS61I, EZYFS62I	The server successfully allocated an MVS data set.
EZYFS63I, EZYFS64I, EZYFS65I	The server could not allocate an MVS data set.

Table 35. EZYFxxxx messages (continued)

FTP log message	Activity
EZYFS67I	The server successfully allocated an MVS data set.
EZYFS68I, EZYFS69I	The server could not allocate a z/OS UNIX file.
EZYFS70I, EZYFS74I, EZYFS75I	The server deallocated an MVS data set.
EZYFS71I, EZYFS72I, EZYFS73I	The server detected an error while deallocating an MVS data set.
EZYFS77I	The server deallocated a z/OS UNIX file.
EZYFS78I, EZYFS79I	The server detected an error while deallocating a z/OS UNIX file.
EZYFS80I	The server sent a reply to the client after data transfer.
EZYFS81I	The server finished processing an MVS data set transfer.
EZYFS82I	The server finished processing a z/OS UNIX data set transfer.
EZYFS83I	The server stored a data set or file into its file system.
EZYFS84I	The server sent a data set or file to the client (or to a server in the case of a proxy transfer).
EZYFS85I	The server finished returning job output to the client.
EZYFS86I	The server assigned a confidence of success level to the completed data transfer.
EZYFS91I	The server submitted a job for the client.
EZYFS92I	The server returned a SQL report.
EZYFS95I	An abend occurred while the server was transferring data.

Configuring to send detailed login failure replies to an FTP client (optional)

The FTP server returns minimal information to the client when the PASS command fails. However, you can configure the FTP server to send additional information by coding ACCESSERRORMSGS TRUE in FTP.DATA. This directs the server to reply to the client with detailed login failure data. The reply might report server errors, such as failing function calls with diagnostic return codes. It might report user errors, such as an expired or incorrect password, an unknown user ID, or a revoked user ID. You should not code ACCESSERRORMSGS TRUE in FTP.DATA if you do not want to share this type of information with users logging in to FTP.

You can capture the same information in syslog by coding FTPLOGGING TRUE and ANONYMOUSFTPLOGGING TRUE in FTP.DATA. You can also turn on the DEBUG option called ACC to log the error messages in the syslog. For more information on coding FTP.DATA statements, see *z/OS Communications Server: IP Configuration Reference*.

Install the SQL query function (optional) and access the DB2 modules

To use FTP to do SQL queries, bind the DBRM called EZAFTPMQ to the plan used by FTP, and grant execution privileges for that plan to PUBLIC. (The name of the plan can be specified by the DB2PLAN keyword in FTP.DATA or the default is EZAFTPMQ.) This FTP facility only performs SELECT operations on the DB2 tables. It does not perform UPDATE, INSERT, or DELETE.

Note: If secondary authorization for SQL queries is required, the DSN3SATH sample exit shipped by DB2 must be modified. The exit will return the primary AUTHID for requests originating from the FTP server.

The following sample job is provided in the FTOEBIND member of the SEZAINST data set. It can be used to enable the FTP server and client to do SQL queries.

```
//FTPSETUP JOB FTPSETUP,
//            CLASS=A,
//            NOTIFY=&SYSUID
//*************************************************************
//*
//*   File name:                 tcpip.SEZAINST(FTOEBIND)
//*   SMP/E distribution name:   EZAFTPAB
//*
//*    Licensed Materials - Property of IBM
//*    This product contains "Restricted Materials of IBM"
//*    5647-A01 (C) Copyright IBM Corp.  1997, 2002
//*    All rights reserved.
//*    US Government Users Restricted Rights -
//*    Use, duplication or disclosure restricted by GSA ADP Schedule
//*    Contract with IBM Corp.
//*    See IBM Copyright Instructions.
//*
//*  This JCL binds the EZAFTPMQ DBRM to the specified
//*  DB2 subsystem and allows execution of the
//*  EZAFTPMQ plan by PUBLIC.
//*
//*  The FTP server and client use this plan. (See
//*  Usage note #7)
//*
//*
//*  Usage notes:
//*
//*    1.  You must execute this job from a user ID that has
//*        the authority to bind the EZAFTPMQ plan.
//*
//*    2.  Change the STEPLIB DD statement in the FTPBIND and
//*        FTPGRANT steps to reflect the DB2 DSNLOAD data set.
//*
//*    3.  Change the DB2 sybsystem name in the FTPBIND and
//*        FTPGRANT steps from SYSTEM(xxx) to the
//*        installation defined DB2 subsystem name.
//*
//*    4.  Change the library parameter in the FTPBIND step from
//*        TCPIP.SEZADBRM to the installation defined TCPIP
//*        SEZADBRM library.
//*
//*    5.  Change the plan name in the FTPGRANT step from
//*        DSNTIAYY to reflect the plan associated with the
//*        program DSNTIAD.
//*
```

```
//*    6.  Change the library parameter in the FTPGRANT step
//*        from xxxxxx.RUNLIB.LOAD to reflect the library
//*        where the DSNTIAD program resides.
//*
//*    7.  You can bind the DBRM to a plan name other than EZAFTPMQ
//*        by changing the plan specified in the FTPBIND and
//*        FTPGRANT steps.  If you do this, you must use the
//*        DB2PLAN keyword in FTP.DATA to change the plan name
//*        used by the FTP server and/or client to the plan name
//*        specified here.
//*
//*************************************************************

```

Accessing DB2 modules

The FTP server or client loads 3 DB2 modules into storage to perform an SQL query. These modules are:

- DSNALI
- DSNHLI2
- DSNTIAR

The modules are usually found in the DB2 load library with the suffix DSNLOAD. The DB2 administrator or system programmer should add the DSNLOAD library to the LINKLIST to ensure FTP has access to this library.

Another way to ensure access is to add the DSNLOAD library to the FTP STEPLIB. For the FTP server this means the JCL used to start the FTP server has a STEPLIB DD statement referring to the DSNLOAD library or, if the FTP daemon is started from the z/OS shell, the STEPLIB environment variable is set. For the FTP client, this means a TSO CLIST must allocate the DSNLOAD library as the STEPLIB.

If the FTP client is to be run from a batch job to perform SQL queries, the DSNLOAD library must be added to the STEPLIB DD statement for the batch job.

Usage notes:

To allow FTP access to multiple levels of DB2, link to the libraries that contain the lowest level of DB2 to be accessed.

FTP.DATA updates for SQL query function

To obtain FTP.DATA updates for the SQL query function, follow these steps:

1. Set the FTP.DATA DB2 statement to specify the name of the DB2 subsystem.
2. Set DB2PLAN to specify the DB2 plan to be used by the FTP server.
3. Set the SPREAD statement to specify whether SQL output is in spreadsheet format.
4. Set SQLCOL to specify the column headings of the output data.

Verifying the FTP server

If FTP is in the autolog list and the TCP/IP address space is restarted, FTP should start automatically. For other cases, it should be started manually. To do this, go to the MVS console and enter the following command:

```
S FTPD
```

Note: This command assumes the FTP procedure name is FTPD.

If the FTP server startup is complete, the following message should be seen on the MVS console:

```
EZY2702I Server-FTP: Initialization completed at 17:37:29 on  12/17/99.
```

If the message is not seen, a message explaining why FTP did not start up will appear in SYSLOG. Even if the above message is issued, it would be beneficial to inspect SYSLOG for warning messages issued during FTP initialization. EZY2700I displays the port FTP uses as the control port, the port it listens to for incoming connections from clients. In this example, FTP is listening to standard port 21.

The file syslog uses is defined in /etc/syslog.conf. The statement **daemon.info /tmp/daemon.log** directs SYSLOGD to save all the daemon messages in /tmp/daemon.log. Below is an example of output error messages.

```
EZYFT18I Using catalog '/usr/lib/nls/msg/C/ftpdmsg.cat' for FTP messages.
EZY2697I IBM FTP CS V1R10 21:04:56 on 04/17/08
EZY2640I Using dd:SYSFTPD=USER1.FTP.DATA for local site configuration parameters
EZYFT46E Error in dd:SYSFTPD file: line 4 near column 9.
EZY2636E SMFLOGN value not specified.
EZYFT46E Error in dd:SYSFTPD file: line 5 near column 8.
EZY2636E SMFREN value not specified.
EZYFT47I dd:SYSFTPD file, line 21: Ignoring keyword "EXTENSIONS REST_STREAM".
EZYFT47I dd:SYSFTPD file, line 29: Ignoring keyword "CTRLCONN".
EZYFT21I Using catalog '/usr/lib/nls/msg/C/ftpdrply.cat' for FTP replies.
EZYFT26I Using 7-bit conversion derived from 'ISO8859-1' and 'IBM-1047' for the control connection.
EZYFT33I Unable to open DDNAME 'SYSFTSX' for the data connection: EDC5129I No such file or directory.
EZYFT31I Using //'TPOUSER.STANDARD.TCPXLBIN' for FTP translation tables for the data connection.
EZYFT09I system information for VIC135: z/OS version 1 release 10 (2094)
EZY2700I Using port FTP control (21)
```

```
EZY2701I Inactivity time is 0
EZYFT57I FTP registering with WLM as group = ftpgroup host = VIC135
EZY2702I Server-FTP: Initialization completed at 21:05:57 on 04/17/08.
EZYFT41I Server-FTP: process id 16777255, server job name FTPD11
```

Verifying the FTP client

To verify that the FTP client works correctly, log onto TSO and issue the NETSTAT HOME command, or issue NETSTAT –h from the z/OS UNIX shell. These commands will show the interface addresses that are known to the system. Below is an example of the output from NETSTAT HOME:

```
MVS TCP/IP NETSTAT CS V1R9       TCPIP Name: TCPCS           14:22:17
Home address list:
LinkName:   OSAQDIO6L
  Address:  9.67.115.13
    Flags:  Primary
LinkName:   LSAMEH
  Address:  9.1.1.1
    Flags:
LinkName:   LOOPBACK
  Address:  127.0.0.1
    Flags:
Address:  fe80::9:6b00:671a:586
    Type:   Link_Local
    Flags:  Autoconfigured
IntfName:   V6SAMEH
  Address:  1::8
    Type:   Global
    Flags:
IntfName:   V6VIRT
Address:  2::55
    Type:   Global
    Flags:
IntfName:   LOOPBACK6
  Address:  3::1
    Type:   Global
    Flags:
  Address:  ::1
    Type:   Loopback
    Flags:
```

To invoke the FTP client, use any address shown on the NETSTAT HOME address list. The first example below shows how you could log in to the FTP server at 9.67.115.13 using a batch job (the output of the batch job is not shown). The second example shows logging in to the FTP server at 9.67.113.37 from the TSO environment.

```
//FTPBATCH JOB FTPUSER,
// USER=USER1,PASSWORD=TCPSUP
//BATCH  EXEC PGM=FTP
//OUTPUT  DD SYSOUT=*
//INPUT DD *
  9.67.115.13
  USER10 tcpusr
  SITE FILE=SEQ
  QUIT
//*

Using 'USER1.FTP.DATA' for local site configuration parameters.

 EZA1460I Command:
```

Verifying anonymous, banner, and other optional configuration information

Depending on your installation's choices for anonymous level, banner support chosen, exits, and so on, verification of support output will differ. To verify anonymous configuration at a particular installation, log in as anonymous and verify the behavior is as expected. For example, if EMAILADDRCHECK FAIL is specified in FTP.DATA, try to log in as anonymous using an incorrect e-mail address as password. To verify banner support, login and verify the banners are displayed as expected. Below is a sample of FTP.DATA and FTP client output for one such installation.

```
; BANNER STUFF
EMAILADDRCHECK FAIL
BANNER USER1.TEST1
ADMINEMAILADDR FTPADMIN@MYSYSTEM.COM
; ANONYMOUS STUFF
ANONYMOUSLEVEL 3
STARTDIRECTORY HFS
```

Verifying the FTP-JES interface (optional)

As with the other optional configuration information, FTP-JES support can best be verified by logging in and confirming the FTP.DATA parameters chosen. To verify JES support, a simple batch job can be created if the JESINTERFACELEVEL is set to the security requirements of an installation. Below is the batch job and FTP client output for JESINTERFACELEVEL 2.

```

Chapter 13. Trivial File Transfer Protocol

Trivial File Transfer Protocol (TFTP) is a UDP protocol used to transfer files. TFTP can read or write files from or to a remote server. On the z/OS system, TFTP is a server you can configure with the command line option during TFTP invocation. TFTP can also be started as a procedure.

TFTP is installed in the /usr/lpp/tcpip/sbin/ directory.

Recommendation: The TFTP server uses well-known port 69. The TFTP server has no user authentication. Any client that can connect to port 69 on the server has access to TFTP. If the TFTP server is started without a directory, it allows access to the entire file system. To restrict access to the file system, start the TFTP server with a list of directories.

The TFTP server preforks a child process to handle incoming requests when the concurrency limit is exceeded. Consequently, immediately after starting the TFTP server, two TFTP processes exist.

In case of a flood of concurrent TFTP commands, the TFTP server may fork additional processes. When the number of concurrent requests being processed drops below the concurrency limit, the number of TFTP processes is decreased back to two.

Starting TFTP from the command line

To start the TFTP server from the command line, type the tftpd command.

```
tftpd [-l] [-p port] [-t timeout] [-r maxretries] [-c concurrency_limit]
   [-s maxsegsize] [-f file] [-a archive directory [-a ...]]
   [-b IP address] [directory ...]
```

The following are parameters used for the tftpd command:

-l Logs all incoming read and write requests and associated information to the system log. Logged information includes the IP address of the requester, the file requested, and whether the request was successful.

-p port
Uses the specified port. The TFTP server usually receives requests on well-known port 69. You can specify the port in which requests are to be received.

-t timeout
Sets the packet timeout. The TFTP server usually waits 5 seconds before assuming a transmitted packet has been lost. You can specify a different timeout period in seconds.

-r maxretries
Sets the retry limit. The TFTP server usually limits the number of retransmissions it performs due to lost packet to 5. You can specify a different retry limit.

-c concurrency_limit
Sets the concurrency limit. The TFTP server spawns both threads and processes to handle incoming requests. You can specify the limit for the

number of threads that may be concurrently processing requests under a single process. When the limit is exceeded, a new process is spawned to handle requests. The default is 200 threads.

-s maxsegsize
Sets the maximum block size that can be negotiated by the TFTP block size option. The default is 8192.

-f file Specifies a cache file. You can specify a file containing information on files to be preloaded and cached for transmission. A cache file consists of one or more entries. For clarity, place each entry on a separate line. An entry has the form:

a | b <pathname>

where:

- *a* indicates that the specified file is cached in ASCII form. The file is preconverted to netascii format.
- *b* indicates that the specified file is cached in binary form, with no conversion.

Following are examples of cache file entries,

```
a  /usr/local/textfile
b  local/binaryfile
```

If a relative pathname to the file is specified, the TFTP server searches the specified directories for the file.

The cached version of a file is only used for requests requiring the specified format. For example, the binary cached version of a file is not used in satisfying a request for the file in netascii format. If a file is to be retrieved in both binary and ASCII formats, the user must specify that two copies of the file be cached with one in binary format, and the other in netascii format.

Caching is not dynamic. The cache files are read in when the TFTP server is started and are not updated, even if the file on disk is updated. To update or refresh the cache, the TFTP server must be recycled.

-a archive directory
Specifies an archive directory. The files in this directory and its subdirectories are treated as binary files for downloading. This option is useful on EBCDIC machines that act as file servers for ASCII clients. Multiple **-a** options can be specified; one directory per **-a** option. Directories must be specified as absolute path names. You can specify no more than 20 directories.

-b IP address
Uses the specified IP address. The TFTP server usually binds to INADDR_ANY or the IPv6 unspecified address, in6addr_any. You can specify the IP address on which requests are to be received. TFTP requests that come in on other IP addresses will not be accepted by this instance of TFTPD.

directory
Specifies an absolute path name for a directory. You may specify no more than 20 directories on the tftpd command line.

If the TFTP server is started without a list of directories, all mounted directories are considered active.

If a list of directories is specified, only those directories specified are active. That list is used as a search path for incoming requests specifying a relative path name for a file.

Activating a directory activates all of its subdirectories.

For a file to be readable by the TFTP server, the file must be in an active directory and have world ("other") read access enabled. For a file to be writable by the TFTP server, the file must already exist in an active directory and have world ("other") write access.

Starting TFTPD as a procedure

Before you begin: Obtain a copy of the sample procedure, shipped as SEZAINST(TFTPD), and store it in one of your PROCLIB concatenation data sets.

Perform the following step to start TFTPD as a procedure:

- Invoke the procedure using the system operator start command. Following is a copy of the sample, which shows how to start TFTPD as a procedure:

```
//TFTPSD   PROC
//*
//* Communications Server IP
//* SMP/E distribution name: EZATTFDP
//*
//*   5694-A01 5655-HAL (C) Copyright IBM Corp. 1997, 2004.
//*   Licensed Materials - Property of IBM
//*   This product contains "Restricted Materials of IBM"
//*   All rights reserved.
//*   US Government Users Restricted Rights -
//*   Use, duplication or disclosure restricted by
//*   GSA ADP Schedule Contract with IBM Corp.
//*   See IBM Copyright Instructions.
//*
//* Function: Trivial File Transfer Protocol Server start
//*
//* Please note:
//*
//* -a  Specify an archive directory.  TFTPD treats files in this
//*     directory and its subdirectories as binary files for uploads
//*     and downloads, regardless of how they were requested by the
//*     client.  Use this option on EBCDIC machines that act as file
//*     servers for ASCII clients.
//*
//*     You can specify up to 20 -a options, one directory per -a
//*     option.  You must specify directories as absolute pathnames.
//*
//* -c  the number of threads to use concurrently.  Make the number
//*     a some reasonable number like 20 and not the default, which
//*     is 200.
//*
//* -t  Set the packet timeout. The TFTP server usually waits 5 seconds
//*     before presuming that a transmitted packet has been lost. You can
//*     specify a different timeout period in seconds.
//*
//* -l  Log all incoming read and write requests and associated
//*     information to the system log. Logged information includes the IP
//*     address of the requestor, the file requested, and whether the
//*     request was successful.
//*
```

```
//* -p  Specify the port. The TFTP server usually receives requests on
//*     well-known port 69. You can specify the port in which requests
//*     are to be received.
//*
//* -r  Set the retry limit. The TFTP server usually limits the number
//*     of retransmissions it performs due to lost packet to 5. You
//*     can specify a different retry limit.
//*
//* -s  Set the maximum block size that can be negotiated by the
//*     TFTP block size option. The default is 8192.
//*
//* -f  Secify a cache file. You can specify a file containing
//*     information on files to be preloaded and cached for transmission.
//*     A cache file consists of one or more entries. For clarity, place
//*     each entry on a separate line. See the IP Configuration Guide for
//*     details on this option.
//*
//* -b  Specify IP address. The TFTP server usually binds to in6addr_any
//*     or inaddr_any. You can specify the IP address on which requests
//*     are to be received.
//*     TFTP requests that come in on other IP addresses will not be
//*     accepted by this instance of TFTPD.
//*
//TFTP     EXEC PGM=TFTPD,REGION=0K,TIME=NOLIMIT,
//             PARM='POSIX(ON),ALL31(ON),TRAP(OFF)/
//             -c 20 -t 300'
//*STEPLIB DD DISP=SHR,DSN=TCP.SEZALOAD,
//*           VOL=SER=,UNIT=
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//SYSIN    DD DUMMY
//SYSERR   DD SYSOUT=*
//SYSOUT   DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//CEEDUMP  DD SYSOUT=*
//SYSABEND DD SYSOUT=*
//         PEND
```

You know that TFTPD is starting when the following message appears on the console:

```
EZZ7001I starting
```

Stopping the TFTP server

To terminate the TFTP server, send a SIGTERM signal using the UNIX kill command to the oldest existing TFTP process. This is the process with a parent process ID of 1. Termination of this process will cause all of its children to terminate.

If multiple instances of the TFTP server are running, to determine the pid and its corresponding start options for each instance of the TFTP server, invoke the following UNIX command:

```
ps -o pid,ppid,args
```

Terminate an instance of the TFTP server using the UNIX kill command with the appropriate pid.

Chapter 14. The resolver

The resolver acts on behalf of programs as a client to perform the following functions:

- Access name servers to provide name-to-address or address-to-name resolution
- Allocate and read the TCPIP.DATA file
- Establish TCP/IP stack affinity for certain socket APIs
- Provide protocol and services information

To resolve the query for the requesting program, the resolver uses information that it obtains from the following sources:

- Available name servers
- The DNS response information that has been cached locally (when system-wide caching is enabled)
- Local definitions, such as /etc/hosts, /etc/ipnodes, HOSTS.SITEINFO, HOSTS.ADDRINFO, and ETC.IPNODES

The TCPIP.DATA statements control how (and if) the resolver uses name servers. For detailed information about TCPIP.DATA configuration statements, see *z/OS Communications Server: IP Configuration Reference*.

Requirement: The resolver address space must be started before any application or TCP/IP stack resolver calls can occur.

Resolver API calls

Application programs invoke resolver functions using resolver API calls such as gethostbyname() and getaddrinfo(). The z/OS resolver supports a number of IBM APIs, although not all APIs support all possible resolver API calls. The z/OS resolver is invoked by the following resolver API calls:

- Application programs using the gethostbyaddr() and gethostbyname() resolver calls from the following IBM APIs:
  - z/OS XL C/C++ Run-time Library functions
  - z/OS UNIX assembler callable services
  - z/OS Communications Server C/C++ API
  - z/OS Communications Server Callable and Macro API
  - z/OS Communications Server REXX API
  - z/OS Communications Server PASCAL API
- Application programs using the getaddrinfo(), getnameinfo(), and freeaddrinfo() resolver calls from the following IBM APIs:
  - z/OS XL C/C++ Run-time Library functions
  - z/OS UNIX assembler callable services
  - z/OS Communications Server Callable and Macro API
  - z/OS Communications Server REXX API
- Application programs using the sethostent(), gethostent(), and endhostent() resolver calls from the following IBM APIs:
  - z/OS XL C/C++ Run-time Library functions

– z/OS Communications Server C/C++ API

The z/OS Communications Server SMTP server, BIND 9 DNS and DNS V9 utilities (dig, nslookup, and nsupdate) provide their own unique resolver services. When their resolver initializes, it uses the appropriate TCPIP.DATA information, including information from the global TCPIP.DATA file, if one is specified. For more information, see "The resolver and the global TCPIP.DATA file" on page 735.

Restrictions for the SMTP resolver:

- The SMTP resolver does not support the EDNS0 standards.
- The SMTP resolver uses only the first value of the SEARCH TCPIP.DATA statement when resolving host names.
- The SMTP resolver does not support IPv6 addresses on a NAMESERVER or NSINTERADDR statement.
- The SMTP resolver does not support caching.
- The SMTP resolver cannot use the name server responsiveness monitor function.

Starting the resolver

There are two ways that the resolver can be started:

- Use z/OS UNIX to start the resolver

  The resolver is started when z/OS UNIX is initialized. This method of starting the resolver ensures that applications that require resolver services are not started before the resolver starts. If you use z/OS UNIX to start the resolver, you can use the default resolver settings (see "The default resolver settings" on page 733), or you can optionally create a start procedure and define the address space (see "Customizing the resolver" on page 733).
- Use automation tools to start the resolver

  The resolver is started by issuing the MVS START operator command. You must customize the resolver to use this starting method; see "Customizing the resolver" on page 733 for more information. If you use this method of starting the resolver, then it is possible that an application that needs resolver services (such as INETD) is started before the resolver address space is initialized. In this case, you might need to remove the starting of INETD from the z/OS UNIX /etc/rc file and start INETD with automation after the resolver has initialized.

If you are using z/OS UNIX to start the resolver, then the following actions occur when z/OS UNIX is initialized:

- z/OS UNIX uses SUB=MSTR to start the resolver (the resolver does not require JES); for information about SUB=MSTR, see *z/OS MVS JCL Reference*
- z/OS UNIX issues an informational message that contains the name of the procedure that it is starting:

  `BPXF224I  THE RESOLVER_PROC, procname, IS BEING STARTED`

  Rule: If the RESOLVER_PROC statement is not present or is specified with the procedure name DEFAULT, the *procname* value is RESOLVER, even though a start procedure was not used. For more information about the RESOLVER_PROC statement, see *z/OS MVS Initialization and Tuning Reference*.
- If the start procedure is not found or if it contains a JCL error, then error messages for the z/OS START command are issued.
- If the address space cannot be started, z/OS UNIX initialization continues.

The default resolver settings

You do not have to perform any customization steps to use the resolver. The default resolver starts automatically when z/OS UNIX is initialized; you cannot use automation tools to start the resolver unless you customize it. z/OS UNIX starts a resolver address space, which uses the assigned name RESOLVER, using the system default procedure IEESYSAS. The resolver uses the applicable native MVS or z/OS UNIX search order to find TCPIP.DATA statements, without a GLOBALTCPIPDATA or a DEFAULTTCPIPDATA specification.

The following resolver functions are active by default:

- System-wide caching, using the default maximum cache size and the default maximum time-to-live (TTL) value (see "Resolver caching" on page 744)
- Responsiveness monitoring of Domain Name System (DNS) servers, using the default threshold setting (see "Monitoring the responsiveness of Domain Name System name servers" on page 752)
- Extension Mechanisms for DNS standards (see "Extension Mechanisms for DNS standards and the resolver" on page 758)

Customizing the resolver

You can customize resolver functions, or enable or disable certain resolver functions, by using resolver configuration statements in a resolver setup file. For example, you can control which resolver statements are used by all applications or TCP/IP stacks for name resolution by specifying the GLOBALTCPIPDATA statement (see "The resolver setup file" for more information about the statements that are supported by the resolver setup file). If you want to customize resolver functions, you must create a resolver setup file and define the resolver address space.

The resolver setup file

The resolver setup file is an optional file (either an MVS data set or a z/OS UNIX file) that contains resolver configuration statements that you can use to customize resolver functions.

If the resolver setup file is an MVS data set, the file must have the following characteristics:

- Use sequential (PS) or partitioned (PO) organization
- Use fixed (F) or fixed block (FB) format
- Contain a logical record length (LRECL) that is 80 - 256 bytes in length
- Contain any valid blocksize (BLKSIZE) for a fixed block
- If you think you will need to modify the setup file, use a member of an MVS partitioned data set

If the resolver setup file is a z/OS UNIX file, the file can be located in any directory. The maximum line length that is supported is 256 characters. If a line is longer than 256 characters, then the line is truncated to 256 characters before it is processed.

If you do not use a resolver setup file, the resolver uses the applicable native MVS or z/OS UNIX search order without any additional information and performs the following functions using the default settings:
