- Enables system-wide caching (using the default maximum cache size and the default time-to-live [TTL] value)
- Monitors Domain Name System (DNS) name server responsiveness (using the default threshold setting)

The following statements are supported by the resolver setup file:

- Comments (; or #)
- CACHE

  Enables system-wide caching of DNS queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. See "Resolver caching" on page 744 for more information about caching.
- CACHESIZE

  Defines the amount of storage that can be allocated by the resolver to manage cached records.
- COMMONSEARCH

  Indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries.
- DEFAULTIPNODES

  Identifies the default local host file.
- DEFAULTTCPIPDATA

  Identifies a default TCPIP.DATA file. The file that is specified by the DEFAULTTCPIPDATA statement becomes the last file that is searched by the resolver for resolver configuration information. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA. See "The resolver and the global TCPIP.DATA file" on page 735 for more information.
- GLOBALIPNODES

  Identifies a local host file that contains hard-coded IP addresses and host names that can be used globally.
- GLOBALTCPIPDATA

  Identifies the file that is the first file that is searched by the resolver for resolver configuration information. Parameters that you specify in the file that is identified by the GLOBALTCPIPDATA statement become the global settings for the entire MVS image and for all TCP/IP stacks. See "The resolver and the global TCPIP.DATA file" on page 735 for more information.
- MAXTTL

  Defines the amount of time that the resolver can use resource information that it receives from a name server.
- NOCACHE

  Disables system-wide caching of DNS response data. If you do not specify this statement, system-wide caching is enabled by default.
- NOCOMMONSEARCH

  Indicates that a different search order for local host files is used for IPv4 and IPv6 name queries.
- UNRESPONSIVETHRESHOLD

  The threshold value that determines when the resolver declares a DNS name server to be unresponsive. The threshold represents a percentage of resolver queries within a sliding 5-minute interval. If the percentage of query failures to a name server is greater than or equal to this threshold value, the resolver

considers the name server to be unresponsive. See "Monitoring the responsiveness of Domain Name System name servers" on page 752 for more information.

For more information about resolver setup statements, see *z/OS Communications Server: IP Configuration Reference*.

The resolver and the global TCPIP.DATA file

The optional GLOBALTCPIPDATA statement identifies a global TCPIP.DATA file, in which you can specify global settings. If you specify a global TCPIP.DATA file, you can control which resolver statements are used for name resolution and you do not need to merge resolver statements from multiple files. TCPIP.DATA statements in this file are the first that are searched, regardless of which socket API library you are using.

If you use a global TCPIP.DATA file, you can specify the following resolver statements, or you can use the default values. These statements are required by the resolver to process queries.

- DomainOrigin or Domain
- NSInterAddr or NameServer
- NSPortAddr
- ResolveVia
- ResolverTimeOut
- ResolverUDPRetries
- Search
- SortList

If you specify any of these statements in the global TCPIP.DATA file, those settings become the global settings for this MVS image and for all users of resolver services, across the entire system. If you do not specify one of these statements in the global TCPIP.DATA file, the resolver uses the default values. The search continues beyond the global TCPIP.DATA file, but any of these resolver statements that are specified in files that are located lower in the search order are ignored.

If you do not identify a global TCPIP.DATA file, then the resolver uses the regular search order until it finds a local TCPIP.DATA file. If you do not specify one of these statements in this local TCPIP.DATA file, the resolver uses the default values. The setting that the resolver uses applies only to this application, not to all users of resolver services. In any case, the search order depends on whether the native MVS or z/OS UNIX application environment is in use. The search order for the local hosts table (HOSTS.*xxxx*INFO, ETC.IPNODES, /etc/hosts, or /etc/ipnodes) remains the same.

You can specify other statements in the global TCPIP.DATA file (for information about configuration statements in TCPIP.DATA, see *z/OS Communications Server: IP Configuration Reference*). There are some statements, like TRACE RESOLVER, for which you likely do not want a global setting. If you do not specify one or more of these other statements in the global file, the resolver uses the regular search order until it finds a local TCPIP.DATA file. If you do not specify these other statements in the local TCPIP.DATA file, the resolver uses the default values.You can implement these global settings gradually, in case there are private TCPIP.DATA files that are in use on your system about which you are unaware.

You can identify a global TCPIP.DATA file in a CINET (common INET) environment. You specify in the global TCPIP.DATA file all the resolver statements for which you want to set a global value, and the resolver conducts its searches in the same way as in a non-CINET environment. However, if you do use a global TCPIP.DATA file in a CINET environment, all the resolver statements must be usable by all stacks. For example, the IP addresses that are specified by the NameServer statement must be accessible from all stacks. If the IP addresses are not accessible, then you should not use a global TCPIP.DATA file; use multiple TCPIP.DATA data sets instead.

You can use the DEFAULTTCPIPDATA setup statement to specify a TCPIP.DATA file as the last TCPIP.DATA file that is searched, instead of TCPIP.TCPIP.DATA. You can specify any file as the default file.

Steps for creating a resolver setup file

The SETUP DD statement in the start procedure for the resolver points to the resolver setup file. The setup file can be an MVS data set or a z/OS UNIX file.

Perform the following steps to create a resolver setup file:

1. Use an MVS data set or a z/OS UNIX file for your setup file, depending on your requirements.
2. Customize the search order that the resolver uses to resolve queries by specifying one or more of the following statements:
   - Specify the GLOBALTCPIPDATA statement to identify the global TCPIP.DATA file that becomes the first file that is searched. Parameters that you specify in this file become the global settings for the entire MVS image and for all users of resolver services, across the entire system.
   - Specify the DEFAULTTCPIPDATA statement to identify a default TCPIP.DATA file. The file specified by the DEFAULTTCPIPDATA statement becomes the last file that can be searched. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA.
   - Specify either the GLOBALIPNODES statement or the DEFAULTIPNODES statement to identify a local host file. The GLOBALIPNODES statement identifies a local host file that contains hard-coded IP addresses and host names that can be used globally. The DEFAULTIPNODES statement identifies the default local host file.
   - Specify the COMMONSEARCH statement or the NOCOMMONSEARCH statement. The COMMONSEARCH statement indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries, and for MVS and UNIX searches. The NOCOMMONSEARCH statement indicates that different search orders for local host files are used for IPv4 and IPv6 name queries, and for MVS and UNIX searches. For more information, see “Search orders used in the z/OS UNIX environment” on page 762 and “Search orders used in the native MVS environment” on page 769.
   - Specify the CACHE statement or the NOCACHE statement. The CACHE statement enables system-wide caching of Domain Name System (DNS) queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. See “Resolver caching” on page 744 for more information about caching. The NOCACHE statement indicates that you do not want to cache DNS response data.
     – If you specified the CACHE statement, specify the CACHESIZE statement to define the amount of storage that can be allocated by the resolver to

manage cached records. If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored.

- Specify the MAXTTL statement to define the amount of time that the resolver can use resource information that it receives from a name server. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored.

- Specify the UNRESPONSIVETHRESHOLD statement to define the threshold value that is used by the resolver to declare that a DNS name server is unresponsive. The monitoring of unresponsive name servers is enabled by default, but you can explicitly enable it using this statement. If you do not want to be notified of unresponsive name servers, you can use this statement to disable resolver monitoring of name server responsiveness to resolver queries.

The following example setup file is located in SEZAINST as member EZBRECNF (alias RESSETUP):

```
;
;   IBM Communications Server for z/OS
;   SMP/E distribution name: EZBRECNF
;
;   5694-A01 Copyright IBM Corp. 2002, 2010,
;   Licensed Materials - Property of IBM
;
;   Function: Sample Resolver setup file
;
;
;  The following statement defines the final search location for
;   TCPIP.DATA statements. It will replace TCPIP.TCPIP.DATA
;  It may be an MVS data set or HFS file.
;
DEFAULTTCPIPDATA('TCPIP.TCPIP.DATA')
;
#  The following statement defines the first search location for
#   TCPIP.DATA statements. It may be an MVS data set or HFS file.

```

The resolver address space

The resolver address space must be started before any application or TCP/IP stack resolver calls can occur. When the address space starts, it reads an optional resolver setup data set that is pointed to by the SETUP DD card in the resolver JCL procedure. To use the functions that are provided by the GLOBALTCPIPDATA statement and other statements, you must define a resolver address space. You use a BPXPRMxx statement, RESOLVER_PROC, to specify the procedure name, if any, to be used by z/OS UNIX to start the resolver address space. If the RESOLVER_PROC statement is not in the BPXPRMxx parmlib member or is specified with the procedure name DEFAULT, z/OS UNIX starts a resolver address space that has the assigned name RESOLVER.

Steps for defining the resolver address space

You must define the resolver address space to use the functions provided by the GLOBALTCPIPDATA statement and other statements.

Before you begin: You must have already created a resolver setup file, if you are using one.

Perform the following steps to define the resolver address space:

1. Create a start procedure.

   The start procedure has the following requirements:

- The procedure must not contain any DD cards that specify SYSOUT=*.
- The procedure must reside in a data set that is specified by the IEFPDSI DD card specification of the MSTJCLxx PARMLIB member. If the procedure is not in this location, the resolver will not start. For information about MSTJCL, see *z/OS MVS Initialization and Tuning Reference*.

To process its definitions, the resolver might need to allocate data sets or files. For those definitions, such as GLOBALTCPIPDATA, DEFAULTTCPIPDATA, /etc/hosts, HOSTS.SITEINFO, and HOSTS.ADDRINFO, allocation messages appear in the JES joblog. For long-running applications that heavily use resolver services, such as IBM Tivoli® NetView for z/OS, consider using a started job that specifies MSGLEVEL=(1,0) to eliminate all allocation messages. This specification could also eliminate allocation messages that might be useful for problem analysis. For information about started jobs and the MSGLEVEL parameter, see *z/OS MVS JCL Reference*.

See "the example resolver startup procedure" on page 740.

2. In the SETUP DD JCL statement, specify the location of the setup file.
3. Grant read access (using RACF or other security program) to the following files for the user ID that is assigned to the resolver address space:
   - SYS1.PARMLIB
   - The resolver setup file
   - The file specified by the GLOBALTCPIPDATA statement, if you are using one
   - The file specified by the DEFAULTTCPIPDATA statement, if you are using one
   - The file specified by the GLOBALIPNODES statement, if you are using one
   - The file specified by the DEFAULTIPNODES statement, if you are using one
4. If you are using any of the following files, grant read access to the files for the user IDs or jobs that are using TCP/IP facilities:
   - The file specified by the GLOBALTCPIPDATA statement
   - The file specified by the DEFAULTTCPIPDATA statement
   - The file specified by the GLOBALIPNODES statement
   - The file specified by the DEFAULTIPNODES statement
   - /etc/hosts
   - /etc/ipnodes
   - /etc/services
   - HOSTS.SITEINFO
   - HOSTS.ADDRINFO
   - ETC.IPNODES

   If you do not specify the correct permission bit settings for a file to allow that file to be read, error message IEC141I 013-C0 is issued. Other error messages might also be issued that indicate that a file cannot be read.
5. If the resolver setup file is a z/OS UNIX file, configure an OMVS segment or use the default OMVS segment for the resolver user ID and for any user IDs or jobs that are using TCP/IP facilities.

   If you do not define an OMVS segment or if you grant insufficient authorization to user IDs or jobs to read a data set, then RACF message ICH408I is issued if a file cannot be accessed. Other error messages might also be issued to indicate that a file cannot be accessed.

6. (Optional) If you want z/OS UNIX to start the resolver (rather than using automation to start the resolver with the MVS START operator command), specify the resolver start procedure name as the *procname* value in the RESOLVER_PROC(*procname*) statement of the BPXPRMxx parmlib member. See "Starting the resolver" on page 732 for information about starting the resolver.

   Guideline: The default procedure name is RESOLVER. If you want to specify a procedure that uses the name RESOLVER, then specify RESOLVER for the *procname* value.

   If you do not specify the RESOLVER_PROC statement or if you specify DEFAULT, then z/OS UNIX starts a resolver address space using the system default procedure IEESYSAS with the assigned name RESOLVER. If you do not want to use z/OS UNIX to start the resolver, you must use the MVS START command to start the resolver address space.

Example: The following example resolver start procedure is located in SEZAINST as member EZBREPRC (alias RESOPROC).

```
//RESOLVER PROC PARMS='CTRACE(CTIRES00)'
//*
//*   IBM Communications Server for z/OS
//*   SMP/E distribution name: EZBREPRC
//*
//*   5694-A01 Copyright IBM Corp. 2001, 2010.
//*   Licensed Materials - Property of IBM
//*
//*   Function: Start Resolver
//*
//EZBREINI EXEC PGM=EZBREINI,REGION=0M,TIME=1440,PARM=&PARMS
//*
//*   When the Resolver is started by UNIX System Services it is
//*     started with SUB=MSTR.
//*   This means that JES services are not available to the Resolver
//*     address space. Therefore, no DD cards with SYSOUT can be used.
//*     See the MVS JCL Reference manual for SUB=MSTR considerations in
//*     section "Running a Started Task Under the Master Subsystem".
//*   This Resolver start procedure will need to reside in a data
//*     set that is specified by the MSTJCLxx PARMLIB member's
//*     IEFPDSI DD card specification. If not, the procedure will
//*     not be found and the Resolver will not start.
//*     See the MVS Initialization and Tuning Reference manual for
//*     MSTJCL considerations in section "Understanding the Master
//*     Scheduler Job Control Language"
//*
//*   SETUP contains Resolver setup parameters.
//*     See the chapter "The resolver" in the
//*     IP Configuration Guide for more information. A sample of
//*     Resolver setup parameters is included in member RESSETUP
//*     of the SEZAINST data set.
//*
//*SETUP   DD   DSN=TCPIP.TCPPARMS(SETUPRES),DISP=SHR,FREE=CLOSE
//*SETUP   DD   DSN=TCPIP.SETUP.RESOLVER,DISP=SHR,FREE=CLOSE
//*SETUP   DD   PATH='/etc/setup.resolver',PATHOPTS=(ORDONLY)
```

Managing the resolver address space

The resolver start procedure name is used with the following MVS system commands to manage the resolver address space:

- Start (S)
- Stop (P)

  You should stop and restart the resolver only when a new level of the resolver code has been installed.
- Force
- Modify (F)

  Use the MODIFY command to dynamically change resolver setup statements, to update the use of TCPIP.DATA statements, or to update the use of local host and services tables. Dynamic changes are not supported by the resolver that is provided by the SMTP server, BIND 9 DNS, and DNS V9 utilities.

  You can also use the MODIFY command to delete the information that the resolver has acquired about name server capabilities.

  You can use the MODIFY FLUSH command to delete all the resolver cache data.

See *z/OS Communications Server: IP System Administrator's Commands* for more information about these commands.

You can use the following MVS system commands to control and display the status of the resolver CTRACE facilities:

- Trace CT
- Display Trace

See *z/OS Communications Server: IP Diagnosis Guide* for information about using CTRACE.

Steps for manually restarting the resolver

If the resolver has stopped for any reason, perform one of the following steps to restart the resolver:

- If you have not customized the resolver (you have not created a start procedure and you have not defined the address space), then issue the following system operator command:

  ```
  START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
  ```
- If you have customized the resolver, issue one of the following system operator commands, where *procname* is the name of the PROCLIB member that you created:

  ```
  START procname,REUSASID=YES
  START procname,SUB=MSTR,REUSASID=YES
  ```

Rule: When you start the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough times and you do not specify REUSASID=YES then when you restart the resolver, all available ASIDs might be exhausted, which would prevent the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information on tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in *z/OS MVS Initialization and Tuning Reference*.

Steps for applying an interim fix to the resolver

To apply IBM-supplied interim fixes to the resolver, you do not need to stop and restart the TCPIP started task or any application programs. However, for the short duration of time that the resolver is not running, all resolver requests will fail.

Perform the following steps to apply an interim fix to the resolver:

1. Use SMP/E to apply the interim fix.
2. If LLA (library lookaside) is running, refresh it by issuing the following operator command:

   ```
   MODIFY LLA,REFRESH
   ```
3. Stop the resolver by performing one of the following steps:
   - If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

     ```
     STOP RESOLVER
     ```
   - If you have customized the resolver, issue the following system operator command, where *procname* is the name of the PROCLIB member that you created:

     ```
     STOP procname
     ```
4. Restart the resolver by performing one of the following steps:
   - If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

     ```
     START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
     ```
   - If you have customized the resolver, issue one of the following system operator commands, where *procname* is the name of the PROCLIB member that you created:

     ```
     START procname,REUSASID=YES
     START procname,SUB=MSTR,REUSASID=YES
     ```

     Rule: When you manually stop and then restart the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough times and you do not specify REUSASID=YES then when you restart the resolver, all available ASIDs might be exhausted, which would prevent the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information on tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in *z/OS MVS Initialization and Tuning Reference*.

IPv6 name servers and the resolver

The z/OS resolver can communicate to a Domain Name System (DNS) name server using either IPv4 or IPv6 communications. When the resolver is operating on an IPv6-capable system, the resolver opens an IPv6 socket to connect to the target DNS name server, regardless of the IP address family type, and relies on TCP/IP stack processing of IPv4-mapped IPv6 addresses to provide the proper communication with the name server. When the resolver is operating on an IPv4-only system, any IPv6 address specified as a target name server is ignored.

The list of name servers to be searched, as defined using the NSINTERADDR or NAMESERVER configuration statements in the TCPIP.DATA file, is stored in the res_state control block structure. Depending on the API used, applications can obtain the res_state control block, and can examine or even modify the contents of

the res_state list of name servers (nsaddr_list). The nsaddr_list structure is not designed to accommodate IPv6 addresses, and changing the structure to accommodate IPv6 addresses would adversely affect existing applications. Therefore, resolver does not save IPv6 addresses into the nsaddr_list array, and returns only the IPv4 addresses coded on the NSINTERADDR or NAMESERVER configuration statements. If only IPv6 addresses are specified for name server addresses, the nsaddr_list array returns as an empty list in res_state. If your application examines the contents of the res_state control block, in particular the nsaddr_list information, and requires that at least one name server IP address be present in the list, you need to specify at least one IPv4 address on a NSINTERADDR or NAMESERVER statement in the TCPIP.DATA file used by the application. Although nsaddr_list does not reflect the IPv6 addresses specified in the TCPIP.DATA file, resolver maintains the full list internally and uses the entire list for searching and caching purposes, unless the application modifies nsaddr_list for its own purposes.

The following z/OS functions do not use the resolver's ability to communicate to a name server using IPv6:

- The TSO DIG and TSO NSLOOKUP commands do not support specification of an IPv6 address as the target server IP address, either explicitly on the command or as an entry in the TCPIP.DATA file.
- SMTP uses the resolver only to obtain TCPIP.DATA configuration information as stored in res_state, and then uses its own customized resolver for communicating with a name server. Because res_state cannot accommodate IPv6 addresses, SMTP does not recognize any IPv6 name server addresses. If your system uses an SMTP server, you must specify at least one NSINTERADDR or NAMESERVER statement with an IPv4 address.

If you choose to use IPv6 name servers, ensure that the setting for the MAXSOCKETS parameter on the BPXPRMxx AF_INET6 NETWORK statement is sufficiently large enough to include the number of IPv6 sockets being opened by resolver. Use the following rough calculations to determine whether the MAXSOCKETS value is large enough:

1. Determine how many concurrent resolver calls typically occur on your system. Each resolver call that involves communication with a DNS name server opens 1 or 2 sockets depending on the actual resolver API being used.
2. Determine the largest number of IPv6 sockets you have open on your system at any one point in time.
3. Add (number of concurrent resolver calls * 2) and the largest number of IPv6 sockets together. Compare this number against the setting of MAXSOCKETS on the appropriate BPXPRMxx AF_INET6 NETWORK statement.
   - If the MAXSOCKETS setting is the larger value, then the setting is acceptable.
   - If the MAXSOCKETS setting is the lesser value, update the MAXSOCKETS setting to the larger number.

Resolver functions

To use the resolver functions efficiently in your environment, you need to be familiar with the following resolver functions that are active, by default, when the resolver is started:

- Resolver caching
- Monitoring responsiveness of Domain Name System name servers

- Extension Mechanisms for DNS standards

Resolver caching

In the context of resolvers, *caching* is defined as saving and storing information from resolved DNS queries so that the information can be reused. A *cache* is the area of memory where the information is kept. The primary advantage of caching is the improved performance that is obtained by the elimination of repetitive queries to the name servers.

For example, in the configuration shown in Figure 77, a local caching-only DNS name server is defined to provide some level of resource caching.

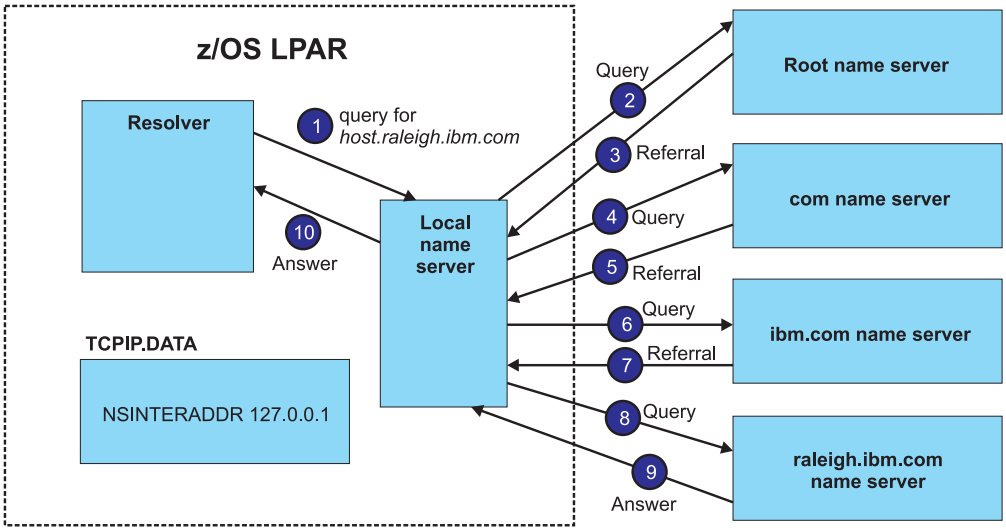

Figure 77. Local caching-only name server example

In the caching-only name server model depicted in Figure 77, when a request for host.raleigh.ibm.com is received, the resolver contacts the local name server (see arrow 1). The local name server then must perform standard name-server processing to locate the resource, which might include contacting one or more name servers (see arrows 2 through 9). When the name server that can provide an authoritative response for the queried host name is found and the response is returned to the local name server, the local name server caches the information and forwards it back to the resolver (arrow 10).

However, in the caching-only name server model depicted in Figure 77, subsequent requests to the resolver for information about host.raleigh.ibm.com still require that a DNS query be created and forwarded to the local name server to obtain the cached results. This DNS query can be eliminated if the resolver itself caches the information, as shown in Figure 78 on page 745.

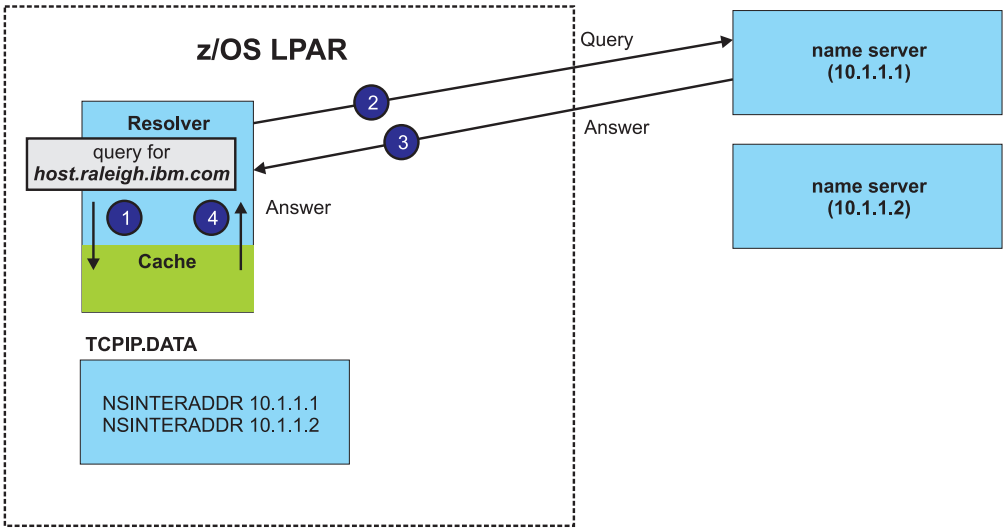

Figure 78. Resolver caching example

In the resolver caching model, when the initial query of the resolver cache does not return any host name information, the DNS query is sent to the network name server, which might or might not already have information cached about host.raleigh.ibm.com. When the response is received, the information is cached by the resolver, and subsequent requests for host.raleigh.ibm.com can be satisfied without a DNS query.

Resolver caching is advantageous for the following reasons:

- You do not need to take any steps to enable resolver caching; it is automatically enabled. As shown in Figure 77 on page 744 and in Figure 78, this eliminates the need to manually configure a local name server to cache the DNS responses.
- The cached information can be used by all applications that are running in the z/OS logical partition (LPAR), which provides the performance benefits of caching across the entire system for the cost of one DNS query.
- Resolver caching provides high performance because it reduces the network traffic to name servers.
- The resolver automatically regulates your storage use.

If you want to manually configure a caching-only name server, see "Configuring a caching-only name server" on page 802.

If you have been using a caching-only name server and you want to use resolver caching, see "Migrating from a local caching-only name server to resolver caching" on page 751.

You can disable resolver caching for selected applications; for more information, see "Steps for disabling caching for selected applications" on page 749.

Information that is cached by the resolver

Table 36 on page 746 shows the application programming interfaces (APIs) that use resolver caching.

Table 36. APIs that use resolver caching

API	Usage
getaddrinfo()	Resolves host name to one or more IP addresses. Supports both IPv4 and IPv6 addresses.
gethostbyaddr()	Resolves an IP address to a host name. Supports only IPv4 addresses.
gethostbyname()	Resolves a host name to one or more IP addresses. Supports only IPv4 addresses.
getnameinfo()	Resolves an IP address to a host name. Supports both IPv4 and IPv6 addresses.

The resolver caches the following DNS response information generated by the APIs in Table 36:

- Forward lookup information (IP addresses as A or AAAA records)

  Forward lookups are host-name-to-IP-address resolution requests. This includes IPv4 (A records) and IPv6 (AAAA records) addressing records from getaddrinfo() and gethostbyname() API calls.
- Reverse lookup information (domain name pointers as PTR records)

  Reverse lookups are IP-address-to-host-name resolution requests. This includes records from getnameinfo() and gethostbyaddr() API calls.
- Negative caching (NX) information

  Negative caching is the storage of the knowledge that a record does not exist, or that a request for a specific resource cannot or does not give an answer. The negative cache represents the received NXDOMAIN (nonexistent domain) responses from the server. The negative cache also represents the received NOERROR responses that did not include answer records of the requested type, such as a request for IPv6 addresses when the resource has only IPv4 addresses defined. Negative cache entries represent resources that are known to not exist and they include both reverse and forward entries.

There is an upper limit on the amount of storage that can be used for negative caching information. The upper limit is 20 percent of the maximum amount of cache storage that the resolver is permitted to use. The resolver does not set aside this amount of storage for exclusive use by negative cache entries; rather, the resolver never exceeds this amount of storage to hold negative cache entries. When the upper limit is reached, no subsequent negative cache entries are saved until some existing entries are deleted and the negative cache entry storage use drops below the 20 percent upper limit. For information about setting the maximum amount of cache storage available to the resolver, see “Steps for configuring resolver caching (optional)” on page 748.

The resolver does not cache information retrieved from local host files, such as /etc/hosts and /etc/ipnodes; that type of information is already cached at a process level. The resolver also does not cache information retrieved using an API not listed in Table 36.

The length of time that cache entries, including negative entries, are valid depends on the time-to-live (TTL) value that is returned by each domain name server. This is consistent with the behavior when using a caching-only name server or an intermediate name server to resolve a query.

In the following situations, cached entries are not saved up to the TTL value that is returned by the name server:

- When you flush the cache using the MODIFY RESOLVER,FLUSH,ALL command to delete all cached entries (for more information, see “Step for deleting cache entries” on page 751)
- When the maximum allocated storage for the cache is exhausted (for more information, see “Managing the cache size and cache storage” on page 750)
- When you limit the duration of time that any individual cache record can be saved using the MAXTTL resolver setup statement (for more information about the MAXTTL statement, see *z/OS Communications Server: IP Configuration Reference*)

The organization of the cached data

The cache is contained in one physical location that has separate logical structures for forward and reverse lookup information. The cache data is organized by DNS name server, which permits different name servers to provide different values for a given host name or IP address.

For example, consider the installation shown in Figure 79. There are two TCP stacks; one TCP stack is used for the core production processing, and a second TCP stack is used for test purposes only. The stacks use different name servers to isolate test resources from the production environment. Each name server can potentially have different IPv4 (A record) definitions for the same host name, as is the case for host.ibm.com. If the test application issues a query for host.ibm.com, the test TCP stack directs the request to the test name server, and IP address 10.45.5.5 is obtained. If the production application issues the same query, a different IP address (10.145.5.5) is obtained. The resolver caches both responses but remembers which response was received from which name server, so that a subsequent request from the test application for host.ibm.com returns the correct test IP address, and not the production IP address.

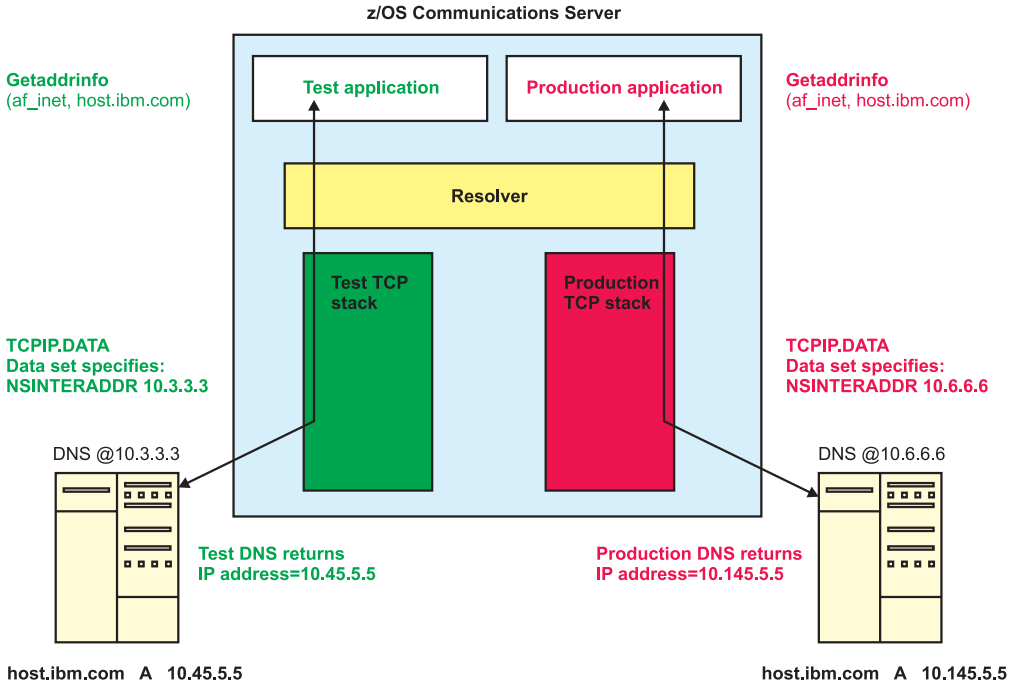

Figure 79. Resolver caching process; each stack specifies one NSINTERRADDR value

The resolver performs cache lookups using the NSINTERADDR search order list in the TCPIP.DATA data set. In Figure 79 on page 747, each stack specifies a single NSINTERADDR value. More likely, in reality, multiple NSINTERADDR definitions are provided, as shown in Figure 80. In this example installation, if the primary name server is unavailable, a secondary name server is used instead. The resolver considers a cache entry that is associated with any name server in the NSINTERADDR list as a match for the target host name; the name resolution is complete and no DNS queries are sent to any of the name servers. The resolver searches the cache in the order that the name servers appear in the NSINTERADDR list; if multiple entries exist for the same target host name (one from each of the name servers in the NSINTERADDR list), the information provided by the first name server in the list is used. In Figure 80, if the test application issues a query for host.ibm.com, IP address 10.145.5.5 is obtained because the first name server IP address in the list is now the production name server (10.6.6.6). If the production application issues the same query, the same IP address, 10.145.5.5 is obtained because there is no entry in the cache for host.ibm.com from the first name server in the list, but there is cache information from the second name server (which is, again, 10.6.6.6).

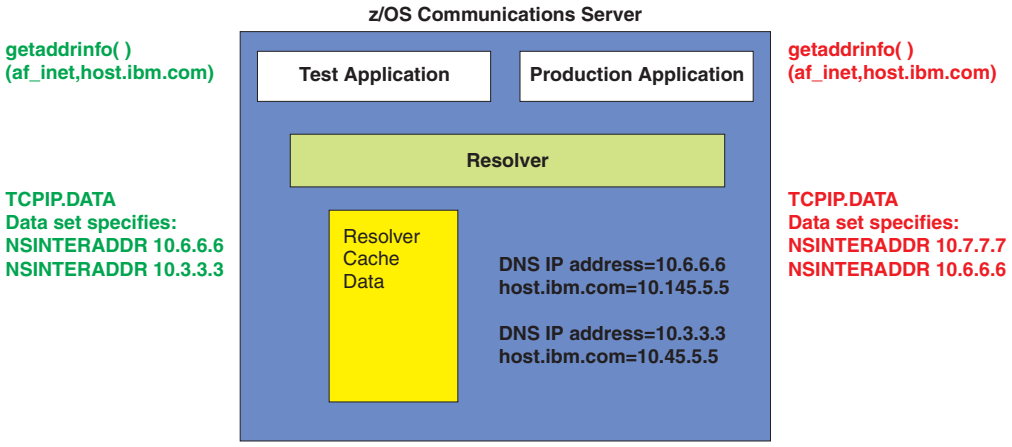

Figure 80. Resolver caching process; each stack specifies multiple NSINTERRADDR values

IPv4 information and IPv6 information are cached as separate entries. A maximum of 35 IP addresses is saved per host name for each name server that provides data for that host name.

Tip: Resolver caching does not provide round-robin support for response data. DNS servers can be configured to use a round-robin method for ordering the IP addresses that are returned by queries, but the resolver always caches the information in the order in which it was received, and returns the IP addresses in the same order, as long as cache information is still valid.

Steps for configuring resolver caching (optional)

Resolver caching is automatically enabled and you do not need to make parmlib or JCL changes. Unless you choose to do so, you do not have to configure the cache; however, you can explicitly configure resolver caching.

Before you begin: You must have already created a resolver setup file; see "The resolver setup file" on page 733 for more information.

Perform the following steps to configure resolver caching:

1. Specify the CACHE statement to enable system-wide caching of Domain Name System (DNS) queries that have been resolved.

   System-wide caching is enabled by default, but you can explicitly enable it by specifying this statement.

2. Specify the CACHESIZE(*cachesize*M) statement to define the amount of storage, in megabytes, that can be allocated by the resolver to manage cached records.

   The default value is 200 megabytes.

   Guideline: If you set a CACHESIZE value that is too low, the resolver might repeatedly take action to reduce cache usage. You should set the CACHESIZE value to be at least 50 percent higher than your expected usage.

   If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored. For more information about cache size, see "Managing the cache size and cache storage" on page 750.

3. Specify the MAXTTL statement to define the maximum amount of time, in seconds, that cache entries are considered to be valid by the resolver.

   The default value is the time-to-live (TTL) value that is provided by the name server for this resource. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored. For more information about cache size, see "Managing the cache size and cache storage" on page 750.

4. Perform one of the following steps:
   - If the resolver is not active, start the resolver.
   - If the resolver is currently active, issue the MODIFY RESOLVER,REFRESH,SETUP=*setup_file_name* command to cause the resolver to use the new settings.

You know you are done when the correct values for the CACHE, CACHESIZE(*cachesize*M), and MAXTTL statements are displayed after you issue the START command or in the MODIFY RESOLVER,REFRESH command output.

For more information about resolver setup statements, see *z/OS Communications Server: IP Configuration Reference*.

For more information about the MODIFY command for the resolver address space, see *z/OS Communications Server: IP System Administrator's Commands*.

Steps for disabling caching for selected applications

All the applications in your environment might not need to use resolver caching. For example, as shown in Figure 79 on page 747, you might have a production network and a test network in your environment. Users of the test network might require specialized host name resolution using a unique set of DNS servers that are not used in the production network. Because the test network is completely isolated and is likely to affect only a small number of users, using resolver caching for the test network could waste cache storage, and could complicate operation of the production network by adding information that is not pertinent to the production network. You can disable resolver caching for applications using the test network, while continuing to use resolver caching for the production network.

Perform the following steps to disable caching for some applications:

1. Identify or create the TCPIP.DATA data set associated with the application for which you want to disable resolver caching.

2. Turn off the resolver caching function by specifying the NOCACHE statement in that TCPIP.DATA data set.
3. Issue the MODIFY RESOLVER,REFRESH command to cause the resolver to refresh the settings for the application.
4. Activate the trace resolver facility to determine which TCPIP.DATA values are being used by the resolver and where they are being read from.
5. When the trace is active, issue the Netstat HOME/**-h** command to display the values.

You know you are done when the value NOCACHE is displayed in the trace resolver output that is generated by the Netstat HOME/**-h** command.

For more information about configuration statements in TCPIP.DATA, see *z/OS Communications Server: IP Configuration Reference*. For more information about the MODIFY command for the resolver address space, see *z/OS Communications Server: IP System Administrator's Commands*.

Managing the cache size and cache storage

Resolver cache information is maintained in 64-bit private storage in the resolver address space, which is also referred to as the storage above the 2 GB bar. This means that caching does not impact common storage.

The default maximum size of the cache is 200 megabytes. The size is allocated incrementally, as the cache increases. For planning purposes, assume that 1 megabyte of storage holds between 400 and 450 cache entries. The actual number of cache entries depends on the amount of storage used for cache infrastructure control blocks, which varies depending on the number of name servers and the number of entries. If you want to control the maximum size of the cache instead of using the 200 megabyte default, you can use the CACHESIZE resolver setup statement. The CACHESIZE statement specifies the maximum amount of storage, in megabytes, that can be allocated by the resolver to manage cached records. The CACHESIZE statement is also used to determine the upper limit of storage that can be used for negative cache entries. If you use the default CACHESIZE value of 200M, then no more than 40 megabytes of that storage will be used for negative cache entries.

The resolver does not automatically delete expired records (those records whose TTL value has been exceeded). Regardless of the amount of cache storage that is in use, the resolver deletes expired records if a new request is received for the expired resource. The resolver also deletes expired records when your cache storage usage has reached the following levels, and takes additional actions to reduce your storage usage.

- When cache storage is less than 75 percent full, the resolver deletes all expired records approximately every 10 minutes, without waiting for a new request to be processed.
- When cache storage is 75 - 97 percent full, the resolver deletes all expired records approximately every minute, without waiting for a new request to be processed.
- When cache storage is 98 percent or more full, the resolver deletes all expired records approximately every 30 seconds, without waiting for a new request to be processed. The resolver does not add new records to the cache while usage is greater than 99 percent. Message EZZ9307E is displayed until usage is less than

90 percent, you increase the CACHESIZE value, or you delete the contents of the cache; see "Step for deleting cache entries" for more information.

Steps for manually managing the storage capacity of the resolver cache: Before you begin: You must have already created a resolver setup file; see "The resolver setup file" on page 733 for more information.

Perform one of the following steps to manage the storage capacity of the resolver cache:

- On the CACHESIZE statement in the resolver setup file, increase the CACHESIZE value and issue the MODIFY RESOLVER,REFRESH,SETUP=*ressetup_filename* command.
- On the MAXTTL statement in the resolver setup file, decrease the MAXTTL value to decrease the length of time that cache records are saved in the cache and issue the MODIFY RESOLVER,REFRESH,SETUP=*ressetup_filename* command. The new MAXTTL value affects only new cache records as they are created; there is no affect on existing cache records.
- Issue the MODIFY RESOLVER,FLUSH,ALL command to delete all cache entries.

You know you are done when message EZZ9307E is no longer displayed on the operator console.

Step for deleting cache entries

You might want to delete the contents of the cache when an IP address has changed for a given host name or when your cache storage is exhausted. Perform the following step to delete the contents of the cache:

- Issue the MODIFY RESOLVER,FLUSH,ALL command to delete all cache entries.

  For more information about the MODIFY command for the resolver address space, see *z/OS Communications Server: IP System Administrator's Commands*.

If you have deleted cache entries because your cache storage was exhausted, you know you are done when message EZZ9307E no longer appears on the screen.

Step for displaying the contents of the cache

Perform the following step to display the contents of the resolver cache:

- Issue the Netstat RESCache/**-q** command to display the RESCache/**-q** report.

  The Netstat RESCache/**-q** report displays the contents of the resolver cache data. You can display statistical data, both overall and by name server. You can also create a report that shows all the cache entries, or you can use filters to produce a report that shows subsets of cache entries.

For details about access control considerations for the Netstat RESCache/-q report, see "Netstat access control" on page 125. For Netstat command syntax and sample report output, see *z/OS Communications Server: IP System Administrator's Commands*.

Migrating from a local caching-only name server to resolver caching

If you have been using a local caching-only name server, you should consider using resolver caching. You can compare the contents of your local caching-only name server with the contents of the resolver cache by performing the following steps:

Before you begin: Resolver caching must be enabled and active. If resolver caching is not enabled (the NOCACHE statement is coded in the resolver setup statement), see "Steps for configuring resolver caching (optional)" on page 748.

Perform the following steps to migrate from a local caching-only name server to resolver caching:

1. Display the contents of your caching-only name server and of the resolver cache at specific intervals.
   - For your caching-only name server, you can dump the contents of the DNS cache using the z/OS UNIX **rndc dumpdb** command.
   - For the resolver cache, use the Netstat RESCache/**-q** report. For more information, see "Step for displaying the contents of the cache" on page 751.
2. Compare the contents of the caching-only name server and the resolver cache, and determine whether to use only resolver caching or resolver caching with the local caching-only name server, using the following criteria:
   - If the contents are similar, and consist primarily of A, AAAA, and PTR DNS records, then you would benefit the most by using only resolver caching. This situation is the most common.
   - If the contents are dissimilar, but the caching-only name server has primarily A, AAAA, and PTR DNS records, then the dissimilar contents are most likely the result of differences in how the resolver cache and the caching-only name server delete expired records. In this situation, you are still most likely to benefit from using only resolver caching.
   - If the contents are dissimilar, and the caching-only name server has many DNS records that are not A, AAAA, or PTR records, you will probably benefit the most by using both resolver caching and the caching-only name server. This situation is not common.
3. Calculate the amount of resolver cache storage that you think you need.

   You can use the default amount of storage (200 megabytes) or you can use the CACHESIZE resolver setup statement to specify a maximum amount of storage. For calculation purposes, 1 megabyte of storage holds roughly 400 - 450 cache entries.
4. If you are not going to use the local caching-only name server, stop that server.

   Guideline: If the local caching-only name server is the only name server in the NSINTERADDR list of name servers to be contacted, replace the caching-only name server entry with one or more name server IP addresses to be contacted. If there is already more than one name server in the NSINTERADDR list of name servers, simply delete the IP address of the local caching-only name server.

For more information about resolver setup statements, see *z/OS Communications Server: IP Configuration Reference*.

Monitoring the responsiveness of Domain Name System name servers

The resolver monitors the responsiveness level of Domain Name System (DNS) name servers that are in the network and alerts the network operator about name servers that fail to respond to a significant percentage of resolver queries. You can use these alerts to better manage the list of name servers that the system uses and to avoid unnecessary delays when a host name or IP address is being resolved.

To determine name server responsiveness, the resolver collects statistics about name server responsiveness in 1-minute intervals, but makes decisions regarding the name server based on the five most recent monitor intervals. These intervals are called sliding 5-minute intervals.

During a given monitoring interval, the resolver keeps system-wide statistics about the total number of resolver queries that are sent to a name server and about the number of those resolver queries that were not responded to by the name server. At the end of the monitoring interval, the resolver calculates a percentage of the total number of queries that were not responded to by the name server over the course of the last five intervals. This percentage is compared to the setting on the UNRESPONSIVETHRESHOLD resolver setup statement; if the percentage of failures equals or exceeds the threshold value, the resolver considers the name server to be unresponsive. For information about the UNRESPONSIVETHRESHOLD statement and how to set its value, see the UNRESPONSIVETHRESHOLD statement in *z/OS Communications Server: IP Configuration Reference* and "Optimizing the UNRESPONSIVETHRESHOLD value for your network" on page 756.

The phrase *resolver queries* does not mean the same thing as *resolver API calls* in the context of name server responsiveness. A single resolver API call, such as getaddrinfo() or gethostbyname(), can generate multiple resolver queries to one or more DNS name servers, based on retry counts, domain names to append to a search, or the type of information that is being requested by the API. Conversely, a resolver API call might not generate any resolver queries to any DNS name servers, if the resource is already in the resolver cache. See "Examples of resolver monitoring of DNS name servers" on page 755 for examples of how different TCPIP.DATA file settings can influence name server responsiveness statistics.

Restriction: The resolver can monitor a maximum of 32 name servers for responsiveness.

The resolver considers the following failures to be indicative of an unresponsive name server:

- The resolver sends a UDP or TCP query to a name server and never receives a response.
- The resolver sends a UDP query to a name server and receives a response after the RESOLVERTIMEOUT value has expired.
- The resolver attempts to send data to a name server using UDP, but the data cannot be sent to the target IP address (for example, because of an error in the route configuration).
- The resolver attempts to connect to a name server using TCP, but the connection attempt times out.
- In some situations, the BIND 9 DNS utilities (for example, dig or nsupdate) issue getaddrinfo() API calls to resolve a host name that represents a remote DNS name server, and those API calls invoke z/OS resolver processing. If any of the previously mentioned failures occur during these BIND 9 resolver calls, the failures are included in the name server statistics.

The resolver does not consider the following failures to be indicative of an unresponsive name server:

- The resolver cannot open a socket (UDP or TCP) to send a request to a name server, including instances in which the system is IPv4-only capable and an IPv6 name server IP address is coded on the NSINTERADDR statement.
- The resolver sends a UDP query to a name server to determine whether the name server is EDNS0-capable, but does not receive a response to that UDP query; see "Extension Mechanisms for DNS standards and the resolver" on page 758 for more information about EDNS0 processing.

- The resolver sends a UDP query to a name server and the name server responds with a DNS return code (such as SERVFAIL or NOTIMPL) that indicates that the name server is active and responding but is unable to process the request that was sent.
- Timeouts or failures occur during SMTP processing (SMTP uses its own resolver services to send queries to a name server).
- Timeouts or failures occur during BIND 9 DNS utility processing that does not involve getaddrinfo() calls (that processing uses BIND 9 resolver services to send queries to a name server).

Resolver notifications for DNS name server responsiveness

If the resolver detects that a name server is not being responsive, a series of network operator messages is issued that relate to that name server. For example, if a name server is operating at IP address 9.42.35.200 and the UNRESPONSIVETHRESHOLD value is 25, then the following sequence of messages might be generated by the resolver:

1. At the end of a 5-minute monitoring interval, the resolver determines that the name server failed to respond to 35% of 6 000 queries that were attempted by the resolver. The resolver considers the name server to be unresponsive and issues the following messages:

   ```
   EZZ9308E UNRESPONSIVE NAME SERVER DETECTED AT IP ADDRESS 9.42.35.200
   EZZ9310I NAME SERVER 9.42.35.200
        TOTAL NUMBER OF QUERIES SENT    6000
        TOTAL NUMBER OF FAILURES        2100
        PERCENTAGE                        35%
   ```

2. At the end of the next 5-minute interval, the resolver determines that the name server failed to respond to 55% of the 3 000 queries that it attempted during that interval. The name server is still considered to be unresponsive, and the following message is issued:

   ```
   EZZ9310I NAME SERVER 9.42.35.200
        TOTAL NUMBER OF QUERIES SENT    3000
        TOTAL NUMBER OF FAILURES        1650
        PERCENTAGE                        55%
   ```

   This message and the statistical information for the name server are issued at 5-minute intervals for as long as the resolver considers the name server to be unresponsive.

3. At the end of a subsequent monitor interval, the resolver determines that the name server failed to respond to 15% of the 4 500 queries that the resolver attempted during the latest sliding 5-minute interval. This percentage is under the threshold value, so the resolver considers this name server to be responsive again. The resolver clears message EZZ9308E from the operator console and issues the following messages:

   ```
   EZZ9309I NAME SERVER IS NOW RESPONSIVE AT IP ADDRESS 9.42.35.200
   EZZ9310I NAME SERVER 9.42.35.200
        TOTAL NUMBER OF QUERIES SENT    4500
        TOTAL NUMBER OF FAILURES         675
        PERCENTAGE                        15%
   ```

4. The resolver also clears message EZZ9308E from the operator console if any of the following situations occur:
   - The network operator disables the monitoring function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see “Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 757.
   - No resolver queries are sent to the name server during the current 5-minute monitor interval.
   - The resolver is stopped.

The resolver issues individual messages for each name server that it considers to be unresponsive at the end of a given monitoring interval. Because the resolver calculates the responsiveness of a name server by using a sliding 5-minute interval, you might see messages for different name servers at different times, rather than see notifications about all unresponsive name servers at the same time.

Use the statistics supplied in message EZZ9310I to determine the severity of the problem that the resolver is reporting. For example, if the unresponsive name server is the primary server for the network, and it is failing to respond to over half of a large number of queries that are directed to it, that situation might be more serious than a secondary name server that is not responding to 25% of a small number of queries. You can also use the statistics that are displayed when message EZZ9309I is issued to determine whether the name server is fully responsive again, is likely to become unresponsive again because the failure rate is still close to the threshold value, or is just not being used in your environment.

Guideline: The resolver does not require that there be a certain number of failed queries to a particular name server before it declares that server to be unresponsive. For example, if only one query is received by a particular name server during a monitoring interval, and that query fails to obtain a response, then the resolver considers that name server to be 100% unresponsive.

Examples of resolver monitoring of DNS name servers

Values in the TCPIP.DATA file can affect the statistics that the resolver collects when it monitors DNS name servers. For example, consider the following settings from TCPIP.DATA:

```
NAMESERVER 9.43.25.200 9.43.125.203 9.43.25.200
RESOLVERUDPTRIES 2
RESOLVERTIMEOUT 0.075
RESOLVEVIA UDP
```

In this example, one name server (9.43.25.200) appears twice in the list of name servers that the resolver will search. The resolver should retry that list of name servers one time before it considers the name servers to be unresponsive. Assume that the resolver generates a query to resolve the address user.ibm.com as part of gethostbyname processing. The following example sequence occurs:

1. The resolver sends the query to name server 9.43.25.200, which times out after 75 milliseconds (based on the RESOLVERTIMEOUT value).
2. The resolver forwards the request to name server 9.43.125.203, which also times out.
3. The request goes to name server 9.43.25.200 a second time (as the last name server in the list), which times out again.

   The first retry of the list name servers is complete.
4. The resolver begins at the top of the list again and sends the request to name server 9.43.25.200 for a third time. A response arrives from this name server, possibly as the result of name server delays.
5. The resolver stops searching for the resource.

Result: Based on the searching that the resolver performed, the system-wide total request count for name server 9.43.25.200 is incremented by 3, and the total failure count is incremented by 2. If the searches that are shown in this example is all the activity for this name server over the course of 5 minutes, the failure rate for this name server is 66%. The system-wide total request count and the total failure count for name server 9.43.124.203 are both incremented by 1. If the resolver does

not send any more queries to this name server during the 5-minute interval, the failure rate for name server 9.43.124.203 is 100%.

Consider these different TCPIP.DATA file settings:

```
NAMESERVER 9.43.25.200
SEARCH raleigh.ibm.com
RESOLVERTIMEOUT 0.075
RESOLVEVIA UDP
```

In this example, only one name server is coded, and only one domain name can be appended to the input host name as an additional search attempt. Assume that an application issues getaddrinfo() for host name `user`, and that ai_family=AF_UNSPEC is specified. The following example sequence occurs:

1. The resolver searches for domain name user.raleigh.ibm.com and requests AAAA records.
2. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver continues to request AAAA records, but searches the next domain in the sequence, which is `user`.
3. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver searches for domain name `user.ibm.com` and requests A records.
4. One of the following actions occurs:
   - If the resolver obtains resource information, the search ends.
   - If the resolver does not obtain resource information, the resolver continues to request A records, but searches the next domain in the sequence, which is `user`.

Result: If the name server at 9.43.25.200 fails to respond to any of the queries, the system-wide total request count and the total failure count for this name server are incremented by 4.

Optimizing the UNRESPONSIVETHRESHOLD value for your network

Every minute, the resolver calculates the percentage of queries to a name server that failed in the previous 5 minutes, and then compares this percentage to the threshold value that you set in the UNRESPONSIVETHRESHOLD statement to determine whether that DNS name server is unresponsive. If the resolver sends a query to a name server multiple times and the name server does not respond to multiple queries, each query is considered to be a unique failure to respond. When you specify the UNRESPONSIVETHRESHOLD value, consider the following factors that have an impact on the effectiveness of your setting:

- If you specify a small percentage for this value, an excessive number of operator notifications might occur. Short network disruptions that occur during the 5-minute monitoring interval might result in some undeliverable resolver queries or name server responses, and a low threshold value might cause the resolver to alert the operator unnecessarily.
- If you specify a large percentage for this value, persistent issues with the network or the name server might be undetected even though a significant portion of resolver queries are not being processed by the name server.

- The setting on the RESOLVERTIMEOUT statement in the TCPIP.DATA file also affects the value that you should specify for the UNRESPONSIVETHRESHOLD setting. If you set a very short timeout value, even slight network disruptions might cause name server responses to be delayed longer than the amount of time specified by the RESOLVERTIMEOUT value. These delays are considered to be non-responses from the name server, which might cause unnecessary messages to be generated for this name server. A less aggressive (higher) percentage setting for the UNRESPONSIVETHRESHOLD value might be warranted in such a situation.
- The settings of the RESOLVERUDPRETRIES, SEARCH, and NAMESERVER statements in the TCPIP.DATA file can also contribute to high numbers of apparent failures on the part of the name server. See "Examples of resolver monitoring of DNS name servers" on page 755 for information about how these settings can influence the statistics that are collected by the resolver.

One strategy that you can use to select the most optimal threshold value is to start with the default setting, which is 25%, and determine how many network operator messages are issued, if any, during normal operation of the network.

- If your network is operating in an acceptable manner (for example, no performance issues are detected and no host name or IP address resolutions delays are detected), examine the number of network operator alerts that are generated by the resolver:
  - If the number of network operator messages is zero or insignificant, leave the setting at the default value, or even decrease the threshold value slightly.
  - If the number of network operator messages is excessive, which suggests that a lot of false negative conditions were detected by the resolver, increase the threshold setting until the number of messages that is generated is appropriate for your network.
- If the name server is now responsive, but the failure rate is just slightly below the threshold value, the name server will probably become unresponsive again with a minor disruption in the network. If your network is currently operating in a satisfactory manner, consider increasing the threshold setting so that the resolver issues EZZ9308E messages only when your network conditions change significantly. Use the statistics that are displayed when message EZZ9309I is issued to modify the threshold setting to a more optimal value.
- If your network is experiencing performance issues that resolver delays might be contributing to (for example, unexplained application delays), consider decreasing the responsiveness threshold setting to determine whether issues with the name servers are being detected by the resolver but are not being reported as unresponsive. If this lower threshold value causes the resolver to generate network operator messages that identify name servers that are unresponsive and that are impacting network operations, consider using this lower value for normal operations to provide more timely identification of name server issues.

Steps for modifying the UNRESPONSIVETHRESHOLD value

Before you begin: You must have already created a resolver setup file; see "Steps for creating a resolver setup file" on page 736 for instructions.

Perform the following steps to modify the UNRESPONSIVETHRESHOLD value.

1. Specify the UNRESPONSIVETHRESHOLD value that you want to use in the resolver setup file:
   - To disable the monitoring function, specify UNRESPONSIVETHRESHOLD(0).

- To set a specific threshold value for the monitoring function, specify UNRESPONSIVETHRESHOLD(*percentage*), where *percentage* is a value in the range 1 - 100.

2. Perform one of the following steps:
   - If the resolver is not active, start the resolver.
   - If the resolver is currently active, issue the MODIFY RESOLVER,REFRESH,SETUP=*setup_file_name* command to cause the resolver to use the new threshold setting.

     The new value will be used at the end of the next sliding 5-minute interval to determine name server responsiveness.

You know you are done when the correct UNRESPONSIVETHRESHOLD value is displayed after you issue the START command or in the MODIFY RESOLVER,REFRESH command output.

Extension Mechanisms for DNS standards and the resolver

The resolver can use UDP protocols to more efficiently obtain resource information when it uses the Extension Mechanisms for DNS (EDNS0) standards. Before these standards existed, UDP responses from a name server were limited to 512 bytes. If a large number of resource records appear on a DNS response message, more than 512 bytes might be required to return all the response data to the resolver. IPv6 resource records are larger than IPv4 resource records, so fewer IPv6 resource records are needed to reach the 512 byte limitation, but the limitation can be reached even with just IPv4 resource records. EDNS0 support permits the resolver to accept DNS messages, using UDP protocols, of greater than 512 bytes, if the name server that is providing the response message also supports EDNS0 (the z/OS Communications Server BIND 9 DNS name server supports the EDNS0 standard).

- If the name server does not support EDNS0, these larger responses are truncated to fit within 512 bytes of UDP packet data, and the resolver resends the request using TCP protocols to acquire the entire response message.
- If the name server does support EDNS0, the resolver accepts up to 3072 bytes of DNS response message data in a single UDP packet.

You do not need to configure support for EDNS0 standards. The resolver dynamically determines whether each name server supports EDNS0 processing, and modifies the DNS requests that are sent to the name servers accordingly. If a name server is upgraded to support EDNS0, the resolver rediscovers the capabilities of the name server dynamically, although the rediscovery period might take some time. You can use the MODIFY RESOLVER,REFRESH command to cause the resolver to rediscover the capabilities of the name servers more quickly. For more information about the MODIFY RESOLVER,REFRESH command, see *z/OS Communications Server: IP System Administrator's Commands*. To verify whether a name server supports EDNS0, use the **dig** command with the +bufsize= option to force **dig** to send an OPT RR record on the request. If the name server supports EDNS0, it responds with its own OPT RR record on the response.

If you have upgraded a name server to support Extension Mechanisms for DNS (EDNS0), you can issue the MODIFY RESOLVER,REFRESH command to force the resolver to dynamically determine name server capability. The resolver can then use EDNS0 support to accept DNS messages of greater than 512 bytes, using the less costly UDP protocol, which results in improved DNS and resolver performance.

Resolver configuration files

Understanding the resolver search orders used in native MVS and z/OS UNIX environments is key to setting up your system properly.

The resolver can use available name servers, local definitions, or a combination of both, to process API resolver requests. Figure 81 shows how local definitions can be specified and searched for when needed.

Use the trace resolver facility to determine what TCPIP.DATA values are being used by the resolver and where they were read from. For information about dynamically starting the trace, see *z/OS Communications Server: IP Diagnosis Guide*. After the trace is active, issue the Netstat HOME/**-h** command to display the values. You can issue a `Ping` of a host name from TSO and from the z/OS UNIX shell to show the activity to the resolver cache and to any DNS servers that might be configured.

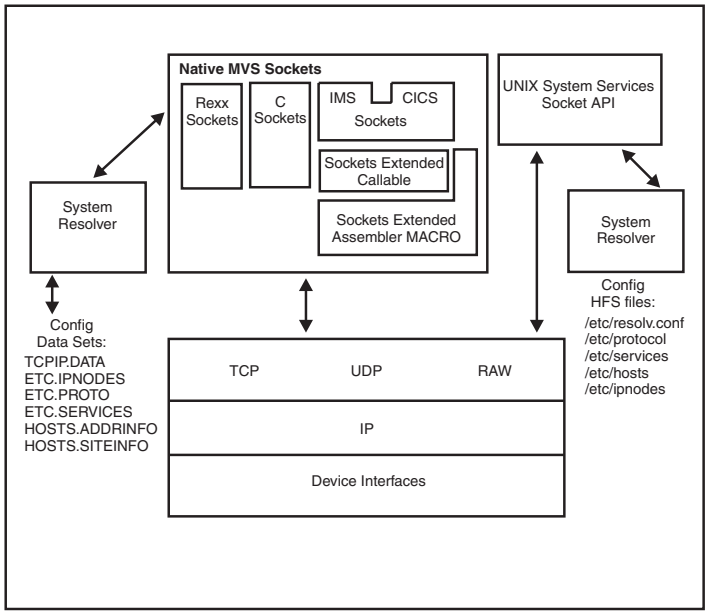

Figure 81. Resolver related configuration files in z/OS UNIX and native MVS environments

Table 37 on page 760 shows the complete set of local definition possibilities available to the resolver.

Table 37. Local definitions available to resolver

File type description	APIs affected	Candidate files
Base resolver configuration files	All APIs	1. GLOBALTCPIPDATA 2. RESOLVER_CONFIG environment variable 3. /etc/resolv.conf 4. SYSTCPD DD-name 5. *userid*.TCPIP.DATA 6. *jobname*.TCPIP.DATA 7. SYS1.TCPPARMS(TCPDATA) 8. DEFAULTTCPIPDATA 9. TCPIP.TCPIP.DATA
Translate tables	All APIs	1. X_XLATE environment variable 2. *userid*.STANDARD.TCPXLBIN 3. *jobname*.STANDARD.TCPXLBIN 4. *hlq*.STANDARD.TCPXLBIN 5. Resolver-provided translate table, member STANDARD in SEZATCPX
Local host tables	endhostent endnetent getaddrinfo gethostbyaddr gethostbyname gethostent GetHostNumber GetHostResol GetHostString getnameinfo getnetbyaddr getnetbyname getnetent IsLocalHost Resolve sethostent setnetent	1. X_SITE environment variable 2. X_ADDR environment variable 3. /etc/hosts 4. *userid*.HOSTS.xxxxINFO 5. *jobname*.HOSTS.xxxxINFO 6. *hlq*.HOSTS.xxxxINFO 7. GLOBALIPNODES 8. RESOLVER_IPNODES environment variable 9. *userid*.ETC.IPNODES 10. *jobname*.ETC.IPNODES 11. *hlq*.ETC.IPNODES 12. DEFAULTIPNODES 13. /etc/ipnodes
Protocol information	endprotoent getprotobyname getprotobynumber getprotoent setprotoent	1. /etc/protocol 2. *userid*.ETC.PROTO 3. *jobname*.ETC.PROTO 4. *hlq*.ETC.PROTO
Services information	endservent getaddrinfo getnameinfo getservbyname getservbyport getservent setservent	1. /etc/services 2. SERVICES DD-name 3. *userid*.ETC.SERVICES 4. *jobname*.ETC.SERVICES 5. *hlq*.ETC.SERVICES
Host alias table	getaddrinfo gethostbyname	HOSTALIASES environment variable

The actual search order of the candidate files varies depending on the type of API used and the resolver's setup. The search orders are explained in more detail in

"Search orders used in the z/OS UNIX environment" on page 762 and "Search orders used in the native MVS environment" on page 769. Because the resolver runs in the address space of the application, the candidate files are accessed from the application address space.

Information about an application's search order can be obtained by using the trace resolver facility. Trace resolver output provides a caller API value that determines which search order is used. For information on dynamically starting the trace, see *z/OS Communications Server: IP Diagnosis Guide*.

The following caller API values indicate the z/OS UNIX environment search order is used:

- Language Environment C Sockets
- Unix System Services

The following caller API values indicate the native MVS environment search order is used:

- TCP/IP C Sockets
- TCP/IP Pascal Sockets
- TCP/IP Rexx Sockets
- TCP/IP Sockets Extended

Following are some examples of Communications Server TSO commands that use the native MVS search order:

- DIG
- FTP (batch only)

  Rule: Batch FTP jobs use //SYSTCPD if specified. If //SYSTCPD is not specified, then the z/OS UNIX search order is used.
- LPR
- NETSTAT
- NSLOOKUP
- PING
- REXEC
- RPCINFO
- RSH
- TRACERTE

Following are some examples of Communications Server UNIX commands that use the z/OS UNIX search order:

- dig
- dnsdomainname
- domainname
- ftp

  Rule: The TSO FTP command also uses the z/OS UNIX search order.
- host
- hostname
- netstat
- nslookup
- ping

- rexec
- rpcinfo
- sendmail
- snmp
- traceroute

Following are some examples of Communications Server applications that use the native MVS search order:

- CICS Listener
- LPD
- Miscellaneous server
- PORTMAP
- RSHD
- SMTP server
- TN3270E Telnet server

Following are some examples of Communications Server applications that use the z/OS UNIX search order:

- CSSMTP
- FTP
- SNMP agent
- z/OS UNIX OPORTMAP
- z/OS UNIX OREXECD
- z/OS UNIX ORSHD

Search orders used in the z/OS UNIX environment

This information describes setting environment variables for configuration files, and the search orders used in the z/OS UNIX environment for the different file types shown in Table 37 on page 760. The z/OS UNIX socket functions utilize various types of TCP/IP data sets and files. They include:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information
- Host alias table

The particular file or table chosen can be either an MVS data set or z/OS UNIX file, depending on the resolver configuration settings and the presence of given files on the system.

Note: A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see *z/OS Communications Server: IP System Administrator's Commands*.

Setting z/OS XL C/C++ environment variables for configuration files

A z/OS XL C/C++ environment variable is an identifier used like a variable in a program. In Table 37 on page 760, the following environment variables appear:

HOSTALIASES
The host aliases data set, file, or ddname.

RESOLVER_CONFIG
The resolver configuration data set, file, or ddname. The RESOLVER_CONFIG environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for TCPIP.DATA.

RESOLVER_IPNODES
The IPNODES data set, file, or ddname.

X_SITE and X_ADDR
The HOSTS.SITEINFO and HOSTS.ADDRINFO data sets or ddnames created by the MAKESITE TSO command. The X_SITE environment variable influences how gethostbyname() resolves the network address of the specified host name. The X_ADDR environment variable is used by some TCP/IP functions, such as getnetbyaddr(), to include the name of an MVS data set or z/OS UNIX file in the search order for the HOSTS.ADDRINFO data set.

X_XLATE
The ASCII-EBCDIC translate table data set or ddname created by the CONVXLAT TSO command. The X_XLATE environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for the STANDARD.TCPXLBIN data set.

Other environment variables that can be explicitly set by the resolver include the following:

LOCALDOMAIN
Defines the domain origin. Once this environment variable is set, it overrides any setting for DOMAIN, DOMAINORIGIN, or SEARCH found in TCPIP.DATA

RESOLVER_TRACE
Defines the data set, file, or ddname into which the resolver trace output is written.

MESSAGECASE
Determines whether messages are translated to all uppercase characters before being sent to the console.

The method used to set an environment variable so that a z/OS C/C++ UNIX application is able to retrieve the value depends on whether the z/OS UNIX application is started from the z/OS shell or from JCL.

If the z/OS C/C++ UNIX application is to be started from the z/OS UNIX shell, the export shell command can be used to set the environment variable. For example, to set the value of RESOLVER_CONFIG to the file /etc/tcpa.data, you can code the following export command:

```
export RESOLVER_CONFIG=/etc/tcpa.data
```

If, instead of a file, you want to set RESOLVER_CONFIG to the data set MVSA.PROD.PARMS(TCPDATA), you can specify the following export command. Be sure to put the single quotation marks around the data set name. If you do not, your user ID will be added as a prefix to the data set name when the resolver tries to open the file.

```
export RESOLVER_CONFIG="//'MVSA.PROD.PARMS(TCPDATA)'"
```

If the z/OS UNIX application is to be started from JCL instead of from the z/OS shell, the environment variable needs to be passed as a parameter in the JCL of the application. For example, the following example shows the RESOLVER_CONFIG variable set to pick up the TCPIP.DATA information from a file:

```
//OSNMPD    PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)/',
//      'ENVAR("RESOLVER_CONFIG=/etc/tcpa.data")/-d 0')
⋮
```

The following example shows the RESOLVER_CONFIG variable set to pick up the TCPIP.DATA information from a partitioned data set:

```
//OSNMPD    PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)/',
//  'ENVAR("RESOLVER_CONFIG=//''TCPA.MYFILE(TCPDATA)''")/-d 0')
⋮
```

The following example shows the RESOLVER_CONFIG variable set to pick up the TCPIP.DATA information from a DD card:

```
//OSNMPD PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)/',
// 'ENVAR("RESOLVER_CONFIG=DD:TCPDATA")/-d 0')
//TCPDATA DD DSN=TCPA.MYFILE(TCPDATA),DISP=SHR
⋮
```

Tip: A ddname can also be specified as //DD:*ddname* as follows:

```
⋮
// 'ENVAR("RESOLVER_CONFIG=//DD:TCPDATA")/-d 0'))
```

The following example shows an alternate method of accessing environment variables:

```
//OSNMPD    PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)/',
// 'ENVAR("_CEE_ENVFILE=DD:STDENV")/-d 0')
//STDENV DD DSN=TCPA.MYFILE(TCPDATA),DISP=SHR
```

In this case, the environment variables will be read from the file specified on the STDENV DD statement. If this file is an MVS data set, the data set must be

allocated with RECFM=V. RECFM=F is not recommended, because RECFM=F enables padding with blanks for the environment variables. See *z/OS XL C/C++ Programming Guide* for more information on specifying a list of environment variables using the _CEE_ENVFILE environment variable.

Regardless of whether the z/OS UNIX application is started from the z/OS shell or from JCL, the RESOLVER_CONFIG environment variable can also be set to indicate that a ddname should be used. The following directs the resolver to read its TCPIP.DATA statements from the ddname MYTCPIPD:

```
RESOLVER_CONFIG=DD:MYTCPIPD
```

For information on how to use a ddname when specifying what kind of file to use, see *z/OS XL C/C++ Programming Guide*.

Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

1. GLOBALTCPIPDATA

   If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see "The resolver and the global TCPIP.DATA file" on page 735.

   The search continues for an additional configuration file. The search ends with the next file found.
2. The value of the environment variable RESOLVER_CONFIG

   The value of the environment variable is used. This search will fail if the file does not exist or is allocated exclusively elsewhere.
3. /etc/resolv.conf
4. //SYSTCPD DD card

   The data set allocated to the ddname SYSTCPD is used. In the z/OS UNIX environment, a child process does not have access to the SYSTCPD DD. This is because the SYSTCPD allocation is not inherited from the parent process over the fork() or exec function calls.
5. *userid*.TCPIP.DATA

   userid is the user ID that is associated with the current security environment (address space or task/thread)
6. SYS1.TCPPARMS(TCPDATA)
7. DEFAULTTCPIPDATA

   If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see "The resolver and the global TCPIP.DATA file" on page 735.
8. TCPIP.TCPIP.DATA

Any TCPIP.DATA statements that have not been found will have their default values, if any, assigned.

Translate tables

The translate tables (EBCDIC-to-ASCII and ASCII-to-EBCDIC) are referenced to determine the translate data sets to be used.

The search order used to access this configuration file is as follows. The search order ends at the first file found:

1. The value of the environment variable X_XLATE

   The value of the environment variable is the name of the translate table produced by the CONVXLAT TSO command.
2. *userid*.STANDARD.TCPXLBIN

   userid is the user ID that is associated with the current security environment (address space or task/thread).
3. *hlq*.STANDARD.TCPXLBIN

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.
4. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

Tip: Preallocating the STANDARD.TCPXLBIN data set using a JCL DD statement stops the resolver from issuing dynamic allocations for the data set. This eliminates the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job's output joblog.

Local host tables

By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following:

- TCPIP.DATA statements

  The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see *z/OS Communications Server: IP Configuration Reference*.
- How your application is written and compiled

  If your application program uses the TCP/IP-provided C/C++ API and the XL C/C++ RESOLVE_VIA_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE_VIA_LOOKUP symbol, see *z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference* and *z/OS XL C/C++ Programming Guide*.

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

IPv4-unique search order for sitename information: The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

- getaddrinfo API is attempting to locate an IPv4 address.
- gethostbyname, sethostent, gethostent, or endhostent API is invoked.

If the COMMONSEARCH statement is specified, see "IPv6/common search order" on page 767, where the resolver can use IPNODES to locate sitenames.

The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. The value of the environment variable X_SITE

   The value of the environment variable is the name of the MVS data set that contains the sitename information. This data set is created by the TSO MAKESITE command.
2. /etc/hosts
3. *userid*.HOSTS.SITEINFO

   userid is the user ID that is associated with the current security environment (address space or task/thread).
4. *hlq*.HOSTS.SITEINFO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

IPv4-unique search order for address information: The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr API is invoked. If the COMMONSEARCH statement is specified, see "IPv6/common search order," where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. The value of the environment variable X_ADDR

   The value of the environment variable is the name of the MVS data set that contains the address information. This data set is created by the TSO MAKESITE command.
2. /etc/hosts
3. *userid*.HOSTS.ADDRINFO

   userid is the user ID that is associated with the current security environment (address space or task/thread).
4. *hlq*.HOSTS.ADDRINFO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

IPv6/common search order: The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the getaddrinfo, gethostbyname, getnameinfo, gethostbyaddr, sethostent, gethostent, or endhostent APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getaddrinfo API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getnameinfo API is attempting to resolve an IPv6 address.

Note: The IPv6/common search order is never used for the following API socket calls:

- getnetbyname
- getnetbyaddr
- setnetent
- getnetent
- endnetent

The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value

   If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the GLOBALIPNODES statement, see "The resolver setup file" on page 733.
2. The value of the environment variable RESOLVER_IPNODES
3. *userid*.ETC.IPNODES

   userid is the user ID that is associated with the current security environment (address space or task/thread).
4. *hlq*.ETC.IPNODES

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.
5. DEFAULTIPNODES

   If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the DEFAULTIPNODES statement, see "The resolver setup file" on page 733.
6. /etc/ipnodes

Protocol information

The protocol information supplies protocol related information for the socket calls listed in Table 37 on page 760.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. /etc/protocol
2. *userid*.ETC.PROTO

   userid is the user ID that is associated with the current security environment (address space or task/thread).
3. *hlq*.ETC.PROTO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCPIP by default.

Services information

The services information supplies the service information for the socket calls listed in Table 37 on page 760.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. /etc/services
2. *userid*.ETC.SERVICES

userid is the user ID that is associated with the current security environment (address space or task/thread).

3. *hlq*.ETC.SERVICES

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCPIP by default.

Host alias table

The host alias table supplies hostname alias information for the socket calls listed in Table 37 on page 760. The format of the alias information is the alias name, followed by a space, followed by the fully qualified domain name that corresponds to the alias name. The domain name is written without a trailing dot, and the alias name cannot contain dots. The search order used to access this configuration file consists only of the value of the environment variable HOSTALIASES.

Search orders used in the native MVS environment

The native MVS environment socket functions utilize various type of TCP/IP data sets, including:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information

The particular file or table chosen depends on the resolver configuration settings and the presence of given files on the system.

Note: A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see *z/OS Communications Server: IP System Administrator's Commands*.

Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

1. GLOBALTCPIPDATA.

   If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see "The resolver and the global TCPIP.DATA file" on page 735.

   The search continues for an additional configuration file. The search ends with the next file found.

2. //SYSTCPD DD card

   The data set allocated to the ddname SYSTCPD is used.

   Rule: Since TCPIP.DATA statements might need to be read and used multiple times by the resolver, the FREE=CLOSE JCL parameter should not be used when allocating SYSTCPD. To allow TCPIP.DATA statements to be changed while still allocated for long running programs, consider using a member of an MVS partitioned data set instead of an MVS sequential data set. For these long

running applications, the resolver MODIFY REFRESH command should then be used to indicate that TCPIP.DATA statements have been changed.

3. *userid/jobname*.TCPIP.DATA

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
4. SYS1.TCPPARMS(TCPDATA)
5. DEFAULTTCPIPDATA

   If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see "The resolver and the global TCPIP.DATA file" on page 735.
6. TCPIP.TCPIP.DATA

Translate tables

The translate tables are referenced to determine the translate data sets to be used.

The search order used to access this configuration file is as follows. The search order ends at the first file found:

1. *userid/jobname*.STANDARD.TCPXLBIN

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
2. *hlq*.STANDARD.TCPXLBIN

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.
3. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

Tip: Preallocating the STANDARD.TCPXLBIN data set using a JCL DD statement stops the resolver from issuing dynamic allocations for the data set. This eliminates the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job's output joblog.

Local host tables

By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following:

- TCPIP.DATA statements

  The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see *z/OS Communications Server: IP Configuration Reference*.
- How your application is written and compiled

  If your application program uses the TCP/IP-provided C/C++ API and the RESOLVE_VIA_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE_VIA_LOOKUP symbol, see *z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference*.

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

IPv4-unique search order for sitename information: The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

- getaddrinfo API is attempting to locate an IPv4 address.
- gethostbyname, GetHostNumber, GetHostResol, IsLocalHost, Resolve, sethostent, gethostent, or endhostent API is invoked.

If the COMMONSEARCH statement is specified, see "IPv6/common search order" on page 772, where the resolver can use IPNODES to locate sitenames.

The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. *userid/jobname*.HOSTS.SITEINFO

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
2. *hlq*.HOSTS.SITEINFO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

IPv4-unique search order for address information: The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr or GetHostString API is invoked. If the COMMONSEARCH statement is specified, see "IPv6/common search order" on page 772, where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. *userid/jobname*.HOSTS.ADDRINFO

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
2. *hlq*.HOSTS.ADDRINFO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

IPv6/common search order: The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the getaddrinfo, gethostbyname, getnameinfo, gethostbyaddr, GetHostNumber, GetHostResol, GetHostString, IsLocalHost, Resolve, sethostent, gethostent, or endhostent APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getaddrinfo API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getnameinfo or Resolve API is attempting to resolve an IPv6 address.

Note: The IPv6/common search order is never used for the following API socket calls:

- getnetbyname
- getnetbyaddr
- setnetent
- getnetent
- endnetent

The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value

   If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the GLOBALIPNODES statement, see "The resolver setup file" on page 733.
2. *userid/jobname*.ETC.IPNODES

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.
3. *hlq*.ETC.IPNODES

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.
4. DEFAULTIPNODES

   If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the DEFAULTIPNODES statement, see "The resolver setup file" on page 733.
5. /etc/ipnodes

Protocol information

The protocol information supplies protocol related information for the socket calls listed in Table 37 on page 760.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. *userid/jobname*.ETC.PROTO

   userid is the user ID that is associated with the current security environment (address space or task/thread).

jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. *hlq*.ETC.PROTO

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCPIP by default.

Services information

The services information supplies service information for the socket calls listed in Table 37 on page 760.

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. //SERVICES DD card

   The data set allocated to the ddname SERVICES is used.

2. *userid/jobname*.ETC.SERVICES

   userid is the user ID that is associated with the current security environment (address space or task/thread).

   jobname is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

3. *hlq*.ETC.SERVICES

   hlq represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCPIP by default.

Chapter 15. Domain Name System

This topic describes the z/OS UNIX Domain Name System (DNS) name server, which uses the Berkeley Internet Name Domain (BIND) software, the accepted standard of DNS. BIND was developed at the University of California, Berkeley and is currently maintained by the Internet Software Consortium (ISC). The name server discussed in this topic is based on BIND 9.

The Domain Name System is a client/server model in which programs called *name servers* contain information about host systems and IP addresses. Name servers provide this information to clients called *resolvers*.

z/OS V1R2 Communications Server BIND 9.1 was the first implementation of BIND 9 on the z/OS platform, which was a complete rewrite of the name server and associated utilities. This allowed IPv6-type records in zone data. It also introduced better transaction security among servers and clients, as well as zone data authentication capability. It introduced the rndc utility to replace and complement UNIX signals for name server local and remote control.

The BIND 9.2 name server was introduced in z/OS V1R4. It makes DNS server-to-server and client-to-server IPv6 connections possible, adding new name server configuration options for IPv6 connections and tuning. BIND 9.2 also provides a new rndc utility with a larger set of commands than was available with BIND 9.1. BIND 9.2 rndc is not compatible with BIND 9.1 rndc.

The configuration file for the name server has changed in both name and syntax between BIND 4.9.3 and BIND 9. The dnsmigrate tool aids in converting a BIND 4.9.3 named.boot file into a BIND 9 named.conf file.

BIND 9 nsupdate utility enables client hosts and many DHCP servers to dynamically and securely register their name and address mappings. The z/OS BIND 9 name server is generally compatible with network DHCP servers.

This topic is not intended to be a comprehensive description of DNS or of BIND. For more complete descriptions, see the latest edition of *DNS and BIND* by Paul Albitz and Cricket Liu (O'Reilly & Associates, Inc.).

DNS and BIND overview

TCP/IP applications map fully qualified domain names to 32-bit IPv4 IP addresses or 128-bit IPv6 addresses to identify network nodes. The z/OS BIND 9 name server supports resource records for IPv6 address mapping. It also accepts IPv6 connections, depending on the z/OS TCP/IP stack setup and profile, and on the name server configuration. While TCP/IP applications refer to host computers by their IP addresses, it is easier to use host names. To enable the use of host names in a network, the Domain Name System (DNS) translates host names to IP addresses. Mapping must be consistent across the network to ensure interoperability. DNS provides the host name-to-IP address mapping through network server hosts called *domain name servers*. For detailed information about name servers, see “Domain name servers” on page 777. DNS can also provide other information about server hosts and networks such as the TCP/IP services available at a server host and the location of domain name servers in a network.

DNS organizes the hosts in a network into domains. A *domain* is a group of hosts that share the same name space in the domain hierarchy and are usually controlled within the same organization. Domains are arranged in a hierarchy. A special domain known as the *root domain* exists at the top of the hierarchy. The root domain servers store information about server hosts in the root domain and the name servers in the delegated, *top-level* domains, such as *com* (commercial), *edu* (education), and *mil* (military). The name servers in the top-level domain, in turn, store the names of name servers for their delegated domains, and so on.

The complete name of a host, also known as the *fully qualified domain name* (FQDN), is a series of labels separated by dots or periods. Each label represents an increasingly higher domain level within a network. The complete name of a host connected to one of the larger networks generally has more than one subdomain, as shown in the following examples:

```
host1.subdomain2a.subdomain2.rootdomain
user4720.eng.mit.edu
```

A domain name server requires the FQDN. The client resolver combines the host name with the domain name to create the FQDN before sending the name resolution request to the domain name server.

DNS also provides IP address-to-host name mapping. The DNS defines a special domain called *in-addr.arpa* to translate IPv4 addresses to host names, and the *ip6.int* and *ip6.arpa* domains for IPv6 address-to-host name translation. This kind of mapping is useful for producing output (host names) that is easy to read. An in-addr.arpa name is composed of the reverse octet order of an IP address concatenated with the *in-addr.arpa* string. For example, a host named `Host1` has `9.67.43.100` as an IP address. The in-addr.arpa domain translates the `Host1` IP address `9.67.43.100` to `100.43.67.9.in-addr.arpa`.

For IPv6 reverse lookups, BIND 9 supports the *bitstring* and *nibble* formats.

A system administrator can name the host systems and domains in the local, private network with any name you want, but to link with name servers in a public network like the Internet, you need to determine which domain you want to be in (which parent domain) and then contact the registrar in that domain to register the names and IP addresses of your name servers. This ensures that queries from outside the domain being defined can be answered by this name server if need be.

Note: Contact the InterNetwork Information Center (InterNIC) for more information about Internet registration. You can contact InterNIC by pointing your Web browser at http://www.internic.net.

Domain names

The DNS uses a hierarchical naming convention for naming hosts. Each host name is composed of domain labels separated by periods. Local network administrators have the authority to name local domains within an intranet. Each label represents an increasingly higher domain level within an intranet. The fully qualified domain name of a host connected to one of the larger intranets generally has one or more subdomains:

- *host.subdomain.subdomain.rootdomain*
- *host.subdomain.rootdomain*

Domain names often reflect the hierarchy level used by network administrators to assign domain names. For example, the domain name `eng.mit.edu.` is the fully qualified domain name, where `eng` is the host, `mit` is the subdomain, and `edu` is the highest level domain (root domain).

Figure 82 is an example of the DNS used in the hierarchy naming structure across an intranet.

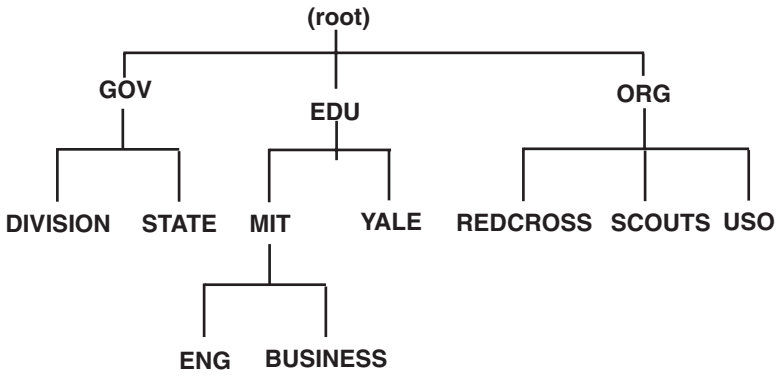

Figure 82. Hierarchical naming tree

You can refer to hosts in your domain by host name only; however, a name server requires a fully qualified domain name. The local resolver appends the domain name before sending the query to the Domain Name Server for address resolution.

Domain name servers

Domain name servers are designated network nodes that maintain a database of information about all nodes in some part of the domain name space, called a *zone*. A name server is said to be *authoritative* for its zone. A zone consists of the resources within a single domain (for example, commercial or `.com`) or subdomain (for example, `raleigh.ibm.com`). Typically, a zone is administered by a single organization or individual. The complete database is not kept by any one name server on a network. A name server is authoritative only within its zone of authority.

All host systems in a given zone share the same higher level domain name (for example, `host1.raleigh.ibm.com`, `host2.raleigh.ibm.com`, `host3.raleigh.ibm.com`, and so on). As system administrator, you create a zone of authority by listing all the host systems in your zone in the database file of the name server that is authoritative for the zone.

If a domain name server receives a query about a host for which it has information in its database or in its cache, it performs the name resolution and returns all the address records associated with the host to the client. Some hosts (for example, routers or gateways between two or more networks) might have more than one IP address.

Alternatively, the name server can query other name servers for information. This process is called *iterative resolution*. The local name server successively queries other name servers, each of which responds by referring the local name server to a remote name server that is closer to the name server authoritative for the target domain. Finally, the local name server queries the authoritative name server and

gets an answer. If the information about a requested host name does not exist or if a name server does not know where to go for the information, it sends a negative response back to the client.

There are multiple name server modes in the DNS:

- Authoritative
  - Master (primary)
  - Secondary
- Caching-only servers
- Forwarders
- Stealth

A single server can perform multiple functions. For example, it can be a primary server and a secondary server for different zones. The purpose of having these different kinds of servers is to provide redundancy (in case of system failure), to distribute the workload among multiple servers, to speed up the name-resolution process, and to provide flexibility in network design. In addition to being an authoritative or caching-only server, a name server can be defined to only contact a specific set of name servers if queries cannot be resolved locally (through the use of forwarders).

The following subtopics discuss authoritative servers, caching-only servers, and forwarding.

Authoritative servers

An authoritative server is the authority for its zone. It queries and is queried by other name servers in the DNS. The data it receives in response from other name servers is cached. Authoritative servers are not authoritative for cached data.

There are two types of authoritative servers: master (primary) and secondary. Each zone must have only one master name server, and it should have at least one secondary name server for backup to minimize dependency on a particular node. Calling a *particular* name server a master or secondary server is misleading. Any given name server can take on either or both roles, as defined by the conf file.

The zone data updates and maintenance are reflected in the master name server. The secondary name servers update their databases by contacting the master name server at regular intervals or possibly (BIND 9) after being notified of an update by the master name server. Both master and secondary name servers are authoritative for a zone.

The zones of authority are arranged in a hierarchy based on the domain origin components. A special zone known as the *root* exists at the top of the domain name hierarchy in a network. The root zone contains a list of all the root servers. For example (see Figure 82 on page 777), in the Internet, the root name servers store information about nodes in the root domain, and information about the delegated domains, such as `com` (commercial), `edu` (education), and `mil` (military). The root name servers store the names of name servers for each of these domains, which in turn store the names of name servers for their delegated subdomains.

TCP/IP applications contact a name server whenever it is necessary to translate a domain name into an IP address, or when information is required about a domain. The name server performs the translation if it has the necessary information. If it does not have the necessary information, the name server can contact other name servers, which in turn can contact other name servers. This process is called a

recursive query. Alternatively, a name server can simply return the address of another name server that might hold the requested information. This is called a *referral response* to a query. Name server implementations must support referrals, but are not required to perform recursive queries. See "Resolvers" on page 780 for more information about query responses.

Master name servers: A master name server maintains all the data for its zone. Static resources are kept in database files called *domain data files*. For information on creating domain data files, see "Step 4: Create the domain data files (master name server only)" on page 787. Master name servers can also receive zone updates dynamically.

Secondary name servers: A secondary name server acts as an alternate to the master server if the master name server becomes unavailable or overloaded. The secondary name server receives zone data directly from the master name server in a process called *zone transfer*. Zone transfers, which only occur when data has changed, are based on the refresh interval in the Start of Authority (SOA) resource record or, for BIND 9 name servers only, on using the DNS Notify function. For a description of the SOA resource record, see *z/OS Communications Server: IP Configuration Reference*. A secondary server, like a master server, is authoritative for a zone.

Caching-only servers

All name servers cache (store) the data they receive in response to a query. A caching-only server, however, is not authoritative for any domain. Responses derived from cached information are flagged in the response. When a caching-only server receives a query, it checks its cache for the requested information. If it does not have the information, it queries a local name server or a root name server, passes the information to the client, and caches the answer for future queries. The names and addresses of the root name servers are acquired from the servers listed in the hints file, the name and file path of which are specified in the name server's configuration file.

You can manually configure a name server to create a large cache of responses to queries that are frequently requested and reduce the number of queries made to master servers. The name server that you configure as a caching-only server stores data for a period of time determined by the time-to-live (ttl) value, and the cached information is lost if the name server is restarted. For more information, see "Configuring a caching-only name server" on page 802.

Tip: As an alternative to manually configuring a caching-only server, you can use the cache that the resolver creates. The resolver cache is enabled by default and typically provides better system performance than using a caching-only name server that you have configured manually. For more information about using, configuring, and managing the resolver cache, see "Resolver caching" on page 744.

Forwarders

Normally, name servers answer queries from cached data or, if that does not succeed, they attempt to contact other name servers identified in their data files as authoritative for certain domains. However, name servers can also be configured to contact special servers called *forwarders* before contacting the name servers listed in their data files. If a forwarder cannot process the query and if the local name server is not a forward-only name server, the local name server contacts the name servers in its data files. A forward-only name server relies completely on its forwarders. It does not try to contact other servers to find out information if the forwarders do not give it an answer.

The forwarding function is useful for reducing the number of queries to servers on the Internet and for creating a large cache of information on forwarders. It is also a useful function for providing Internet access for local servers that, for one reason or another, do not have access themselves.

Stealth server

A *stealth server* is a server that answers authoritatively for a zone, but is not listed in that zone's NS records. Stealth servers can be used as a way to centralize distribution of a zone, without having to edit the zone on a remote name server. When the master file for a zone resides on a stealth server in this way, it is often referred to as a *hidden primary* configuration. Stealth servers can also be a way to keep a local copy of a zone for rapid access to the zone's records, even if all official name servers for the zone are inaccessible.

Resolvers

Programs that query a name server are called *resolvers*. Because many TCP/IP applications need to query the name server, a set of routines is usually provided for application programmers to perform queries. On z/OS, these routines are available in the resolver provided by z/OS Communications Server.

z/OS Communications Server provides programs for interactively querying a name server:

- NSLOOKUP (TSO)
- onslookup/nslookup (z/OS UNIX)
- DIG (TSO)
- dig (z/OS UNIX)
- host

Note: The nsupdate program also makes queries to name servers as part of its operations.

For information on these programs, see *z/OS Communications Server: IP System Administrator's Commands*.

The BIND 9 **onslookup** and **dig** commands use the resolver initialization facilities of the resolver provided by z/OS Communications Server, but use their own resolver for any additional resolver facilities needed.

Resolver directives for nslookup

The onslookup program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr
- sortlist
- options debug/options ndots

Resolver directives for dig

The dig program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr

- options ndots

Query Packets

Resolvers operate by sending query packets to a name server, either over the network or to the local name server.

A query packet contains the following fields:

- Domain name
- Query type
- A query class

For information on valid query class (network class) and query type (data type) values, see *z/OS Communications Server: IP Configuration Reference*. The name server attempts to match the three fields of the query packet to its database. For flexibility, the following wildcard query types are defined:

Type	Description
ANY	Indicates any record type for the domain name.
AXFR	Indicates the query type used by secondary name servers to transfer all records in the zone. (The query class is set to IN when using the AXFR query type.)
MAILB	Indicates any mailbox records for the domain name.

The name server can return the following query responses:

Response	Description
Authoritative	Is returned from a primary or secondary name server. The name server contains all the domain data used to define the zone for the specified query.
BADVERS	The name server received a request that contained a EDNS0 version that was not valid.
Nonauthoritative	Is returned from a cache kept by a name server. The cache does not contain the domain data used to define the zone for the specified query.
Format Error	The name server found an error in the query packet sent by the resolver.
Name Error	No resource records of any type (including wildcards) exist for the domain name specified.
NXDOMAIN (negative)	No records of the requested type were found for the domain name specified.
Not-implemented	The name server does not support the type of query requested.
NOTAUTH	The name server is not authoritative for the zone.
NOTZONE	A dynamic update failed because the name to be updated is not contained within the given zone.
NXRRSET	A dynamic update failed because the prerequisites were not satisfied. The Resource Record set existed when the prerequiste stated it should not.
Referral	Contains the addresses of other name servers that might be able to answer the query. A referral response is returned when a recursive query is not supported, not requested, or cannot be answered because of network connectivity.

Response	Description
Refused	The name server refuses to perform the specified operation. For example, some root name servers limit zone transfers to a set number of IP addresses.
YXDOMAIN	DNAME mapping failed because the new name was too long.
YXRRSET	A dynamic update failed because the prerequisites were not satisfied. The Resource Record set did not exist when the prerequiste stated it should.

Resource Records

Data from a name server is stored and distributed in a format known as a resource record. Resource record fields are described in detail in *z/OS Communications Server: IP Configuration Reference*. Each response from a name server can contain several resource records, which can contain a variety of information. The format of a response is defined in RFC 1035. It includes the following sections:

- A question section, echoing the query for which the response is returned.
- An answer section, containing resource records matching the query.
- An additional section, containing resource records that do not match the query, but might provide useful information for the client. For example, the response to a query for the host name of a name server for a specific zone includes the IP address of that name server in the additional section.
- An authority section, containing information specific to the type of response made to the query. If a referral is returned, this section contains the domain names of name servers that could provide an authoritative answer. If a negative response is returned indicating the name does not exist, this section contains a Start Of Authority (SOA) record defining the zone of authority of the responding name server.

Recommended reading

The latest edition of *DNS and BIND* by Paul Albitz and Cricket Liu (O'Reilly & Associates, Inc.) gives a comprehensive description of DNS and BIND. The BIND 9 name server is based upon BIND 9.2.0.

For additional information about DNS in a sysplex, see *TCP/IP in a Sysplex, SG24-5235* (IBM Redbooks).

You can subscribe to a BIND users mailing list at https://lists.isc.org/mailman/listinfo.

DNS protocols are described in various Request for Comments (RFC) papers and Internet drafts. RFCs outline existing protocols, suggest new protocols, and establish standards for the Internet protocol suite. Internet drafts are proposals, techniques, and mechanisms that document Internet Engineering Task Force (IETF) work-in-progress.

For information about obtaining RFCs, see Appendix G, “Related protocol specifications,” on page 1555.

For a list of RFCs related to DNS, see “DNS-related RFCs” on page 827.

Performance issues

The BIND 9 name server supports multithreading and DNSSEC which creates extra overhead. Multithreading might improve performance for large zones but can be a disadvantage for small zones.

Because of the multithreading, BIND 9 name servers are able to answer queries during zone transfers. BIND 9 name servers are also capable of Incremental Zone Transfers. Incremental Zone Transfer allows only the changed information in a zone to be sent to secondary name servers instead of the entire zone. If your name servers employ dynamic update for frequent zone changes, the Incremental Zone Transfer feature of BIND 9 might offer some performance advantages while reducing network traffic.

The BIND 9 name server randomizes the UDP source port that is used for processing recursive queries. Randomizing the port provides additional security against DNS spoofing. When random ports are used, the CPU time used by BIND 9 can increase up to 50 percent for a recursive request. If you use the PORT or PORTRANGE statement to reserve a large portion of the UDP ports, the BIND 9 name server consumes higher amounts of CPU time and might be unable to process recursive requests. You can disable port randomization by coding `random-port-attempts 0` in the options statement. However, disabling port randomization increases the exposure to DNS spoofing attacks. When using BIND 9 in environments that might be susceptible to spoofing attacks, you can use port randomization to minimize this exposure or you can disable recursive queries in the BIND 9 name server by coding `recursion no` in the options statement. In environments with a limited number of UDP ports available to the BIND 9 name server, recursive queries should not be used in conjunction with port randomization.

The use of DNSSEC (authenticating DNS data with digital signatures) will have a performance cost. The authentication process requires more CPU, and signing a zone greatly increases the zone's size. DNS message sizes will also increase between client and server, and between DNS servers. If the message size becomes too large for UDP, the message will be sent by TCP, which is more resource intensive. Some resolvers, including the z/OS resolver, support the Extension Mechanisms for DNS (EDNS0) standards, which permit receipt of larger UDP message sizes (the default is 512 bytes) and lessens the need to use TCP for larger DNS messages. The z/OS resolver accepts UDP message sizes up to 3072 bytes in length. The BIND 9 name server supports the EDNS0 mechanisms.

Since the BIND 9 name server is multithreaded, it can take advantage of any additional processors you add to the system. The BIND 9 name server will detect the number of logical CPUs configured for the system (if not running partitioned) or LPAR (if running partitioned), and create additional worker threads accordingly. For simply configured name servers that are small, are not using DNSSEC, or are not kept busy, the overhead in managing the extra threads created on a multiprocessor image can actually be disadvantageous. If you feel this might be the case, you can override the number of worker threads created by using the *-n* option when starting the name server. The number of logical CPUs detected (and therefore, the number of worker threads created by default) is logged when the name server is started.

Setting up and running the name server

This topic describes the tasks involved in configuring the name server and verifying that the name server is working correctly.

Name server configuration files must exist in the z/OS UNIX file system. Before configuring DNS, the TSO user ID from which the name server is started must have the proper authority to access the name server configuration and zone files. For a complete description of file permissions, see *z/OS UNIX System Services Planning*.

Requirement: When you are starting the name server from a start procedure or from the z/OS UNIX shell command line, ensure that the user is defined as a superuser [UID(0)] or is permitted access to the BPX.SUPERUSER profile. For instructions on how to set up permissions to BPX.SUPERUSER, see the steps for setting up BPX.SUPERUSER in *z/OS UNIX System Services Planning*. Also see *z/OS UNIX System Services Planning* for instructions on changing a superuser from UID(0) to a unique nonzero UID.

Configuring a master (primary) name server

The name resolution process is an example of a client/server relationship in which clients, through their resolvers, request a service (name resolution) from name servers. For a general overview of name servers, see "Domain name servers" on page 777.

The following summary lists the steps for configuring a master server or a caching-only server:

1. Create a configuration file for BIND 9–DNS.
2. Specify port ownership.
3. Update the name server start procedure.
4. Create the domain data files (master name server only).
5. Create the hints (root server) file.
6. Create the loopback file.
7. Configure logging.
8. Ensure that the syslog daemon is running on your system.
9. Specify whether the name server is to run as swappable or nonswappable.
10. Start the name server.
11. Verify that the name server started correctly.
12. Verify that the name server can accept queries.

The difference between configuring a master (primary) name server and secondary name server and caching-only servers is the creation of domain data files (the database files containing host-to-address and address-to-host mappings). The domain data files are maintained on the master name server, and the secondary name server transfers this data to its own database. Examples of secondary, caching-only, and forward-only configurations are in "Configuring a secondary name server" on page 800, "Configuring a caching-only name server" on page 802, and "Adding forwarding to your name server" on page 805.

Step 1: Create the configuration file for BIND 9–DNS

The sample BIND 9-DNS configuration file shipped in /usr/lpp/tcpip/samples/named.conf is shown below. See the program directory for its location. All zone

data files referenced within the sample configuration file, with the exception of the hints file, can be found in the samples directory. To obtain the hints file, follow the instructions in "Step 5: Create the hints (root server) file" on page 790.

# IS WITH YOU.  SHOULD ANY PART OF THE SOURCE CODE EXAMPLES PROVE DEFECTIVE
# YOU ASSUME THE ENTIRE COST OF ALL NECESSARY SERVICING, REPAIR OR
# CORRECTION.
#
# Note:  This file must be copied and renamed to /etc/named.conf and all
#        all zone files referenced below must be copied to /etc/dnsdata/ for
#        this file to function as intended.  In addition, the default location
#        for the process id file is in /var/run/pid.file; if that directory
#        does not exist a different one can be configured with the option:
#
#        pid-file "path/file-name";
#
#  /etc/named.conf
#
#        conf file for name server
#

options {
   directory "/etc/dnsdata";
};

logging {
   category "queries" {
      default_syslog;
   };
};

zone "mycorp.com" in {
   type master;
   file "db.mycorp.v9";
};

zone "34.37.9.in-addr.arpa" in {
   type master;
   file "db.34.37.9.v9";
};

zone "0.0.127.in-addr.arpa" in {
   type master;
```

```
   file "db.loopback.v9";
};

zone "." in {
   type hint;
   file "db.cache";
};
```

Step 2: Specify port ownership

The name server uses a single port (53) for TCP and UDP sessions. A BIND 9 server can specify IP addresses to listen on and from which to send queries, notifies, and zone transfers in its configuration file.

To specify port ownership when using the named start procedure for BIND 9, add the following statements to the PROFILE.TCPIP data set:

```
PORT
  53 TCP NAMED1
  53 UDP NAMED1
```

Notes:

1. The jobname on the TCP and UDP port reservation statements requires a suffix of *1* for BIND 9.
2. PORT 53 UDP can only be reserved for one jobname because of a TCP/IP profile restriction.
3. Jobname/step is unpredictable if the name server is directly started from the z/OS UNIX shell.
4. Whether started from an MVS procedure or the z/OS UNIX shell, the port can be generically reserved to UNIX applications: PORT 53 TCP (also UDP) OMVS.

For more information on the PORT statement, see *z/OS Communications Server: IP Configuration Reference*.

Note: In order to pick up changes in the PROFILE.TCPIP data set, stop and restart TCP/IP. As an alternative to stopping the stack, use the VARY TCPIP,,OBEYFILE command to reserve the ports while the stack is up.

Step 3: Update the name server start procedure (optional)

When choosing to start the name server from MVS, create a start procedure. This is not necessary if the name server is started from the z/OS UNIX shell. Move the sample start procedure, `SEZAINST(NAMED)`, to a recognized PROCLIB. Specify name server parameters and change the data set names as required to suit local configuration. The conf file path can also be changed as shown in the sample start procedure. If you want to have NAMED messages written out to SYSLOGD instead of the system console (syslog), then you must start NAMED via BPXBATCH.

```
//*
//* TCP/IP for MVS
//* SMP/E Distribution Name: EZANSPR9
//*
//*        Licensed Materials - Property of IBM
//*        This product contains "Restricted Materials of IBM"
//*        5694-A01 Copyright IBM Corp. 2001, 2009.
//*        All rights reserved.
//*        US Government Users Restricted Rights -
//*        Use, duplication or disclosure restricted by
//*        GSA ADP Schedule Contract with IBM Corp.
//*        See IBM Copyright Instructions.
```

```
//*
//*        NAMED can be started with a variety of parameters.
//*        In this example, the "-c" parameter describes which
//*        configuration file NAMED should be started with.
//*
//NAMED    PROC C='/etc/named.conf'
//NAMED    EXEC PGM=BPXBATCH,REGION=0K,TIME=NOLIMIT,
//         PARM='PGM /usr/lpp/tcpip/sbin/named -c &C '
//*
//*        NAMED can use certain environmental variables, such
//*        as NLSPATH (to determine the location of the message
//*        catalog), and RESOLVER_CONFIG (to determine the location
//*        of the file that contains the parameter TCPIPjobname).
//*        These variables can be specified in a file defined
//*        by STDENV.
//*        An example of the contents of this file follows:
//*
//*             RESOLVER_CONFIG=//'SYS1.TCPPARMS(TCPDATA2)'
//*                          or
//*             RESOLVER_CONFIG=/etc/resolv.conf.tcp2
//*
//*        Define STDENV with the name of the file that contains
//*        the environmental variables to be used for this
//*        invocation of NAMED.
//*
//*STDENV   DD PATH='/etc/named.env',
//*            PATHOPTS=(ORDONLY)
//*STDENV  DD DSN=SAMPLE.NAMED(ENV&SYSCLONE),DISP=SHR
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//SYSIN    DD DUMMY
//SYSERR   DD SYSOUT=*
//SYSOUT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//CEEDUMP  DD SYSOUT=*
```

Step 4: Create the domain data files (master name server only)

The domain data files contain information about a domain, such as the IP addresses and names of the hosts in the domain for which the master name server is authoritative. The *forward* domain data file contains entries that provide forward mapping (host names-to-IP addresses for each host system in the zone) as well as additional information about system resources. The *reverse* domain data file contains entries that provide reverse mapping (IP addresses-to-host names). A separate reverse domain data file for each network (or subnet) in a domain can be created.

Note: The TSO user ID from which the name server is started must have the proper authority to access the name server configuration and zone files. For a complete description of file permissions, see *z/OS UNIX System Services Planning*.

Naming of domain data files is flexible. For convenience in maintaining the database files, it is common to give them names such as *db.extension*, where *extension* identifies the domain of the data contained within. This information uses this convention. It also uses the suffix *.bak* to specify a secondary server backup file.

Use the following to create domain data files:

- Control entries
- Resource records

- Special characters

Note: See *z/OS Communications Server: IP Configuration Reference* for more information about these files.

The sample forward domain file, /usr/lpp/tcpip/samples/db.mycorp.v9, is listed below. The file would be /etc/dnsdata/db.mycorp.v9.

ftp                IN   CNAME ns2
```

{1}
The rules for time-to-live values have been complicated somewhat in BIND v9. If named finds a $TTL directive it follows TTL semantics defined in RFC 2308, which states that records not explicitly setting a TTL inherit the TTL from the $TTL value. If there is no $TTL set, it follows TTL semantics from RFCs 1034 and 1035, which state that records with no explicit TTL inherit one from the previous record. This implies that to follow RFC 1034/1035 semantics, the SOA RR must set its TTL value. For simplicity, it is recommended that you always specify a $TTL value. This line sets the default TTL for all records to 86400 seconds (one day).

{2}
The SOA (Start of Authority) record specifies the name server ns1 as the authoritative name server for the domain mycorp.com. The mail address of the person responsible for domain data is admin@mycorp.com. The numbers enclosed in parentheses are parameters used to set different values for the zone.

{3}
The last SOA value represents length of time other servers should cache negative responses from this zone. This line sets that value to 86400 seconds (1 day).

{4}
The control entry $ORIGIN appends the string mycorp.com. to all the following host names that do not end with a dot ('.').

{5}
The NS (Name Server) records specify the name servers in the zone. Note that NS records do not distinguish between primary and secondary name servers.

{6}
The SRV records specify the location for the 'http' service using the 'tcp' protocol. The first record has a priority of 0, a weight of 0, uses port 80 and the service is provided at host, www.mycorp.com. The second record has a priority of 10 which is lower, a different port and target. A web client capable of using SRV records requesting http://mycorp.com/ would be directed to www.mycorp.com and www2.mycorp.com. The client would be responsible for determining which site to connect to first based first on priority and then on weight.

{7}
The SRV record also specifies the location for the 'http' service using the 'tcp' protocol. A web client capable of using SRV records requesting http://w3.mycorp.com/ would also be directed www.mycorp.com and www2.mycorp.com.

{8}
These A (Address) records map the host name (gateway.mycorp.com) to the IP addresses of the two networks to which it is connected.

{9}
The AAAA IPv6 record type sets the IPv6 address of www.mycorp.com to 3ffe:8050:201:1860:42::1.

{10}
The A6 IPv6 record type is an experimental way of specifying IPv6 addresses. This record sets the address of www.mycorp.com to 3ffe:8050:201:1860:42::1. The '0' indicates that the address value is fully qualified (starts at bit 0). See the most recent edition of DNS and BIND by Cricket Liu and Paul Albitz (O'Reilly and Associates, Inc.) for more information on A6 records.

```
{11}
    The CNAME record specifies that the name mail is an alias for the host name
ns1.mycorp.com.
```

The sample reverse domain file /usr/lpp/tcpip/samples/db.34.37.9.v9 is listed below. Continuing the example, the file would be /etc/dnsdata/db.34.37.9.v9.

```

6             IN      PTR    www.mycorp.com.
7             IN      PTR    www.mycorp.com.

20            IN      PTR    printserver.mycorp.com.

{1}
  $GENERATE is a v9-specific directive that is useful for creating a series of
records that differ only by an iterator.  This line prompts the name server to
create the records listed below upon zone load.  For more information on
$GENERATE, refer to the z/OS Communications Server:  IP Configuration Reference.
```

Note: Data files created locally for use by the name server are assumed to be in code page IBM-1047. For systems using other code pages, use the `iconv` command to translate from the local code page to code page IBM-1047. See *z/OS UNIX System Services Command Reference* for more detailed information about this command. Files read through a network connection (for example, secondary data files) are converted to IBM-1047 by the name server before they are written to the local file system.

FTP can also be used to convert the files to code page IBM-1047.

Step 5: Create the hints (root server) file

The hints file contains the names and IP addresses of the authoritative root domain name servers. The root name servers contain the names of name servers in the top-level domains such as com, edu, and mil. The name server uses root server information when deciding which name server to contact when it receives a query for a host outside its zone of authority and it does not have the data in its cache.

Note: The hints file does not contain cached data nor does the name server provide other hosts with the information contained in the hints file. A forward-only server is the only type of name server that does not require a hints file.

To obtain a hints file, point your Web browser at `ftp://ftp.rs.internic.net` and retrieve the file `named.root` from the `domain` subdirectory. Update your hints file on a regular basis.

The hints file in a BIND 9 config file is specified with a zone{} statement of type 'hints'.

An example of a hints file originally copied from `ftp://ftp.rs.internic.net/domain/named.root` is listed below. Continuing the example, the file would be /etc/dnsdata/db.cache.

```
;   This file holds the information on root name servers needed to
;   initialize cache of Internet domain name servers
;   (e.g., reference this file in the
;   zone "." { type hint; file "db.cache"; };
;   in the configuration file of BIND domain name servers).
;
;   This file is made available by InterNIC registration services
;   under anonymous FTP as
;   file                    /domain/named.root
;   on server               FTP.RS.INTERNIC.NET
;   -OR- under Gopher** at RS.INTERNIC.NET
;       under menu          InterNIC Registration Services (NSI)
;         submenu           InterNIC Registration Archives
;       file                named.root

; End of File
```

Step 6: Create the loopback file

The loopback file contains the loopback address. This is the address that a host uses to route queries to itself. The preferred loopback address is `127.0.0.1`, although you can configure additional loopback interfaces in the PROFILE.TCPIP. BIND 9 mode requires the availability to bind onto loopback address 127.0.0.1.

This guide uses the extension `.loopback` to specify the loopback file.

Note: In addition to creating the loopback file, add an address resource record called *localhost* to the forward domain data file. This record supports proper two-way resolution.

Use the following elements to create the loopback file:

- Control entries
- Resource records
- Special characters

Note: See *z/OS Communications Server: IP Configuration Reference* for more information about these files.

The sample loopback file for BIND 9 shipped in /usr/lpp/tcpip/samples/db.loopback.v9 is listed below. Continuing the example, the file would be /etc/dnsdata/db.loopback.v9.

```
;           LICENSED MATERIALS - PROPERTY OF IBM
;             "RESTRICTED MATERIALS OF IBM"
;          5694-A01 (C) COPYRIGHT IBM CORP. 2001
```

```
;

0.0.127.in-addr.arpa.   IN   NS  ns1.mycorp.com.
0.0.127.in-addr.arpa.   IN   NS  ns2.mycorp.com.
1.0.0.127.in-addr.arpa. IN   PTR localhost.
```

A separate loopback file is required for use with the IPv6 loopback address (::1). The following shows an example named.conf configuration and the associated zone file.

```
IPv6 loopback master zone simple definition in named.conf: zone
"1.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.0.ip6.arpa" { type master; file "loopback.v6"; };

loopback.v6 zone file (with implied domain origin from above master zone definition)

$TTL 86400
@   IN SOA ns1.mycorp.com. admin.mycorp.com. (
     1
     10800
     3600
     604800
     7200 )
        NS ns1.mycorp.com.
        PTR localhost.
```

Step 7: Configure logging

A wide variety of logging options for the name server can be configured with the *logging* statement. Its *channel* phrase associates output methods, format options and severity levels with a name that can then be used with the *category* phrase to select how various classes of messages are logged.

Only one *logging* statement is used to define as many channels and categories as are wanted. If there is no logging statement, the logging configuration will be:

```
logging {
     category "default" { "default_syslog"; "default_debug"; };
  };
```

In BIND 9, the logging configuration is only established when the entire configuration file has been parsed. When the server is starting up, all logging messages regarding syntax errors in the configuration file go to the default channels. Therefore, if started from a procedure, the logging messages will be written to syslogd. If started from z/OS UNIX, the logging messages may be written to 'named.run' if started with the **-d** option, in addition to syslog.

All log output goes to one or more channels; you can make as many of them as you want. Every channel definition must include a clause that says whether messages selected for the channel go to a file, to a particular syslog facility, or are discarded. It can optionally also limit the message severity level that will be accepted by the channel (the default is *info*), and whether to include a named-generated time stamp, the category name, the severity level, and the thread ID (the default is to include all).

Messages written to logging files can be buffered according to the value on the *max-buffered-messages* options statement. The default value is the maximum allowed value of 35. Buffering messages to logging files will provide some amount of a performance advantage. However, it might be misleading when viewing a logging file while the name server is running, since the most recent logging information might not have been written yet to the file.

The word *null* specified as the destination option for the channel will cause all messages sent to it to be discarded; in that case, other options for the channel are meaningless.

The *file* names the path name for the log file and can include limitations, both on how large the file is allowed to become and how many versions of the file will be saved each time the file is opened.

The *size* option for files is simply a hard ceiling on log growth. If the file ever exceeds the size and the version is zero, then named will not write anything more to it until the file is reopened, which will be done after the file is renamed or erased. If version option value is 1 or more, the current file, when full, is renamed with a suffix and another file is opened with the original name. In the latter case, logging will continue in a round robin fashion using the current file name and the suffixed file names. The default behavior is not to limit the size of the file. Note that if debug is enabled, the logs can grow large very quickly and you might run the risk of filling up your z/OS UNIX file system. Therefore, you should limit the size of the file when debugging is enabled.

If you use the *version* log file option, then named will retain that many backup versions of the file by renaming them when opening. For example, if you choose to keep 3 old versions of the file *lamers.log* then just before it is opened *lamers.log.1* is renamed to *lamers.log.2* , *lamers.log.0* is renamed to *lamers.log.1* , and *lamers.log* is renamed to *lamers.log.0* . No rolled versions are kept by default; any existing log file is simply appended. The *unlimited* keyword is synonymous with 99 in current BIND releases.

Example usage of the size and versions options:

```
channel "an_example_channel" {
        file "example.log" versions 3 size 20m;
        print-time yes;
        print-category yes;
        print-threadid yes;
    };
```

The argument for the *syslog* clause is a syslog facility. See *z/OS Communications Server: IP Configuration Reference* for more detailed parameter information.

The severity clause works like syslog's priorities, except that they can also be used if you are writing straight to a file rather than using syslog . Messages which are not at least of the severity level given will not be selected for the channel; messages of higher severity levels will be accepted. Severity level decreases from critical down to info, and further decreases from debug 1 down to debug 99.

If you are using syslog , then the syslog.conf priorities will also determine what eventually passes through. For example, defining a channel facility and severity as *daemon* and *debug* but only logging daemon.warning via syslog.conf will cause messages of severity *info* and *notice* to be dropped. If the situation were reversed, with named writing messages of only warning or higher, then syslogd would print all messages it received from the channel.

The server can supply extensive debugging information when it is in debugging mode. If the server's global debug level is greater than zero, then debugging mode will be active. The global debug level is set by starting the named server with the **-d** flag followed by a positive integer. All debugging messages in the server have a debug level, and higher debug levels give more detailed output. The maximum debug level is 99. Channels that specify a specific debug severity, for example:

```
channel "specific_debug_level" {
      file "foo";
      severity debug 3;
  };
```

will get debugging output of level 3 or less any time the server is in debugging mode, regardless of the global debugging level. Channels with *dynamic* severity use the server's global level to determine what messages to print.

The *print-* options can be used in any combination.

If the following is turned on . . .	Then the following is logged . . .
print-time	date and time
print-category	category of the message
print-severity	severity level of the message
print-threadid	the thread ID that is issuing the message

Note: *print-time* can be specified for a syslog channel, but is usually pointless since syslog also prints the date and time.

The *print-* options are always printed in the following order: time, category, severity, and thread ID. Here is an example:

```
Apr 24 09:28:05.848 queries: info: 0a923850: EZZ8828I client 127.0.0.1#20021:
                    query: host1.mycorp.com IN A
```

There are four predefined channels that are used for named's default logging as follows:

```
channel "default_syslog" {
        syslog daemon;                          // send to syslog's daemon
                                                // facility
        severity info;                          // only send priority info
                                                // and higher
    };
    channel "default_debug" {
        file "named.run";                       // write to named.run in
                                                // the working directory
                                                // Note: stderr is used instead
                                                // of "named.run"
                                                // if the server is started
                                                // with the '-f' option.
        severity dynamic                        // log at the server's
                                                // current debug level
    };
    channel "default_stderr" {                  // writes to stderr
        file "<stderr>";                        // this is illustrative only;
                                                // there's currently no way of
                                                // specifying an internal file
                                                // descriptor in the
                                                // configuration language.
        severity info;                          // only send priority info
                                                // and higher
    };
```

```
    channel "null" {
       null;                                    // toss anything sent to
                                                // this channel
 };
```

The *default_debug* channel normally writes to a file named.run in the server's working directory. For security reasons, when the **-u** command line option is used, the named.run file is created only after named has changed to the new UID, and any debug output generated while named is starting up and still running as root is discarded.

Once a channel is defined, it cannot be redefined. Thus you cannot alter the built-in channels directly, but you can modify the default logging by pointing categories at channels you have defined.

There are many categories, so you can send the logs you want to see wherever you want, without seeing logs you do not want. If you don't specify a list of channels for a category, then log messages in that category will be sent to the *default* category instead. If you don't specify a default category, the following "default default" is used:

```
category "default" { "default_syslog"; "default_debug"; };
```

As an example, say you want to log security events to a file, but you also want to keep the default logging behavior. You would specify the following:

```
channel "my_security_channel" {
    file "my_security_file";
    severity info;
};
category "security" {
    "my_security_channel";
    "default_syslog";
    "default_debug";
};
```

To discard all messages in a category, specify the null channel:

```
category "xfer-out" { "null"; };
category "notify" { "null"; };
```

In the following example:

- Four channels have been defined to make it possible to browse and keep logs for some categories separately. In theory, each category can log to one or more different channels, but keeping the number of channels to a minimum is recommended.
- Most existing categories have been specifically associated with one or more channels to demonstrate logging flexibility. However, categories directed to the main log only may be omitted and instead, covered by the default category. One exception is the *queries* category, which requires a specific channel association to enable queries logging.
- Every channel log entry will be prefixed with time stamp, category, severity, and thread ID.

  Note: The default for all print- options is *yes*.
- Every channel has been customized for maximum file size and for keeping 2 archived files in addition to the active log file. Make sure the disk has enough space for the total maximum size of active and archived log files, and extra space for any other growing logs or files.

- Every channel but transfer_log will log messages up to debug level 99 which is the suggested detailed level to gather problem documentation but can fill up logging files quickly. Lower debug levels (e.g. 11, info, error) may be used for normal operation.
- - transfer_log is shown at debug level 7, where minimal zone transfer starting and stopping activity is recorded. Increasing level to 8 and above will considerably increase logging activity, mainly for large zones with one-answer transfer format.
- "severity dynamic;" can also be set for any channel, in which case debug level is determined by named **-d** start option value.
- The default_debug channel can be specified instead of one or more user defined channels, in which case logging goes to "named.run" file in the named working directory. No maximum file size will stop logging to named.run.

```
logging {
 channel main_log {
      file "/tmp/named_main.log" versions 2 size 20M;
      print-time yes;
      print-category yes;
      print-severity yes;
      print-threadid yes;
#     severity debug 99;
  severity info;
 };
 channel security_log {
      file "/tmp/named_security.log" versions 2 size 1M;
      severity info;
#     severity debug 99;
 };
 channel query_log {
      file "/tmp/named_query.log" versions 2 size 10M;
 #    severity debug 99;
  severity info;
 };
 channel transfer_log {
      file "/tmp/named_transfer.log" versions 2 size 10M;
      severity debug 7;
                       };

     category client   { main_log; };
     category config   { main_log; };
     category database { main_log; };
     category dispatch { main_log; };
     category dnssec { security_log; main_log; };
     category general  { main_log; };
     category network  { main_log; };
     category notify   { main_log; };
     category resolver { main_log; };
     category security { security_log; main_log; };
     category update   { main_log; };
     category queries  { query_log;};
     category lame-servers { query_log; main_log; };
     category xfer-in  { "transfer_log"; };
     category xfer-out { "transfer_log"; };
     category default  { main_log; };
     category unmatched { main_log; };
        };
```

More detail about the available categories and brief descriptions of the types of log information they contain can be found in the *z/OS Communications Server: IP Configuration Reference*.

Step 8: Ensure that the syslog daemon is running on your system

The name server uses the syslog daemon to log messages. To verify that the name server starts correctly or to diagnose problems, the syslog daemon should be running.

Guideline: Unless syslogd is running, no messages will be produced by NAMED during name server initialization. This includes event logging and any syntax errors that might be detected in the configuration file. Not performing this step complicates problem determination, especially for failures at startup.

If your syslog daemon is not configured, see "Creating the syslog file" on page 806 for information regarding the syslog daemon.

Step 9: Specify whether the name server is to run as swappable or nonswappable

You might want to run the name server in a swappable state, as it has in the past. This is an optional step. Keep in mind that when an application makes an address space nonswappable, it might convert additional real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing the name server to run in a nonswappable state can reduce the installation's ability to reconfigure storage in the future.

If you want to run the name server as swappable, you must have the BPX.STOR.SWAP resource in the FACILITY class defined to RACF with no universal access. To do this, enter the following commands from a RACF user ID.

```
RDEFINE FACILITY BPX.STOR.SWAP UACC(NONE)
SETROPTS RACLIST(FACILITY) REFRESH
```

If you want the name server to run in a nonswappable state, do one of the following:

- Do not define the BPX.STOR.SWAP resource to RACF. Start the name server from a user ID with a UID equal to 0.
- Define the BPX.STOR.SWAP resource to RACF and allow the appropriate users at least READ access to the profile.

The latter method can be accomplished with the following set of commands:

```
RDEFINE FACILITY BPX.STOR.SWAP UACC(NONE)
PERMIT BPX.STOR.SWAP CLASS(FACILITY) ID(userid) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

Step 10: Start the name server

Your name server is ready to start. Start the name server using the following methods:

- An authorized TSO ID can start a name server from the MVS operator's console by starting the named start procedure. If the config file path is not `/etc`, specify the correct path in the start procedure. See *z/OS Communications Server: IP Configuration Reference* for start options. A sample start procedure is provided with the product and is found in SEZAINST(NAMED9).
- A user ID with superuser authority [UID(0)] or a user ID permitted to the BPX.SUPERUSER profile can start the name server from the shell, by starting z/OS UNIX and issuing the **named** command along with any optional parameters.

- It is also possible to start the server automatically when z/OS UNIX is started by specifying the path and file name of the z/OS UNIX initialization shell script in the /etc/init.options file using the -sc option:

  ```
  -sc /etc/rc       shell script = /etc/rc
  ```

  The file /etc/rc is the default z/OS UNIX initialization shell script that is executed when z/OS UNIX is started. Information such as the following can be entered in /etc/rc:

  ```
  # Start name server
  /usr/lpp/tcpip/sbin/named -c /named/production/named.conf &
  ```

  Port 53 may be reserved for the name server in the PROFILE.TCPIP data set. For directions on specifying port ownership, see "Step 2: Specify port ownership" on page 786. The name server may only be started after TCP/IP is up. In rare circumstances, the name server may complete initialization before all of the stack's interfaces have been brought up. In this case, the name server will not be listening on all desired interfaces. Eventually, the name server will scan the stack interfaces again, and begin listening on all desired interfaces. The default time period for this rescan is one minute. You can have the name server rescan the interfaces at the interval you desire by specifying the "interface-interval" option in the named.conf file.
- If you are starting the name server in a single stack environment, use the AUTOLOG statement to start the name server automatically during initialization with z/OS UNIX running. Insert the name of the named start procedure in the AUTOLOG statement of the PROFILE.TCPIP data set.

  ```
  AUTOLOG
    NAMED
  ENDAUTOLOG
  ```

  The JOBNAME keyword should not be added to the AUTOLOG statement for named.

  If you are starting the name server in a multiple stack environment, use some other automation outside of AUTOLOG to automatically start the name server, since it is a generic server. For more information on the AUTOLOG statement, see *z/OS Communications Server: IP Configuration Reference*.

  Note: Named cannot be started from INETD.

Step 11: Verify that the name server started correctly

After starting the name server, ensure that no errors occurred when it was started. Look at the syslog daemon output data set for name server messages. If startup is successful, messages similar to the following are displayed:

```
Mar 26 ... mvsw named[...29]: EZZ9172I VM mode detected. Using 1 CPU(s) for -n option
Mar 26 ... mvsw named[...56]: EZZ9547I starting named, BIND 9.2.0 -c /etc/namedgm.conf
Mar 26 ... mvsw named[...56]: EZZ9095I STARTING NAMED, BIND 9.2.0
Mar 26 ... mvsw named[...56]: EZZ9217I Running non-swappable
Mar 26 ... mvsw named[...56]: EZZ9540I using 1 CPU
Mar 26 ... mvsw named[...56]: EZZ9126I loading configuration from '/etc/namedgm.conf'
Mar 26 ... mvsw named[...56]: EZZ8842I the default for the 'auth-nxdomain' option is now 'no'
Mar 26 ... mvsw named[...56]: EZZ9052I no IPv6 interfaces found
Mar 26 ... mvsw named[...56]: EZZ9046I listening on IPv4 interface VLINK1, 9.67.116.122#53
Mar 26 ... mvsw named[...56]: EZZ9046I listening on IPv4 interface TR1, 9.67.113.75#53
Mar 26 ... mvsw named[...56]: EZZ9046I listening on IPv4 interface loopback127, 127.0.0.1#53
Mar 26 ... mvsw named[...56]: EZZ9111I command channel listening on 9.67.113.75#953
Mar 26 ... mvsw named[...56]: EZZ9130I NAMED, BIND 9.2.0 IS RUNNING
```

To stop the name server from the z/OS UNIX shell, issue:

```
kill -TERM $(cat /etc/named.pid)
```

To stop the name server from the MVS console, issue the following:

```
p named1
(Use the name of the procedure that is currently active. This is
usually the proc name that was used to start the name server, followed
by a '1' due to extra forking steps on startup)
```

To reload the name server with a signal, issue the following command from the z/OS UNIX shell:

```
kill -HUP $(cat bind9_pid_file)
```

where *bind9_pid_file* is derived from pid-file option in named v9 configuration file.

rndc can also be used to reload or stop the server. See "Remote Name Daemon Control" on page 807 for more details on the rndc command.

Step 12: Verify the name server can accept queries

When the name server is up with no logged errors, ensure that it can accept queries. Ensure that the name server can accept queries locally from both the MVS and z/OS UNIX environments. In order to correctly set up these environments, see "Understanding search orders of configuration information" on page 19 for instructions.

After the resolver configuration is correct, test with the **nslookup** or **dig** command. An example using nslookup follows.

Issue the following command from both the z/OS UNIX shell and the TSO ready prompt. In the following example, the name 'host1.mycorp.com.' is used for the search.

Note: Choose any name in the domain you have defined.

```
nslookup host1.mycorp.com
```

Using the sample files in this example, the following should be the result when the command is issued:

```
$ nslookup host1.mycorp.com
Running nslookup version 9
Note:  nslookup is deprecated and may be removed from future releases.
Consider using the `dig' or `host' programs instead.  Run nslookup with
the `-sil[ent]' option to prevent this message from appearing.
Allocated socket 5, type udp
Server:         9.42.106.2
Address:        9.42.106.2#53

Non-authoritative answer:
Name:   host1.mycorp.com
Address: 9.37.34.1
```

Configuring a secondary name server

After setting up a working master name server, you can set up one or more secondary name servers. This process is very similar as configuring a master name server. The differences are in the conf file and the absence of the domain data files.

For example, see "Configuring a master (primary) name server" on page 784 to configure a secondary server for the forward and reverse mapping zones. The steps are identical to the steps for configuring a master name server, except for step 1. For step 1, more information is included in the subtopics following the steps.

1. Create the configuration file for BIND–DNS. See “Step 1: Create the configuration file for BIND 9-DNS.”
2. See “Step 2: Specify port ownership” on page 786.
3. See “Step 3: Update the name server start procedure (optional)” on page 786.
4. See “Step 4: Create the domain data files (master name server only)” on page 787.
5. See “Step 5: Create the hints (root server) file” on page 790.
6. See “Step 6: Create the loopback file” on page 792.
7. See “Step 7: Configure logging” on page 793.
8. See “Step 8: Ensure that the syslog daemon is running on your system” on page 798.
9. See “Step 9: Specify whether the name server is to run as swappable or nonswappable” on page 798.
10. See “Step 10: Start the name server” on page 798.
11. See “Step 11: Verify that the name server started correctly” on page 799.
12. See “Step 12: Verify the name server can accept queries” on page 800.

The difference between configuring a master and secondary name server is the creation of domain data files (the database files containing host-to-address and address-to-host mappings). The domain data files are maintained on the master name server, and the secondary name server transfers this data to its own database.

For instructions to create the configuration file for a secondary name server, see “Step 1: Create the configuration file for BIND 9-DNS.” All remaining steps are identical to those in “Configuring a master (primary) name server” on page 784.

Step 1: Create the configuration file for BIND 9-DNS

This example illustrates the equivalent configuration for a v9 name server where the sample configuration file, /usr/lpp/tcpip/samples/slave.conf (based on named.conf), reflects the setup for a secondary name server. All zone data files referenced within the sample configuration file, with the exception of the hints file, can be found in the samples directory. To obtain the hints file, follow the instructions in “Step 5: Create the hints (root server) file” on page 790.

zone "." in {
  type hint;
  file "db.cache";
};
```

Configuring a caching-only name server

When you are configuring a name server, decide whether the name server has to be authoritative for any data. If it does not, you can configure a special type of name server called a caching-only name server. A caching-only name server can improve performance by reducing the number of network flows required for names or addresses that are frequently requested. This topic explains how to manually configure a caching-only name server.

Tip: As an alternative to manually configuring a caching-only server, you can use the cache that the resolver creates. The resolver cache is enabled by default and

typically provides better system performance than using a caching-only name server that you have configured manually. For more information about using, configuring, and managing the resolver cache, see “Resolver caching” on page 744.

To manually configure a basic caching-only name server, use the following steps. More information for step 1 is included in the subtopics following the steps. All remaining steps are identical to those described in “Configuring a master (primary) name server” on page 784

1. Create the configuration file for BIND 9–DNS. See “Step 1: Create the configuration file for BIND 9-DNS.”
2. See “Step 2: Specify port ownership” on page 786.
3. See “Step 3: Update the name server start procedure (optional)” on page 786.
4. See “Step 5: Create the hints (root server) file” on page 790.

   Following is an example of a hints (root server) file for a cache-only server:

   ```
   ;
   ;  Cache-only "hints" file
   ;
   .                        3600000 IN NS   hostname
   hostname.               3600000    A    ipaddress
   ```

   where *hostname* is the fully qualified host name of an authoritative name server for the root ('.') domain and *ipaddress* is the IP address for the specified hostname. How this file is configured depends on whether you are behind a firewall or not. If behind a firewall, hostname should be the name of an internal root name server if internal roots are being used. If you are behind a firewall and not using internal roots, then requests are probably being forwarded to a name server on a bastion host, which can resolve internal and internet names. In the latter case, what is in the hints file is unimportant since it will not be used, and if the name server does attempt to use it, the firewall would block it from contacting the internet root name servers. If you are not behind a firewall, follow the example in “Step 5: Create the hints (root server) file” on page 790 and instructions on getting a recent copy of the internet root name servers.
5. See “Step 6: Create the loopback file” on page 792.
6. See “Step 7: Configure logging” on page 793.
7. See “Step 8: Ensure that the syslog daemon is running on your system” on page 798.
8. See “Step 9: Specify whether the name server is to run as swappable or nonswappable” on page 798.
9. See “Step 10: Start the name server” on page 798.
10. See “Step 11: Verify that the name server started correctly” on page 799.
11. See “Step 12: Verify the name server can accept queries” on page 800.

The difference between configuring a master name server and configuring a caching-only server is the creation of domain data files (the database files containing host-to-address and address-to-host mappings). A caching-only name server will only contain the loopback zone file and the hints file.

Step 1: Create the configuration file for BIND 9-DNS

The following sample configuration sets up an equivalent configuration for a BIND 9 name server where the sample configuration file, /usr/lpp/tcpip/samples/caching.conf (based on named.conf), reflects the setup for a caching-only name server. All zone data files referenced within the sample configuration file, with the

exception of the hints file, can be found in the samples directory. To obtain the hints file, follow the instructions in “Step 5: Create the hints (root server) file” on page 790.

#
#
# Note:  This file must be copied and renamed to /etc/named.conf and all
#        all zone files referenced below must be copied to /etc/dnsdata/ for
#        this file to function as intended.  In addition, the default location
#        for the process id file is in /var/run/pid.file; if that directory
#        does not exist a different one can be configured with the option:
#
#        pid-file "path/file-name";
#
#  /etc/named.conf
#
#        conf file for name server
#
options {
   directory "/etc/dnsdata";
};

logging {
   category "queries" {
     default_syslog;
  };
};

zone "0.0.127.in-addr.arpa" in {
  type master;
  file "db.loopback.v9";
};

zone "." in {
  type hint;
  file "db.cache";
};
```

Configuring a stealth name server

A stealth server is a server that answers authoritatively for a zone, but is not listed in that zone's NS records. Configure a master or secondary stealth server for a zone like you would configure a visible master or secondary server for the zone, except do not create an NS record for the stealth server in the master zone. The named server configuration option *also-notify* may be used to notify stealth secondary servers of a zone update. In order to configure a stealth server, follow the steps in "Configuring a secondary name server" on page 800.

Adding forwarding to your name server

In order to use forwarding in any name server, update the conf file.

Add the following statement to the conf file in the options section:

```
options {
     ..............
     forwarders {9.4.2.1;};
     ..............
};
```

where `9.4.2.1` is the IP address of the machine where queries should be forwarded. This sends unresolved queries to `9.4.2.1` before trying to resolve the query using root name servers (specified in the hints file) or other cached name servers authoritative for or 'closer' to the authoritative name server.

For a name server to *only* use forwarders and not use the root servers, in addition to the forwarders directive, also add the following directive to its conf file:

```
options {
     ..............
     forward only;
};
```

A name server with this option can still answer queries from its cached data. The cache is checked first and if the cache does not contain the answer, the query is sent to the name servers in the forwarders list.

Configuring host resolvers: Name server considerations

If the name server will run on the host being configured, create a loopback file. Specify the loopback address in the *first* name server directive of the resolver configuration file so local clients can access the name server. See "Step 6: Create the loopback file" on page 792 for loopback address considerations.

The name server and DNS utilities (for example, nslookup and z/OS UNIX dig) use a private resolver that is different from the resolver used by other z/OS UNIX socket programs. The name server has the following functional differences:

- z/OS UNIX nslookup does not use site tables (for example, /etc/hosts) for host name resolution.
- Only the built-in translation table is used for BIND 9 and all DNS utilities (for example, nslookup, dig, and so on).

For a complete discussion of resolver configuration files, see *z/OS Communications Server: IP Configuration Reference*.

Configuring host resolvers: onslookup considerations

Programs that query a name server are called resolvers. Because many TCP/IP applications need to query the name server, a set of routines is usually provided

for application programmers to perform queries. Under MVS, these routines are available in the TCP/IP application programming interface (API) for each supported language, Language Environment for z/OS UNIX C/C++ Sockets API or z/OS UNIX assembler callable services API.

The nslookup command uses a private resolver that is different from the z/OS UNIX resolver used by other z/OS UNIX socket programs. The onslookup command has the following functional differences:

- The file `/etc/hosts` is required for host table lookup if name services do not exist. Following is a sample `/etc/hosts` file:

```
#
# z/OS UNIX Resolver /etc/hosts file on mvss18oe.
#
# The format of this file is:
#
# Internet Address      Hostname   Aliases     # Comments
#
# Items are separated by any number of blanks and/or tabs.  A '#'
# indicates the beginning of a comment; characters up to the end of the
# line are not interpreted by routines which search this file.  Blank
# lines are allowed in this file.

9.24.104.126    mvs18oe mvsoe # z/OS UNIX host
192.168.210.1   mvs18an       # MVS host
192.168.210.8   mypcaa        # gw host
9.24.104.79     mypc          # A workstation
```

  Note: The presence of /etc/hosts will prevent the z/OS UNIX resolver from accessing *prefix*.HOSTS.SITEINFO and *prefix*.HOSTS.ADDRINFO data sets. The use of /etc/hosts is not recommended unless it is used for purposes other than onslookup.

- Only the built-in translation table is used.

If the z/OS UNIX name server will run on the host being configured, you need to configure the *first* name server (or NsInterAddr) directive in the resolver configuration file as the loopback address (127.0.0.1 or ::1) or any address in your home list.

Creating the syslog file

If your syslog daemon is not configured, see "Configuring the syslog daemon" on page 185 for information regarding the syslog daemon.

Syslog daemon (syslogd) is a server process that is typically started as one of the first processes in a z/OS UNIX environment. Servers and stack components use syslogd for logging purposes and can also send trace information to syslogd. The named daemon logs messages to the syslog daemon. For BIND 9, specify the *syslog* option in the *channel* phrase of the *logging* statement in the named.conf file in order to use this function. Also for BIND 9, you can direct a category to the *default_syslog* channel. For information about the syslog daemon, see "Configuring the syslog daemon" on page 185.

If you will be using syslogd with BIND 9, see "Step 7: Configure logging" on page 793 for detailed information.

The name and location of your syslog file is specified in `/etc/syslog.conf`.

BIND 9 security considerations

This topic describes BIND 9 security considerations.

Remote Name Daemon Control

Remote Name Daemon Control (rndc) is a tool that allows the system administrator some degree of control over the name server. The functions available are:

- Reload configuration file and zones.
- Reload the given zone.
- Schedule zone maintenance for the given zone.
- Reload the configuration file and load new zones, but do not reload existing zone files even if they have changed. This is faster than a full reload, when there is a large number of zones, because it avoids the need to examine the modification times of the zone files.
- Write server statistics to the statistics file.
- Toggle query logging.
- Dump the current contents of the cache.
- Stop the server, making sure any recent changes made through dynamic update or IXFR are first saved to the master files of the updated zones.
- Stop the server immediately. Recent changes made through dynamic update or IXFR are not saved to the master files, but will be rolled forward from the journal files when the server is restarted.
- Increment the server's debugging level by one.
- Set the server's debugging level to an explicit value.
- Set the server's debugging level to 0.
- Flush the server's cache.
- Display status of the server.

For more detail, see *z/OS Communications Server: IP System Administrator's Commands*, the rndc man page, the rndc.conf man page, and the rndc-confgen man page.

A configuration file is required, since all communication with the server is authenticated with digital signatures that rely on a shared secret, and there is no way to provide that secret other than with a configuration file. The default location for the rndc configuration file is /etc/rndc.conf, but an alternate location can be specified with the **-c** option. If the configuration file is not found, rndc will also look in /etc/rndc.key. The rndc.key file is generated by running **rndc-confgen -a**.

The format of the configuration file is similar to that of named.conf, but limited to only four statements:

- options
- key
- server
- include

These statements are what associate the secret keys to the servers with which they are meant to be shared. The order of statements is not significant.

The options statement has three clauses:

- default-server

- default-key
- default-port

The default-server clause takes a host name or address argument and represents the server that will be contacted if no **-s** option is provided on the command line. The default-key clause takes the key name as its argument, as defined by a key statement. The default-port clause specifies the port to which rndc should connect if no port is given on the command line or in a server statement.

The key statement names a key with its string argument. The string is required by the server to be a valid domain name, though it need not actually be hierarchical; thus, a string like "rndc_key" is a valid name. The key statement has two clauses:

- algorithm
- secret

While the configuration parser will accept any string as the argument to algorithm, currently only the string "hmac-md5" has any meaning. The secret is a base-64 encoded string.

Since the tool may be used remotely, rndc and the name server must communicate using digital transaction signatures (TSIG). Therefore, rndc and the name server must be configured with a *shared-secret*. There are two ways to configure a shared-secret key. One way is to use the /etc/rndc.key file generated by the **rndc-confgen -a** command. This file is shared between the name server and the rndc utility. The other way is to generate a shared-secret TSIG key with the HMAC-MD5 algorithm using the dnssec-keygen utility. The key must be configured in the name server under the *controls* section, and in the rndc.conf file on the key clause.

The server statement uses the key clause to associate the server with a key. The argument to the server statement is a host name or address (addresses must appear in double quotation marks). The argument to the key clause is the name of the key as defined by the key statement. The port clause can be used to specify the port to which rndc should connect on the given server.

The include statement can be used to insert the contents of another file within the rndc configuration file (for example, to include the contents of a file that contains sensitive key information).

A sample minimal configuration file is as follows:

```
key rndc_key {
     algorithm "hmac-md5";
     secret "c3Ryb25nIGVub3VnaCBmb3IgYSBtYW4gYnV0IG1hZGUgZm9yIGEgd29tYW4K";
};
options {
     default-server localhost;
     default-key    rndc_key;
};
```

This file, if installed as /etc/rndc.conf, would allow the rndc reload command to connect to 127.0.0.1 port 953 (the default port) and cause the name server to reload, if a name server on the local machine were running with the following controls statements and it had an identical key statement for rndc_key:

```
controls {
        inet 127.0.0.1 allow { localhost; } keys { rndc_key; };
};
```

Running the rndc-confgen program will conveniently create a rndc.conf file for you, and also display the corresponding controls statement that you need to add to named.conf. Alternatively, you can run **rndc-confgen -a** to set up a rndc.key file and not modify named.conf at all.

Access Control Lists

Access Control Lists (ACLs) are address match lists that you can set up and nickname for future use in allow-query, allow-recursion, blackhole, allow-transfer, and so on. Using ACLs enables you to have finer control over who can access your name server, without cluttering up your configuration files with huge lists of IP addresses. It is a good idea to use ACLs, and to control access to your server. Limiting access to your server by outside parties can help prevent spoofing and DoS (Denial of Service) attacks against your server. Here is an example of how to properly apply ACLs:

```
// Set up an ACL named "bogusnets" that will block RFC1918 space,
// which is commonly used in spoofing attacks.

acl bogusnets { 0.0.0.0/8; 1.0.0.0/8; 2.0.0.0/8; 192.0.2.0/24; 224.0.0.0/3;
10.0.0.0/8; 172.16.0.0/12; 192.168.0.0/16; };

// Set up an ACL called our-nets. Replace this with the real IP numbers.

acl our-nets { x.x.x.x/24; x.x.x.x/21; };

options {
  ...
  ...
  allow-query { our-nets; };
  allow-recursion { our-nets; };
  ...
  blackhole { bogusnets; };
  ...
};
zone "example.com" {
  type master;
  file "m/example.com";
  allow-query { any; };
};
```

This allows non-recursive queries for example.com from inside and outside nets, except from bogusnets, and allows recursive queries from our-nets to outside nets unless *recursion no;* is also specified in the configuration file.

For more information on how to use ACLs to protect your server, see AUSCERT advisory AL-1999.004 at the Australian Computer Emergency Response Team Web site.

chroot and setuid

It is possible to run BIND in a chrooted environment (**chroot()**) by specifying the **-t** option. This can help improve system security by placing BIND in a sandbox, which will limit the damage done if a server is compromised.

Another useful feature is the ability to run the daemon as a nonprivileged user (-u user). We suggest running as a nonprivileged user when using the **chroot** feature.

Here is an example command line to load BIND in a **chroot()** sandbox, **/var/named**, and to run **named setuid** to user 202:

```
<>/usr/local/bin/named -u 202 -t /var/named
```

The chroot environment: In order for a **chroot**() environment to work properly in a particular directory (for example, /var/named), you will need to set up an environment that includes everything BIND needs to run. From BIND's point of view, /var/named is the root of the filesystem. You will need /dev/null, and any library directories and files that BIND needs to run on your system.

Using the setuid function: Prior to running the **named** daemon, use the **touch** utility (to change file access and modification times) or the **chown** utility (to set the user id and/or group id) on files to which you want BIND to write.

Dynamic update security

Access to the dynamic update facility should be strictly limited. For these reasons, we strongly recommend that updates be cryptographically authenticated by means of transaction signatures (TSIG). That is, the **allow-update** option should list only TSIG key names, not IP addresses or network prefixes. Alternatively, the **update-policy** option can be used.

Some sites choose to keep all dynamically updated DNS data in a subdomain and delegate that subdomain to a separate zone. This way, the top-level zone containing critical data such as the IP addresses of public web and mail servers need not allow dynamic update at all.

General VIPA considerations

If any VIPA addresses are used for zone delegation in the name server zone data files, ensure that IPCONFIG SOURCEVIPA is coded in PROFILE.TCPIP on the host to which a delegation has been made and that the SOURCEVIPA address that is used to respond to queries matches the VIPA used in the zone delegation. If this is not done, recursive queries could fail (nslookup will fail with "No response from server", dig will respond with, "no servers could be reached"). The UDP query response packets will be discarded when they are received because the source IP address of the response will not match the destination IP address of the request. These addresses are required to match by the name server as a minimal security check.

Special considerations when using dynamic VIPA

If you run a name server on a host that is using dynamic VIPA (DVIPA), you might be required to do some additional configuration. Name servers running on a host using DVIPA need to BIND the UDP port that the name server listens on (usually 53) to the DVIPA, if you want DNS to make use of the DVIPA. This can be done by using the BIND option on the UDP PORT statement in PROFILE.TCPIP, or by using the MODDVIPA utility. If you do BIND the DNS UDP port to the DVIPA, then all references to that name server must use the DVIPA whether those references are from other name servers or from resolvers.

References to a name server could occur in a number of places, and should be changed to use the DVIPA if BINDing a DNS UDP port to the DVIPA. This list is not exhaustive, but is intended to aid you for some of the most common cases. In general, you may need to change any place that references a name server by its IP address when using DVIPAs.

Task	Location
Delegating a DNS subdomain to a name server running on a host using DVIPA	The 'A' record in the glue records for the delegated (child) name server in the domain data file of the delegating (parent) name server

Task	Location
Designating a secondary name server when master (primary) name server is running on a host using DVIPA	The 'secondary' statement in the 'masters' option of the 'zone' statement
Configuring resolvers	'NSINTERADDR' or 'nameserver' directive of the resolver configuration file
Using a name server as the target of other forwarding name servers when the target name server resides on a host using DVIPA	'forwarders' directive in the 'forwarders{}' option of the 'options{}' statement
Using a name server as an intranet root name server when the root name server is running on a host using DVIPA	'A' record of the intranet root name server in the hints file on all name servers within the intranet

Dynamic primary DNS movement using dynamic VIPA

To use DNS along with DVIPA takeover functionality to provide a high availability environment, perform the following steps:

1. Define a DVIPA. For example:

```
VIPADYNAMIC
VIPADEFINE     255.255.255.192 10.134.61.190
```

2. Define VIPABACKUPs on all the members that will be backup servers. For example:

```
VIPADYNAMIC
VIPABACKUP  50  10.134.61.190
ENDVIPADYNAMIC
```

3. Update /etc/resolv.conf and TCPDATA on all SYSPLEX members to point to that address. For example:

```
⋮
NSINTERADDR  10.134.61.190
⋮
```

4. Update all of the glue records (NS records and their corresponding A records), in the sysplex name servers and the sysplex parent's name servers that point to the sysplex name server, to use the dynamic VIPA.

After doing the above configuration, stack termination will cause the DVIPA to be taken over, making DNS on the new DVIPA owning stack reachable after route convergence completes (OMPROUTE recommended).

Querying name servers

This topic describes how to use the nslookup command to query the name server. onslookup is an alias of nslookup in the z/OS UNIX environment.

Notes:

1. The z/OS UNIX nslookup command runs only from the z/OS shell. The nslookup command can query the name server from TSO or the z/OS shell. However, only the legacy TSO version of NSLOOKUP is available from TSO. See *z/OS Communications Server: IP System Administrator's Commands* for detailed information.
2. The **host** and **dig** commands are another way to query name servers from the z/OS shell. For information on the **host** and **dig** commands, see *z/OS Communications Server: IP System Administrator's Commands*.

nslookup command

The z/OS UNIX nslookup and TSO NSLOOKUP commands can be used to query the name server to perform the following tasks:
- Identifying the location of name servers
- Examining the contents of a name server database
- Establishing the accessibility of name servers

Note: sortlist is not supported by nslookup

The z/OS UNIX nslookup and TSO NSLOOKUP commands have two modes of operation: interactive mode and command mode. The address of the default name server comes from the resolver configuration data. In the sample data below, the default domain is raleigh.ibm.com, and the default name server is at 9.37.34.149. If that name server fails to respond, the one at 9.37.34.7 is used.

```
domain   raleigh.ibm.com
nameserver   9.37.34.149
nameserver   9.37.34.7
```

Entering the interactive mode

Interactive mode can be used to repetitively query one or more name servers for information about various hosts and domains, to display that information on the console, and, in some cases, to write response data to a file.

You can enter the interactive mode under the following conditions only:
- No arguments are supplied on command invocation or the **-v** option is specified; the default name server is used.
- The first argument is a hyphen, and the second argument is the host name or Internet address of a name server.

For a complete description of the z/OS UNIX and TSO nslookup interactive modes, see *z/OS Communications Server: IP System Administrator's Commands*.

Entering the command line mode

The command line mode displays or stores the output from the query supplied as part of the invocation string and then exits.

To enter the command line mode, provide a complete query with the z/OS UNIX nslookup command invocation string.

For a complete description of the z/OS UNIX and TSO nslookup command line modes, see *z/OS Communications Server: IP System Administrator's Commands*.

nslookup configuration

There are only two places to specify **nslookup** options: as command options, or from the resolver configuration data set. Only a few of the options may be set in the resolver configuration data set. The command options always have precedence over any option configured in the resolver configuration data set.

Only the following options can be specified in the resolver configuration data set for v9 **nslookup**:
- nameserver/nsinteraddr
- options ndots: *n*
- search
- domain/domainorigin

Programs that query a name server are called resolvers. See Chapter 14, "The resolver," on page 731 for more detailed information. Because many TCP/IP applications need to query the name server, a set of routines is usually provided for application programmers to perform queries. Under MVS, these routines are available in the TCP/IP application programming interface (API) for each supported language, Language Environment for z/OS UNIX C/C++ Sockets API or z/OS UNIX assembler callable services API.

The z/OS UNIX **nslookup** command uses a private resolver that is different from the resolver used by other z/OS UNIX socket programs. The z/OS UNIX **nslookup** command has the following functional differences:

- z/OS UNIX **nslookup** does not use SiteTables (for example, /etc/hosts) for host name resolution.
- Only the built-in translation table is used for **nslookup**.

For a complete discussion of resolver configuration files, see Chapter 2, "IP configuration overview," on page 11.

If the name server will run on the host being configured, you need to configure the *first* name server (or NsInterAddr) directive in the resolver configuration file as the loopback address (127.0.0.1, ::1 or any address in your home list). If any VIPA addresses are used with the NsInterAddr statement, ensure that IPCONFIG SOURCEVIPA is coded in PROFILE.TCPIP. If it is not, UDP packets returned from the VIPA address will have the physical interface address as the destination address instead of the VIPA address that it sent. The UDP packet will be discarded when it is received because the addresses do not match.

Diagnosing problems

This topic describes the following methods for diagnosing problems:

- Checking messages on the operators console
- Checking the syslog messages
- Using name server signals
- Using rndc to diagnose BIND 9 problems
- Checking name server logging files to diagnose BIND 9
- Using nslookup program
- Using the **dig** command

These methods are discussed in the subtopics below. In addition to these methods, diagnosing problems for a dynamic zone can be done with nsupdate.

For DNS configuration firewall considerations, see "Split DNS" on page 817, and the latest edition of *DNS and BIND* by Paul Albitz and Cricket Liu (O'Reilly & Associates, Inc.).

Checking messages sent to the operators console

Messages displayed on the operators console indicate the status of your DNS. Messages fall into the following categories:

- Name server initialization
- Name server initialization failure
- Name server initialization complete
- Name server termination
- Assertion failures (unexpected errors)

Regularly check console messages to identify problems.

Checking the syslog messages

Error messages may also be displayed in the syslog output file, which is pointed to by the syslog configuration file. (`/etc/syslog.conf` is the default configuration file.) For BIND 9, see “Step 7: Configure logging” on page 793. For the BIND 9 name server, initial startup messages go to syslog, later messages will be directed to other defined or default logs according to logging statements found or implied in the configuration file. For descriptions of the syslog file and the syslog daemon, see “Configuring the syslog daemon” on page 185.

Using name server signals to diagnose BIND 9 DNS problems

You can use name server signals to send messages to a BIND 9 DNS name server. These signals control various functions that can be used to diagnose problems.

The BIND 9 name server relies on a start option, rndc, or the configuration file to define and alter the debug level. You can change the logging options in named.conf to gather more information, and then issue the SIGHUP signal or 'rndc reload' to have the new logging options take effect. However, the preferred method is by using 'rndc trace level'.

For an explanation of the format of the dumped database or the name server statistics file that can be generated with these signals, see publications like *DNS and Bind* by Albitz and Liu.

Signals are issued with the z/OS UNIX kill command using the name server process ID as a parameter. The file where the BIND 9 process ID is stored is determined by the user. The file name is specified by the 'pid-file' option in the named.conf file. See *z/OS Communications Server: IP Configuration Reference* for further details.

Using rndc to diagnose BIND 9 problems

The rndc utility can be used to provide a variety of functions that can be helpful in debugging name server problems. For example, the name server's cache can be viewed using the dumpdb parameter and debug trace can be turned on or off using the trace parameter. If you suspect your cache is corrupted, you can flush the name server's cache with the flush parameter. For more information, see *z/OS Communications Server: IP System Administrator's Commands*.

Checking name server logging files to diagnose BIND 9

Error, debug and informational messages can be written to the name server's logging files. See “Step 7: Configure logging” on page 793 for more information.

Using nslookup to diagnose problems

The z/OS UNIX nslookup program lets you query other name servers with the same query packet another name server would use. This is helpful in diagnosing lookup problems in TCP/IP.

It is recommended that you use z/OS UNIX or TSO nslookup with each NSINTERADDR used in TCPIP.DATA to ensure you receive the expected results. Some name server clients, on other platforms, may require the address you specify for the name server to match the source IP address in the response from the name server. For example, if a static VIPA address is specified as the address of the name

server, and IPCONFIG SOURCEVIPA is not specified in PROFILE.TCPIP, then nslookup on some platforms will discard the returned packet because it will have the destination address of the physical interface instead of the VIPA interface. If you wish to specify a dynamic VIPA (DVIPA) as the address of the name server, then the name server must BIND the UDP port to the DVIPA. See *z/OS Communications Server: IP Configuration Reference* for information on how to specify the BIND parameter on the PORT statement in PROFILE.TCPIP. Zone delegation using VIPA addresses also has special considerations and can cause name server operation to fail in some situations if not configured properly. For more information, see "General VIPA considerations" on page 810.

See *z/OS Communications Server: IP System Administrator's Commands* for more detailed information on the z/OS UNIX nslookup command.

Using dig to diagnose problems

The **dig** command is an alternate and recommended choice for resource record lookup. The dig response format is similar to the resource record (RR) definitions in master zone files. The **dig** command will not attempt a reverse lookup on the address provided for the server, which sometimes makes nslookup fail initialization if reverse lookup fails. The **dig** command offers flexible options, including toggling flags for checking response authority or authentication. It is the only v9 lookup utility that can list the complete contents of a zone. This can be accomplished with the -t AXFR option. For more detailed information on the z/OS UNIX **dig** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Advanced BIND 9 name server topics

This topic includes more advanced BIND 9 name server topics.

Multiple TCP/IP stack (common INET) considerations

The BIND 9 name server is a *generic* server which does not have stack affinity. This has certain implications.

- If you wish to run multiple BIND 9 name servers, you must divide the interfaces between the name servers with the **listen-on** named.conf file option. For example, you may want one stack serviced by one BIND 9 name server, and a second stack serviced by a second BIND 9 name server. Each name server would contain only the IP addresses of the assigned stack in its **listen-on** option.
- Any time a stack is brought up or a stack is brought down, the name server will essentially restart. On the MVS console, you will see the NAMED Exiting, NAMED Starting, and NAMED Running messages (messages EZZ9096I, EZZ9095I, and EZZ9130I).
- Be aware, that once you start a TCP/IP stack, all of the adapters may not be active immediately, and therefore will not be usable by the name server immediately. When the name server is started manually or restarted automatically by stack bring up or bring down, it immediately queries the available TCP/IP stacks for active adapters. Often times, it will take some time for all of the adapters to become active (this is independent of the name server). The name server will re-query the stacks every minute, by default, for any changes in the active/inactive status of adapters and then make use of them once they are active. The one minute interval can be lengthened by the **interface-interval** named.conf file option if desired, but this is not recommended.

- By default, the name server will unpredictably choose one adapter from any of the active stacks to use when it must communicate with other name servers. If some adapters do not have the capability to route into the network, you might see undesired results on name server queries. This unpredictable behavior can be eliminated by making use of the **query-source** option in the named.conf file. The **query-source** option should specify an adapter address that will always have network routing capability. The **query-source** option then places a dependency on the stack that owns that address to be active. If the owning TCP/IP stack of the **query-source** option address is taken down, the name server will end, since it will no longer have a way to communicate with the network, and thus, other name servers.
- BIND 9 is restricted to listening on all IPv6 interfaces or none of them. Therefore, if you want to run multiple BIND 9 name servers, you need to choose one of them to answer all IPv6 queries. Use the listen-on-v6 named.conf option with the value of *any;* to get BIND 9 to listen on your IPv6 interfaces.

Dynamic update

Dynamic update is the term used for the ability under certain specified conditions to add, modify or delete records or RRsets in the master zone files. Dynamic update is fully described in RFC 2136.

Dynamic update is enabled on a zone-by-zone basis, by including an **allow-update** or **update-policy** clause in the **zone** statement. Preferably, use TSIG security between the nsupdate utility and the targeted name server. BIND 9 name server configuration processing messages will remind you when nsupdate authorization is only based on client IP address.

Updating of secure zones (zones using DNSSEC) is modelled after the simple-secure-update proposal, a work in progress in the DNS Extensions working group of the IETF. (See http://www.ietf.org/html.charters/dnsext-charter.html for information about the DNS Extensions working group.) SIG and NXT records affected by updates are automatically regenerated by the server using an online zone key. Update authorization is based on transaction signatures and an explicit server policy. On z/OS, dynamic DNSSEC zones should use the RSA encryption algorithm when creating the zone key, or they can use the DSA algorithm if the 'random-device' option is also specified in the named.conf file. Non-dynamic DNSSEC zones can use any other supported encryption algorithm.

The zone files of dynamic zones must not be edited by hand. If the zone file of a dynamic zone is edited by hand, corrupt .jnl files can result and all changes not written to the zone file may be lost. The zone file on disk at any given time may not contain the latest changes performed by dynamic update. The zone file is written to disk only periodically, and changes that have occurred since the zone file was last written to disk are stored only in the zone's journal (.jnl) file. Depending on signal or rndc stop options, BIND 9 name server may or may not update the zone file. Therefore, editing the zone file manually is unsafe even when the server has been shut down.

Incremental zone transfers

The incremental zone transfer (IXFR) protocol is a way for secondary servers to transfer only changed data, instead of having to transfer the entire zone. The IXFR protocol is documented in RFC 1995.

When acting as a master server, BIND 9 supports IXFR for those zones where the necessary change history information is available. These include master zones

maintained by dynamic update and secondary zones (to transfer to other secondary servers) whose data was obtained by IXFR, but not manually maintained master zones or secondary zones obtained by performing a full zone transfer (AXFR).

When acting as a secondary server, after the initial full zone transfer, BIND 9 will request IXFR by default when notified of a change by the zone master server. IXFR updates are applied to the secondary zone database and also kept in a journal file (*.jnl) associated with any existing backup file for the secondary zone.

Master and secondary servers can each have IXFR globally or partially disabled through the use of the *provide-ixfr* and *request-ixfr* options under the general options or the *server* statements of the BIND 9 configuration file.

Split DNS

Setting up different views, or visibility, of DNS space to internal and external resolvers is usually referred to as a Split DNS setup. There are several reasons an organization would want to set up its DNS this way.

One common reason for setting up a DNS system this way is to hide *internal* DNS information from *external* clients on the Internet. There is some debate as to whether or not this is actually useful. Internal DNS information leaks out in many ways (via e-mail headers, for example) and most savvy attackers can find the information they need using other means.

Another common reason for setting up a Split DNS system is to allow internal networks that are behind filters or in RFC 1918 space (reserved IP space, as documented in RFC 1918) to resolve DNS on the Internet. Split DNS can also be used to allow mail from outside back in to the internal network.

Here is an example of a split DNS setup:

A company named Example, Inc. (example.com) has several corporate sites that have an internal network with reserved Internet Protocol (IP) space and an external demilitarized zone (DMZ), or *outside* section of a network, that is available to the public.

Example, Inc. wants its internal clients to be able to resolve external host names and to exchange mail with people on the outside. The company also wants its internal resolvers to have access to certain internal-only zones that are not available at all outside of the internal network.

In order to accomplish this, the company will set up two sets of name servers. One set will be on the inside network (in the reserved IP space) and the other set will be on bastion hosts, which are *proxy* hosts that can talk to both sides of its network, in the DMZ.

The internal servers will be configured to forward all queries, except queries for site1.internal, site2.internal, site1.example.com, and site2.example.com, to the servers in the DMZ. These internal servers will have complete sets of information for site1.example.com, site2.example.com, site1.internal, and site2.internal.

To protect the site1.internal and site2.internal domains, the internal name servers must be configured to disallow all queries to these domains from any external hosts, including the bastion hosts.

The external servers, which are on the bastion hosts, will be configured to serve the *public* version of the site1 and site2.example.com zones. This could include things such as the host records for public servers (www.example.com and ftp.example.com), and mail exchange (MX) records (a.mx.example.com and b.mx.example.com).

In addition, the public site1 and site2.example.com zones should have special MX records that contain wildcard (*) records pointing to the bastion hosts. This is needed because external mail servers do not have any other way of looking up how to deliver mail to those internal hosts. With the wildcard records, the mail will be delivered to the bastion host, which can then forward it on to internal hosts.

Here's an example of a wildcard MX record:

```
*   IN MX 10 external1.example.com.
```

Now that they accept mail on behalf of anything in the internal network, the bastion hosts will need to know how to deliver mail to internal hosts. In order for this to work properly, the resolvers on the bastion hosts will need to be configured to point to the internal name servers for DNS resolution. Queries for internal host names will be answered by the internal servers, and queries for external host names will be forwarded back out to the DNS servers on the bastion hosts. In order for all this to work properly, internal clients will need to be configured to query only the internal name servers for DNS queries. This could also be enforced using selective filtering on the network.

If everything has been set properly, Example, Inc.'s internal clients will now be able to:

- Look up any hostnames in the site1 and site2.example.com zones.
- Look up any hostnames in the site1.internal and site2.internal domains.
- Look up any hostnames on the Internet.
- Exchange mail with internal and external people.

Hosts on the Internet will be able to:

- Look up any hostnames in the site1 and site2.example.com zones.
- Exchange mail with anyone in the site1 and site2.example.com zones.

Here is an example configuration for the setup that was just described. Note that this is only configuration information; for information on how to configure your zone files, see “Step 4: Create the domain data files (master name server only)” on page 787.

Internal DNS server config:

```
acl internals { 172.16.72.0/24; 192.168.1.0/24; };

acl externals { bastion-ips-go-here; };

options {
    ...
    ...
    forward only;
    forwarders {     // forward to external servers
     bastion-ips-go-here;
    };
    allow-transfer { none; };   // sample allow-transfer (no one)
    allow-query { internals; externals; }; // restrict query access
```

```
    allow-recursion { internals; };  // restrict recursion
    ...
    ...
};

zone "site1.example.com" {
  type master;
  file "m/site1.example.com";
  forwarders { };     // do normal iterative
      // resolution (do not forward)
  allow-query { internals; externals; };
  allow-transfer { internals; };
};

zone "site2.example.com" {
  type slave;
  file "s/site2.example.com";
  masters { 172.16.72.3; };
  forwarders { };
  allow-query { internals; externals; };
  allow-transfer { internals; };
};

zone "site1.internal" {
  type master;
  file "m/site1.internal";
  forwarders { };
  allow-query { internals; };
  allow-transfer { internals; }
};

zone "site2.internal" {
  type slave;
  file "s/site2.internal";
  masters { 172.16.72.3; };
  forwarders { };
  allow-query { internals };
  allow-transfer { internals; }
};
```

External (bastion host) DNS server config:

```
acl internals { 172.16.72.0/24; 192.168.1.0/24; };

acl externals { bastion-ips-go-here; };

options {
  ...
  ...
  allow-transfer { none; };   // sample allow-transfer (no one)
  allow-query { internals; externals; }; // restrict query access
  allow-recursion { internals; externals; }; // restrict recursion
  ...
  ...
};

zone "site1.example.com" {
  type master;
  file "m/site1.foo.com";
  allow-query { any; };
  allow-transfer { internals; externals; };
};

zone "site2.example.com" {
  type slave;
  file "s/site2.foo.com";
```

```
  masters { another_bastion_host_maybe; };
  allow-query { any; };
  allow-transfer { internals; externals; }
};
```

In the resolv.conf (or equivalent) on the bastion host(s):

```
search ...
nameserver 172.16.72.2
nameserver 172.16.72.3
nameserver 172.16.72.4
```

Implementing split DNS with views

The view statement is a powerful new feature of BIND 9 that lets a name server answer a DNS query differently depending upon who is asking. It is particularly useful for implementing split DNS setups without having to run multiple servers.

Each view statement defines a view of the DNS namespace that will be seen by a subset of clients. A client matches a view if its source IP address matches the address_match_list of the view's match-clients clause and its destination IP address matches the address_match_list of the view's match-destinations clause. If not specified, by default, both match-clients and match-destinations match all addresses. A view can also be specified as match-recursive-only, which means that only recursive requests from matching clients will match that view. The order of the view statements is significant; A client request will be resolved in the context of the first view that it matches.

Zones defined within a view statement will only be accessible to clients that match the view. By defining a zone of the same name in multiple views, different zone data can be given to different clients (for example, internal and external clients in a split DNS setup.

Many of the options given in the options statement can also be used within a view statement, and then apply only when resolving queries with that view. When no view-specific value is given, the value in the options statement is used as a default. Also, zone options can have default values specified in the view statement. These view-specific defaults take precedence over those in the options statement.

Views are class specific. If no class is given, class IN is assumed. Note that all non-IN views must contain a hint zone, since only the IN class has compiled-in default hints.

If there are no view statements in the configuration file, a default view that matches any client is automatically created in class IN, and any zone statements specified on the top level of the configuration file are considered to be part of this default view. If any explicit view statements are present, all zone statements must occur inside view statements.

Following is an example of a typical split DNS setup implemented using view statements:

```
view "internal" {
               // This should match our internal networks.
      match-clients { 10.0.0.0/8; };
               // Provide recursive service to internal clients only.
      recursion yes;
               // Provide a complete view of the example.com zone
               // including addresses of internal hosts.
      zone "example.com" {
            type master;
```

```
            file "example-internal.db";
      };
};
view "external" {
      match-clients { any; };
               // Refuse recursive service to external clients.
      recursion no;
               // Provide a restricted view of the example.com zone
               // containing only publicly accessible hosts.
      zone "example.com" {
           type master;
           file "example-external.db";
      };
};
```

TSIG

This is a short guide to setting up Transaction SIGnatures (TSIG) based transaction security in BIND. It describes changes to the configuration file as well as what changes are required for different features, including the process of creating transaction keys and using transaction signatures with BIND.

BIND primarily supports TSIG for server to server communication. This includes zone transfer, notify, and recursive query messages. Resolvers on other platforms which are based on newer versions of BIND 8 have limited support for TSIG.

TSIG might be most useful for dynamic update. A master server for a dynamic zone should use access control to control updates, but IP-based access control is insufficient. Key-based access control is far superior. The **nsupdate** program supports TSIG through the **-k** and **-y** command line options.

Generate shared keys for each pair of hosts

A shared secret is generated to be shared between host1 and host2. An arbitrary key name is chosen: "host1-host2.". The key name must be the same on both hosts.

Automatic generation: The following command will generate a 128-bit (16-byte) HMAC-MD5 key. Longer keys are better, but shorter keys are easier to read. Note that the maximum key length is 512 bits; keys longer than that will be digested with MD5 to produce a 128 bit key.

```
dnssec-keygen -a hmac-md5 -b 128 -n HOST host1-host2.
```

The key is in the file Khost1-host2.+157+00000.private. Nothing directly uses this file, but the base-64 encoded string following "Key:" can be extracted from the file and used as a shared secret:

```
Key: La/E5CjG9O+os1jq0a2jdA==
```

The string "La/E5CjG9O+os1jq0a2jdA==" can be used as the shared secret.

Manual generation: The shared secret is simply a random sequence of bits, encoded in base-64. Most EBCDIC strings are valid base-64 strings (assuming the length is a multiple of 4 and only valid characters are used), so the shared secret can be manually generated. Also, a known string can be run through *mmencode* on another platform (such as Linux), or through a similar program, to generate base-64 encoded data.

Copying the shared secret to both machines

This is beyond the scope of DNS. A secure transport mechanism should be used. This could be secure FTP, ssh, telephone, etc.

Informing the servers of the key's existence

Imagine *host1* and *host2* are both servers. The following is added to each server's named.conf file:

```
key host1-host2. {
  algorithm hmac-md5;
  secret "La/E5CjG9O+os1jq0a2jdA==";
};
```

The algorithm, hmac-md5, is the only one supported by BIND. The secret is the one generated above. Since this is a secret, it is recommended that either named.conf be non-world-readable, or the key directive be added to a non-world-readable file that is included by named.conf.

At this point, the key is recognized. This means that if the server receives a message signed by this key, it can verify the signature. If the signature succeeds, the response is signed by the same key.

Instructing the server to use the key

Since keys are shared between two hosts only, the server must be told when keys are to be used. The following is added to the named.conf file for host1, if the IP address of host2 is 10.1.2.3:

```
server 10.1.2.3 {
  keys { host1-host2. ;};
};
```

Multiple keys can be present, but only the first is used. This directive does not contain any secrets, so it can be in a world-readable file. A world-readable file or directory is one that anyone can read. For directories, assuming the directory is also world-executable, world-readable means that anyone can list the files contained inside the directory. Passwords and other sensitive data should never be in world-readable files. For information about setting the *other* permissions that make a file or directory world-readable or non-world-readable, see *z/OS UNIX System Services Command Reference*.

If host1 sends a message that is a request to that address, the message will be signed with the specified key. host1 will expect any responses to signed messages to be signed with the same key. A similar statement must be present in host2's configuration file (with host1's address) for host2 to sign request messages to host1.

TSIG key based access control

BIND allows IP addresses and ranges to be specified in ACL definitions, and in access control directives such as allow-query, allow-transfer, and allow-update. This has been extended to allow TSIG keys also. An example of an allow-update directive would be:

```
allow-update { key host1-host2. ;};
```

This allows dynamic updates to succeed only if the request was signed by a key named "**host1-host2**.".

Errors

The processing of TSIG signed messages can result in several errors. If a signed message is sent to a non-TSIG aware server, a FORMERR will be returned, since the server will not understand the record. This is a result of misconfiguration, since the server must be explicitly configured to send a TSIG signed message to a specific server.

If a TSIG aware server receives a message signed by an unknown key, the response will be unsigned with the TSIG extended error code set to BADKEY. If a TSIG aware server receives a message with a signature that does not validate, the response will be unsigned with the TSIG extended error code set to BADSIG. If a TSIG aware server receives a message with a time outside of the allowed range, the response will be signed with the TSIG extended error code set to BADTIME, and the time values will be adjusted so that the response can be successfully verified. In any of these cases, the message's rcode is set to NOTAUTH.

DNSSEC

Cryptographic authentication of DNS information is possible through the DNS Security (DNSSEC) extensions, defined in RFC 2535. This topic describes the creation and use of DNSSEC signed zones.

The set of *dnssec-* tools rely on a /dev/random device for the entropy it needs to generate cryptographically strong keys. If RSA keys are used, only *dnssec-keygen* requires random data. z/OS UNIX does not include such a device, but the tools provide alternate methods of providing them with random data. The user can specify a file containing random data or can provide random data via the keyboard. To specify a file, use the **-r** *random data file* option on the tool command line. The *dnssec-* tools use the timing between keystrokes as the source of entropy. As such, TN3270 terminal emulation is not the ideal interface. Setting up a VT100 terminal session is a better solution. See “Configuring the z/OS UNIX Telnet server” on page 649 for more information on setting up otelnetd.

To set up a DNSSEC secure zone, there are a series of steps which must be followed. z/OS ships with several tools that are used in this process. In all cases, the **-h** option prints a full list of parameters. Note that the keyset and signedkey files created by some DNSSEC tools must be put in the name server working directory before another DNSSEC tool is used for signing a master zone file.

There must also be communication with the administrators of the parent and/or child zone to transmit keys and signatures. A zone's security status must be indicated by the parent zone for a DNSSEC capable resolver to trust its data.

For other servers to trust data in this zone, they must be statically configured with either this zone's zone key or the zone key of another zone above this one in the DNS tree, using the *trusted-keys* statement in the configuration file.

Generating keys

The **dnssec-keygen** program is used to generate keys.

A secure zone must contain one or more zone keys. The zone keys will sign all other records in the zone, as well as the zone keys of any secure delegated zones. Zone keys must have the same name as the zone, a name type of **ZONE**, and must be usable for authentication. On z/OS, you should use the RSA algorithm for DNSSEC if the zone you will sign with the key will be a dynamic zone (that is, one maintained with nsupdate). You can also use the DSA algorithm, provided you have the 'random-device' option coded in the named.conf file.

The following command will generate a 768-bit RSA key for the child.example zone:

```
dnssec-keygen -a RSA -b 768 -n ZONE child.example
```

Two output files will be produced: Kchild.example.+001+12345.key and Kchild.example.+001+12345.private (where 12345 is an example of a key tag). The key file names contain the key name (child.example.), algorithm (3 is DSA, 1 is RSA, etc.), and the key tag (12345 in this case). The private key (in the .private file) is used to generate signatures, and the public key (in the .key file) is used for signature verification.

To generate another key with the same properties (but with a different key tag), repeat the above command.

The public keys should be inserted into the zone file with **$INCLUDE** statements, including the .key files.

Creating a key set

The **dnssec-makekeyset** program is used to create a key set from one or more keys.

Once the zone keys have been generated, a key set must be built for transmission to the administrator of the parent zone, so that the parent zone can sign the keys with its own zone key and correctly indicate the security status of this zone. When building a key set, the list of keys to be included and the TTL of the set must be specified, and the desired signature validity period of the parent's signature may also be specified.

The list of keys to be inserted into the key set may also include non-zone keys present at the top of the zone. dnssec-makekeyset may also be used at other names in the zone.

The following command generates a key set containing the child.example.+001+12345 key and another key similarly generated, with a TTL of 3600 and a signature validity period of 10 days starting from now.

```
dnssec-makekeyset -t 3600 -e +8640 Kchild.example.+001+12345
Kchild.example.+001+23456
```

One output file is produced: keyset-child.example. This file should be transmitted to the parent to be signed. It includes the keys, as well as signatures over the key set generated by the zone keys themselves, which are used to prove ownership of the private keys and encode the desired validity period.

Signing the child's key set

The **dnssec-signkey** program is used to sign one child's key set.

If the child.example zone has any delegations which are secure, for example, grand.child.example, the child.example administrator should receive key set files for each secure subzone. These keys must be signed by this zone's zone keys.

The following command signs the child's key set with the zone keys:

```
dnssec-signkey keyset-grand.child.example. Kchild.example.+001+12345
Kchild.example.+001+23456
```

One output file is produced: signedkey-grand.child.example.. This file should be both transmitted back to the child and retained. It includes all keys (the child's keys) from the key set file and signatures generated by this zone's zone keys.

Signing the zone

The **dnssec-signzone** program is used to sign a zone.

Any **signedkey** files corresponding to secure subzones should be present, as well as a signedkey file for this zone generated by the parent (if there is one). The zone signer will generate NXT and SIG records for the zone, as well as incorporate the zone key signature from the parent and indicate the security status at all delegation points.

The following command signs the zone, assuming it is in a file called zone.child.example. By default, all zone keys which have an available private key are used to generate signatures.

```
dnssec-signzone -o child.example zone.child.example
```

One output file is produced: zone.child.example.signed. This file should be referenced by named.conf as the input file for the zone.

Configuring servers

Data is not verified on load in BIND 9, so zone keys for authoritative zones do not need to be specified in the configuration file. The public key for any security root must be present in the configuration file's **trusted-keys** statement.

IPv6 support in BIND 9

BIND 9 fully supports all currently defined forms of IPv6 name to address and address to name lookups.

For forward lookups, BIND 9 supports both A6 and AAAA records. The use of AAAA records is recommended, as A6 records have been made experimental by RFC 3363.

For IPv6 reverse lookups, BIND 9 supports the standard *nibble* label format, as well as the experimental *bitstring* format. Both formats are used under the ip6.arpa domain, although some resolvers and applications use the nibble format under the deprecated ip6.int domain.

Address lookups using AAAA records

The AAAA record is a parallel to the IPv4 A record. It specifies the entire address in a single record. For example:

```
$ORIGIN example.com.
host  3600 IN AAAA 3ffe:8050:201:1860:42::1
```

Address lookups using A6 records

A6 records are supported, but have been moved to experimental status by RFC 3363. The use of AAAA records is strongly recommended.

The A6 record can be used to form a chain of A6 records, each specifying part of the IPv6 address. It can also be used to specify the entire record as follows:

```
$ORIGIN example.com.
host  3600 IN A6 0 3ffe:8050:201:1860:42::1
```

For more information on A6 records and A6 chaining, see RFC 2874.

Synthetic IPv6 responses

Synthetic IPv6 responses were previously enabled with the allow-v6-synthesis option statement. This option is now obsolete.

Address to name lookups using nibble format

When looking up an address in nibble format, the address components are simply reversed, just as in IPv4, and ip6.arpa. is appended to the resulting name. For example, the following would provide reverse name lookup for a host with address 3ffe:8050:201:1860:42::1.

```
$ORIGIN 0.6.8.1.1.0.2.0.0.5.0.8.e.f.f.3.ip6.arpa.
1.0.0.0.0.0.0.0.0.0.0.0.2.4.0.0   14400 IN  PTR
host.example.com.
```

Address to name lookups using bitstring format

Bitstring labels can start and end on any bit boundary, rather than on a multiple of 4 bits as in the nibble format.

For example:

```
$ORIGIN \[x3ffe805002011860/64].ip6.arpa.
\[x0042000000000001/64]  14400  IN  PTR
host.example.com.
```

Using DNAME for delegation of IPv6 reverse addresses

DNAME is supported, but is considered experimental.

In IPv6, the same host may have many addresses from many network providers. Since the trailing portion of the address usually remains constant, **DNAME** can help reduce the number of zone files used for reverse mapping that need to be maintained.

For example, consider a host which has two providers (example.net and example2.net) and therefore two IPv6 addresses. Since the host chooses its own 64 bit host address portion, the provider address is the only part that changes:

```
$ORIGIN example.com.
host   A6 64 ::1234:5678:1212:5675
cust1.example.net.
   A6 64 ::1234:5678:1212:5675
subnet5.example2.net.
$ORIGIN example.net.
cust1   A6 48 0:0:0:dddd::
ipv6net.example.net.
ipv6net   A6 0 aa:bb:cccc::
$ORIGIN example2.net.
subnet5   A6 48 0:0:0:1::
ipv6net2.example2.net.
ipv6net2  A6 0 6666:5555:4::
```

This sets up forward lookups. To handle the reverse lookups, the provider example.net would have:

```
$ORIGIN \[x00aa00bbcccc/48].ip6.arpa.
\[xdddd/16]  DNAME  ipv6-rev.example.com.
```

and example2.net would have:

```
$ORIGIN \[x666655550004/48].ip6.arpa.
\[x0001/16]  DNAME  ipv6-rev.example.com.
```

example.com needs only one zone file to handle both of these reverse mappings:

```
$ORIGIN ipv6-rev.example.com.
\[x1234567812125675/64] PTR  host.example.com.
```

DNS-related RFCs

The following RFCs contain basic information about the DNS:

Chapter 16. Policy-based networking

Businesses typically define goals for network behavior in human terms. Network implementations provide a variety of application-transparent controls for priority treatment of traffic, bandwidth management, security, and control of network behavior. The link between the high-level business goals and network implementations is defined as policy-based networking and is provided by policies. Policies are usually defined in a centralized repository and are accessed by nodes that need to make policy decisions (Policy Decision Point, or PDP) or implement such decisions (Policy Enforcement Point, or PEP).

Policy types and infrastructure overview

To implement networking policies for your users, you must use the z/OS Communications Server policy infrastructure. You can use the policy types supported by the Policy Agent for any of the following purposes:

- Policy-based routing (See "Policy-based routing" on page 337)
- Quality of service (See Chapter 17, "Quality of service," on page 873)
- Intrusion Detection Services (See Chapter 18, "Intrusion Detection Services," on page 897)
- IP filtering, and manual and dynamic virtual private network (VPN) tunnels, collectively referred to as IPSec policies (See Chapter 19, "IP security," on page 923)
- Application Transparent Transport Layer Security (AT-TLS, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193)

For more information about the policy types, see "Policy types" on page 843.

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components:

- TCP/IP stack

  TCP/IP stacks implement most of the policy types. You need to start one or more stacks per logical partition (LPAR).
- Syslog daemon (syslogd)

  Syslogd acts as the central message logging facility for z/OS UNIX applications. Syslogd is not specific to the policy infrastructure, but the policy infrastructure depends on syslogd to provide a central logging facility to maintain an audit trail. If you do not start syslogd, messages are lost. You should start one syslog daemon per LPAR.
- Policy Agent

  You must start Policy Agent to install and maintain policies in the TCP/IP stacks in an LPAR. You need one Policy Agent per LPAR.
- Traffic regulation management daemon (TRMD)

  TRMD formats and sends policy-related messages to your syslog daemon. You need one TRMD per TCP/IP stack in an LPAR.
- Internet Key Exchange daemon (IKED)

IKED is used for negotiating and setting up dynamic VPN tunnels. If you are not using dynamic VPN tunnels, you do not need to start IKED; otherwise, you need one IKED per LPAR.

- Network security services daemon (NSSD)

  NSSD can be used as the central certificate and key server for z/OS IKE daemons, or as a network security server for selected non-z/OS platforms. NSSD can be used independently of any z/OS networking policies, but is an element of the overall z/OS networking policy infrastructure. Typically, you do not need an NSSD on every LPAR; one NSSD per sysplex is more likely.
- Defense Manager daemon (DMD)

  DMD provides support for short-term defensive filters. You can use DMD without defining any IPSec filter policies, but typically you use DMD in addition to IPSec filter policy. You need one DMD per LPAR.
- Network service level agreement performance monitor 2 (NSLAPM2)

  NSLAPM2 is an SNMP subagent that provides QoS metrics through MIB variables. You need one NSLAPM2 per TCP/IP stack in an LPAR.

For more information about syslogd, see "Configuring the syslog daemon" on page 185. For more information about the other policy infrastructure components, see "Policy infrastructure components" on page 835.

To determine the policy infrastructure components that you need to start based on which policy types you are implementing, see Table 38.

Table 38. Policy components needed per policy type

Policy type	Component							
	One or more instances per LPAR	One instance per LPAR					One instance per TCP/IP stack in an LPAR	
	TCP/IP stack	Policy Agent	syslogd	IKED	NSSD	DMD	NSLAPM2	TRMD
QoS	Required	Required	Required				Optional	
IDS	Required	Required	Required					Required
AT-TLS	Required	Required	Required					
IPSec filters	Required	Required	Required			Optional		Required
IPSec VPNs	Required	Required	Required	Optional (dynamic VPNs)	Optional (central key and certificate server)			Required
Policy-based routing	Required	Required	Required					

You can use the IBM Configuration Assistant for z/OS Communications Server for assistance with setting up and configuring security, JCL procedures, and configuration files for the following policy infrastructure components:

- Policy Agent, including policy definition files for QoS, IDS, AT-TLS, IPSec, and policy-based routing

- IKED
- NSSD
- DMD

Configuration files and policy definition files

To operate correctly, the policy infrastructure depends on various configuration files and policy definitions files.

The IBM Configuration Assistant for z/OS Communications Server enables flat-file configuration of all supported policy types for z/OS. The IBM Configuration Assistant for z/OS Communications Server is an optional GUI-based tool that provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF)

  z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.
- As a standalone application that you can run on your workstation

  You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

Table 39 lists the policy-related configuration and definition files, whether the files can be created using the Configuration Assistant, and the default location of the configuration files. You can manually edit all files listed in Table 39.

Table 39. Configuration files and policy definition files

Configuration file or policy definition file	Can be created by the Configuration Assistant?	Default z/OS location
Configuration files		
Policy agent	Yes	/etc/pagent.conf
syslogd	No	/etc/syslog.conf
IKED	Yes	/etc/iked.conf
NSSD	Yes	/etc/nssd.conf
Policy definition files		
QoS	Yes	None
IDS	Yes	None
AT-TLS	Yes	None
IPSec	Yes	None
Policy-based routing	Yes	None

Managing changes to configuration files and policy definition files

Typically, you use a change management procedure when you install a set of new or changed policies, or when you modify the configuration files for the Policy Agent or other policy-related applications. A structure for storing and maintaining the configuration files and policy definition files that are related to the general policy infrastructure is provided by the Configuration Assistant, and you can use it to manually create and edit the configuration files and policy definition files. The structure is based on three location levels:

- Staging

  The staging level is the location in which you manually edit your definitions, or into which you upload definitions from the Configuration Assistant.
- Production

  The production level is the location to which you copy your staging definitions when you are ready to put your changes into production. This is the location from which your Policy Agent and other policy infrastructure components read their definitions.
- Backup and recovery

  The backup and recovery level is the location to which you copy your existing production definitions before you copy your staging definitions to your production location. If the changes are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.

Storing configuration files and policy definition files

You can store configuration files and policy definition files in the z/OS UNIX file system or in traditional MVS data sets.

Some definitions are shared by all TCP/IP stacks on a z/OS image, and some definitions are specific to individual TCP/IP stacks on a z/OS image.

For example, if you are using the z/OS UNIX file system to store your configuration files and policy definition files, a directory structure for z/OS image SYSA with TCP/IP stacks TCPIP1 and TCPIP2 might look as follows:

- Staging

  Image-wide /etc/tcpip/POLTRANS/SYSA/

  TCPIP1 /etc/tcpip/POLTRANS/SYSA/TCPIP1/

  TCPIP2 /etc/tcpip/POLTRANS/SYSA/TCPIP2/
- Production

  Image-wide /etc/tcpip/POLPROD/SYSA/

  TCPIP1 /etc/tcpip/POLPROD/SYSA/TCPIP1/

  TCPIP2 /etc/tcpip/POLPROD/SYSA/TCPIP2/
- Backup and recovery

  Image-wide /etc/tcpip/POLBACK/SYSA/

  TCPIP1 /etc/tcpip/POLBACK/SYSA/TCPIP1/

  TCPIP2 /etc/tcpip/POLBACK/SYSA/TCPIP2/

Similarly, you can use MVS partitioned data set (PDS) or partitioned data set extended (PDSE) libraries to store the configuration files and policy definition files as follows:

- Staging

  Image-wide *hlq*.TCPPARMS.POLTRANS.SYSA

  TCPIP1 *hlq*.TCPPARMS.POLTRANS.SYSA.TCPIP1

  TCPIP2 *hlq*.TCPPARMS.POLTRANS.SYSA.TCPIP2
- Production

  Image-wide *hlq*.TCPPARMS.POLPROD.SYSA

  TCPIP1 *hlq*.TCPPARMS.POLPROD.SYSA.TCPIP1

  TCPIP2 *hlq*.TCPPARMS.POLPROD.SYSA.TCPIP2
- Backup and recovery

  Image-wide *hlq*.TCPPARMS.POLBACK.SYSA

  TCPIP1 *hlq*.TCPPARMS.POLBACK.SYSA.TCPIP1

  TCPIP2 *hlq*.TCPPARMS.POLBACK.SYSA.TCPIP2

You can maintain a number of members in each of these libraries, using your own naming convention or the following suggested naming convention:

- LPAR-wide configuration files

  CONF (configuration file)
- Stack-specific configuration and policy definition files
  - TLSPOL (AT-TLS policy definitions)
  - IDSPOL (IDS policy definitions)
  - IPSPOL (IPSec policy definitions)
  - QOSPOL (QoS policy definitions)
  - PBRPOL (Policy-based routing policy definitions)

The following example shows the IKE daemon configuration file and the IPSec policy definitions for stack TCPIP1 as members of PDS or PDSE libraries:

```
USER.LPAR1.POLTRANS.SYSA.IKED(CONF)
USER.LPAR1.POLTRANS.SYSA.TCPIP1(IPSPOL)
```

Steps for managing policy changes

As shown in Figure 83 on page 834, perform the following steps to activate changes to your policies:

1. Transfer the policy flat file to the staging library

   hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1(*xyz*)
2. Back up the current production policy flat file

   Copy *hlq*.TCPPARMS.POLPROD.SYSA.TCPIP1(*xyz*) to *hlq*.TCPPARMS.POLBACK.SYSA.TCPIP1(*xyz*)
3. Copy the new policy flat file into production

   Copy *hlq*.TCPPARMS.POLTRANS.SYSA.TCPIP1(*xyz*) to *hlq*.TCPPARMS.POLPROD.SYSA.TCPIP1(*xyz*)

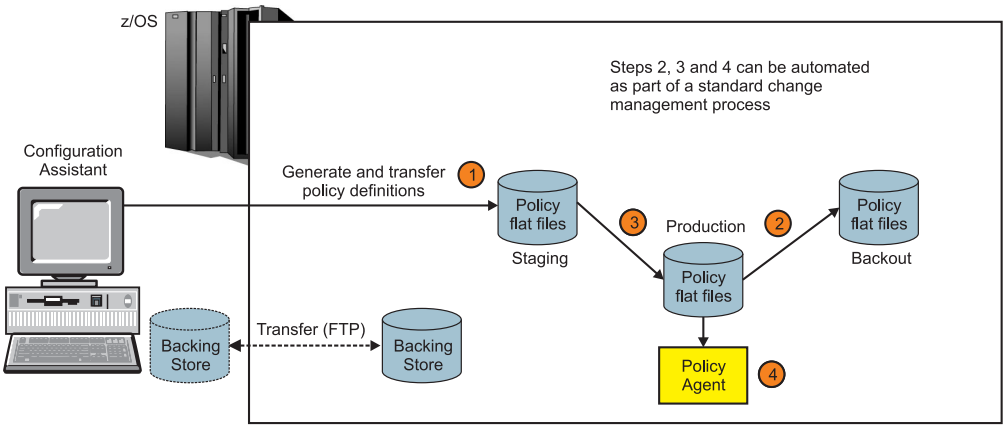

Figure 83. Activating changes to your policies

Policy Agent reads the definitions from the production location, as shown by step 4 in Figure 83.

Tips:

- If the changes you make are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.
- In your procedure to move objects from POLTRANS to POLPROD, you might have to include a utility step to change location references from POLTRANS to POLPROD.

  Some configuration files might include references to other configuration file locations or policy definition file locations. Those locations are initially the POLTRANS location.
- You can override names suggested by the Configuration Assistant and choose to use other names.

  If you are using the Configuration Assistant, you are prompted for the base location for a z/OS image. For each configuration file, policy definition file, sample RACF job, sample JCL procedure, and so on, the Configuration Assistant suggests a name to serve as the file name in the z/OS UNIX file system directories, or as the member name in the PDS or PDSE libraries.
- Specifying an EBCDIC code page that matches your default country settings makes it easier to browse the files with ISPF.

  Most policy-related configuration files and all the policy definition files support an optional **Codepage** parameter that you can use to indicate the EBCDIC code page in which the contents are encoded. When you use the Configuration Assistant, you specify the EBCDIC code page when you define the base location for a z/OS image. The Configuration Assistant transfers configuration files and policy definitions files to that z/OS image using the specified code page and includes the **Codepage** option in the files. Following is an example of the initial section of a Policy Agent configuration file that uses the **Codepage** option:

```
## Configuration Assistant, 2008.11.25 09:33:12
## Pagent Configuration for system MVS098
## Target Codepage = IBM-278
TcpImage TCPCS 'USER1.TCPPARMS.MVS098.TCPCS(STKPAG)' FLUSH NOPURGE 360
Codepage  IBM-278
## Loglevel 127         ## default 31
```

Policy infrastructure components

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components.

For more information about syslogd, see “Configuring the syslog daemon” on page 185.

TCP/IP stack

Most policy types are implemented by the TCP/IP stack. IPSec dynamic VPNs are implemented by the IKE daemon.

As packets are sent or received, they are matched against policies of the appropriate type as needed. In general, policy processing occurs at the following layers in the stack:

- Application layer - AT-TLS
- IP layer - IPSec filtering and policy-based routing
- Transport layer - IDS and QoS

Some types of IDS checks are also performed at the IP layer in the stack.

When a matching policy is found, it is implemented against the packet. Depending on the policy type and packet contents, this results in a wide variety of actions. For example, the packet might be discarded, processed according to its priority, or have its routing changed. For information about the policy action statements and the kinds of processing that can be applied for each policy type, see the Policy Agent and policy applications information in *z/OS Communications Server: IP Configuration Reference*.

Policy Agent

Policy Agent can act in any of several roles, and provides various services, such as managing dependent components of the policy infrastructure.

The term *Policy Agent* refers to any roles or services provided by Policy Agent. The terms *policy server* and *policy client* refer to those specific roles, and the term *import requestor* refers to the configuration file import service.

Policy Agent roles

The Policy Agent runs in the z/OS environment and can act in any of several roles, depending on configuration options:

- The Policy Agent can act as a self-contained Policy Decision Point (PDP) on a single system, installing policies in one or more z/OS Communications Server stacks on that z/OS image, as shown by system SYSA in Figure 84 on page 836.
- The Policy Agent can act as a policy client, retrieving remote policies from the policy server, as shown by system SYSB in Figure 84 on page 836. Each stack in a Common INET (CINET) environment that is configured to the Policy Agent acts as a separate policy client.
- The Policy Agent can act as a centralized policy server, providing PDP services for one or more remote policy clients, as shown by system SYSC in Figure 84 on page 836.
- A single Policy Agent can act as a policy client or a policy server, but not both.

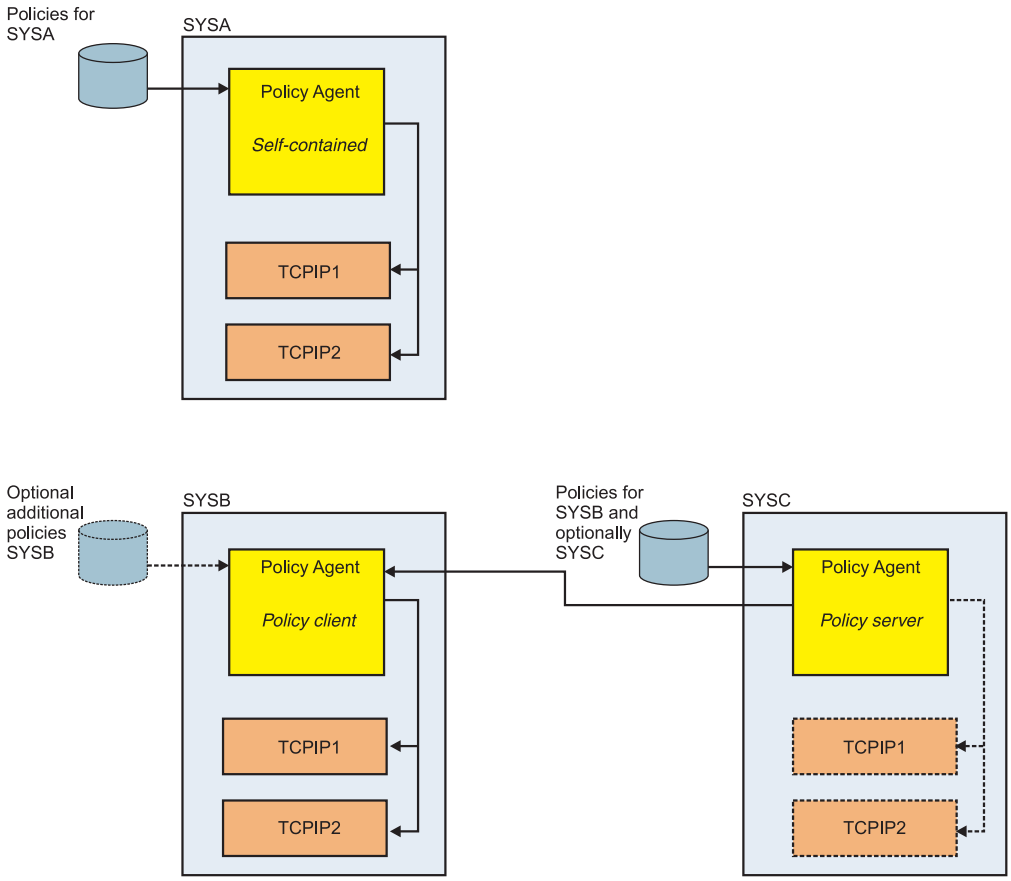

Figure 84. Policy Agent roles

Policy Agent services

Policy Agent provides the following services:

- Reads and parses policy definitions, and provides those policies to one or more TCP/IP stacks or policy clients. The Policy Agent actively participates in maintaining the policies by monitoring the policy files, detecting changes, and informing the TCP/IP stacks or policy clients about any changes.
- Imports policy through a passive service known as policy file import. The main user of this service is the IBM Configuration Assistant for z/OS Communications Server, through its Policy Data Import function.

  For this configuration file import service, the Policy Agent reads and parses policy definitions one time, and provides the policies to an import requestor. The import requestor can import the policies into an existing configuration, or can just verify that the policy definitions are without errors.
- Starts, monitors, stops, and restarts dependent components of the policy infrastructure. You can instruct Policy Agent to manage the following components:
  - DMD
  - IKED
  - NSSD
  - syslogd
  - TRMD per stack on a system

Policy Agent policies

Policies can be defined in several different ways.

Table 40 shows the format you can use for different policy types.

Table 40. Policy formats

Policy type	Text file format [1]	LDAP format
QoS	Yes	Yes [2]
IDS	Yes	Yes [2]
AT-TLS	Yes	No
IPSec	Yes	No
Policy-based routing	Yes	No

[1] The Configuration Assistant builds policy definitions only in text file format.

[2] The format of the LDAP schema for IDS and QoS policies was stabilized in z/OS V1R2. Only IDS and QoS policies supported by that release are supported when you are using an LDAP server to store IDS and QoS policies. For information about defining policies on an LDAP server, see Appendix F, "Using an LDAP server for policy definitions," on page 1519.

When acting as the Policy Decision Point (PDP) for a single system, Policy Agent can read policy definitions from local configuration files, a central repository that uses the Lightweight Directory Access Protocol (LDAP), or both. The Policy Agent also installs policies in one or more z/OS Communications Server stacks. It can be used to replace existing policies or to update them as necessary.

When acting as a policy server, Policy Agent also acts as a PDP for the local system, and thus can read policies from local configuration files or an LDAP server and install them in local stacks. However, it also reads policies from local configuration files on behalf of policy clients. These policies are retrieved by policy clients, but are not installed in the local stacks on the policy server.

Restriction: Dynamic monitoring for file updates using the **-i** startup option is not supported for files read on behalf of policy clients.

When acting as a policy client, Policy Agent retrieves remote policies from the policy server, and can also use local policies from configuration files or an LDAP server. The choice of local or remote policies can be made separately for each supported policy type (QoS, IDS, IPSec, Routing, or AT-TLS). The policy client informs the policy server of its local capabilities, so that the policy server can perform appropriate parsing of the policies. For example, the policy client might not support the IPSec 3DES encryption algorithm, so the policy server needs to fail IPSec policies that specify 3DES, even if the policy server itself does support 3DES.

If the policy client and policy server are at different release levels, you must be careful when defining policies on the policy server.

- If the policy client is at a higher release level than that of the policy server, you can define policies using the syntax and semantics of only the lower-level policy server. You cannot use the capabilities that exist only in the higher release level, such as new statements, parameters, or parameter values. Error checking might also be unavailable for use; rules or restrictions might be added to or removed from the higher release level.

- If the policy server is at a higher release level than that of the policy client, you cannot define policies using syntax and semantics that are available only in the higher release level. The policy server cannot parse such policies on behalf of a policy client at a lower release level, so the policies are reported as containing errors.
- If the policy server is at a lower release level than that of the policy client, any polices using syntax and semantics that were removed from the higher release level are still parsed and returned from the policy server to the policy client.

As a general rule, configure policies based on the target system, not on the system where the policies are defined.

For a table of statements, parameters, parameter values, and rules or restrictions that are valid only for certain release levels, see *z/OS Communications Server: IP Configuration Reference*.

The policy client can be configured with a backup as well as a primary policy server. The policy client continually retries the connection to the primary policy server (and the connection to the backup if a backup is configured) using the connection retry values configured on the ServerConnection statement, until a connection is successfully established.

For more information, see the following topics:

- "Policy-based routing" on page 337
- Chapter 17, "Quality of service," on page 873
- Chapter 18, "Intrusion Detection Services," on page 897
- Chapter 19, "IP security," on page 923
- Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193

Restriction: You cannot define AT-TLS policies, IPSec policies, or routing policies on LDAP servers.

Tip: Policies defined on an LDAP server use the configuration files and mechanisms provided by the LDAP server product. The definition of the elements of policies is known as the *schema*. z/OS Communications Server provides the schema definition for policies that may be defined on an LDAP server in a set of sample files. The sample files are provided in LDAP protocol version 3 format (see "LDAP sample files" on page 1530 for the names of these samples). These sample files must be installed on the LDAP server as the schema definition. Policy Agent uses the z/OS Integrated Security Server LDAP Client library to communicate with an LDAP server. See *z/OS Integrated Security Services LDAP Server Administration and Use* for more information about LDAP. A copy of the LDAP definition files that define the policy definitions for LDAP is available in *z/OS Communications Server: IP Configuration Reference*.

Local policies are defined in Policy Agent configuration files, in the LDAP server, or both. Remote policies are defined in Policy Agent configuration files on the policy server. Policies from configuration files and the LDAP server are combined into a single list. This requires unique policy object names per type (QoS, IDS, IPSec, Routing, and AT-TLS). On a policy client, policies for a given type are retrieved either locally or remotely, but not both.

For policies defined on the LDAP server, the distinguished name (DN) must be unique, but the user-friendly name does not have to be unique (although it should be). The Policy Agent appends a unique suffix if it is required to make LDAP user-friendly names unique within the scope of policies defined on the LDAP server. When policies from a configuration file are combined with LDAP-defined policies, the LDAP user-friendly names must be unique with respect to the names defined in the configuration file. Any policy objects of the same type (that is, QoS or IDS) with duplicate names at this point are discarded by the Policy Agent and an error is reported.

Configuration file import services

The IBM Configuration Assistant for z/OS Communications Server can request that existing configuration files be imported for further changes and additions. When the Policy Agent provides this configuration file import service, the IBM Configuration Assistant is acting as an *import requestor*. These files are *import configuration files* and the resulting policies are *import policies*. When the IBM Configuration Assistant is acting as an import requestor, the required input values are configured on its Import Policy Data panel:

- Host connection IP address and port for the Policy Agent
- Host connection user name and password to identify resources that this user can access
- Indication of whether a secure connection (SSL) should be used

  You configure the type of security for a connection (basic or secured) on the ServicesConnection statement for the Policy Agent. For more details, see "Step 6: Configure Policy Agent for configuration file import services" on page 860.
- Policy type to identify what type of policies to import
- Optional policy configuration file names (common file, stack-specific file, or both)
- Import request name to identify the stack name

  The import request name, user name, and policy type are used to identify resources this user can access.

  If no import configuration files are passed, the import request name is used to match an existing TcpImage or PEPInstance statement to find the import configuration file names for the input policy type.

Restrictions:

- The import requestor's port value must be the same as the port value defined on the ServicesConnection statement.
- The import requestor's type of security (SSL or not) must match the type of security configured on the ServicesConnection statement (secured or basic).
- The import configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the FLUSH and PURGE parameters and the MODIFY REFRESH and MODIFY UPDATE commands do not apply to these files. These files are not monitored for changes.
- You can define import policies only in configuration files. You cannot define them on an LDAP server.
- The import request name, user name, and policy type are required for security product authorization in the SERVAUTH class. For authorization details, see "Step 1: Configure general information" on page 849.

For detailed configuration information, see "Step 6: Configure Policy Agent for configuration file import services" on page 860.

Additional QoS services

The Policy Agent supports QoS functions other than reading and installing policies, such as sysplex distributor policy performance monitoring, and mapping IPv4 Type of Service (ToS) byte or IPv6 Traffic Class values to outbound interface and virtual LAN (VLAN) user priorities. The QoS specific Policy Agent functions are further described in "QoS-specific Policy Agent functions" on page 876.

Policy API

A Policy API (PAPI) is provided to allow access to policy information by external user applications. The PAPI interface can be used by policy performance monitoring applications to retrieve policy performance data. For more information on PAPI, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Traffic regulation management daemon

Intrusion Detection Services (IDS) support is available to detect and report on network intrusion events. The Traffic Regulation Management (TRM) support has been extended and incorporated into the IDS support. IDS policy regulates the types of events to report and provides the definition of several types of events. IDS policy may be defined for scans, attacks and traffic regulation for both TCP and UDP ports.

IKE daemon

IPSec services include IP filtering and support for manual and dynamic VPN tunnels. The Internet Key Exchange (IKE) daemon works with the stack to provide IPSec support. IPSec policy can be defined for IP filtering (including manual VPN tunnels), key exchange, and dynamic VPN tunnels.

Network security services daemon

A network security services daemon (NSSD) provides network security services for one or more security disciplines, including IPSec. For the IPSec discipline, these services include the IPSec certificate service and the IPSec remote management service. For more information, see Chapter 20, "Network security services," on page 1149.

Tip: You do not define policies for NSSD.

Defense Manager daemon

The Defense Manager daemon (DMD) provides defensive filters, which are IP filter rules to discard packets that are separate from IP security filters, and which are typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. For more information, see Chapter 21, "Defensive filtering," on page 1177.

Tip: You do not define policies for DMD.

SNMP Network SLAPM2 subagent

The z/OS CS Network SLAPM2 subagent (nslapm2) allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. See usr/lpp/tcpip/samples/slapm2.mi2 for more information about the Network SLAPM2 MIB.

Sample policy infrastructure

Figure 85 shows the Policy Agent in a sample policy infrastructure.

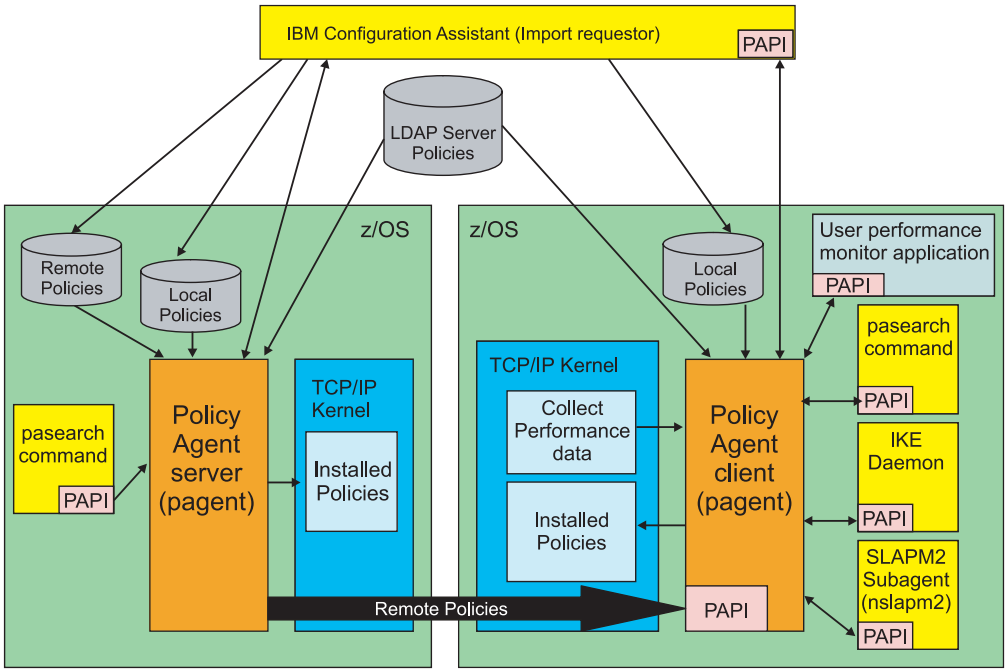

Figure 85. Sample policy infrastructure

The IBM Configuration Assistant for z/OS Communications Server performs the following functions:

- GUI to build the configuration flat-files for IPSec, AT-TLS, IDS, Routing, and QoS policies.
- Import requestor to request configuration file import services from the Policy Agent. For details, see "Configuration file import services" on page 839.

Policy sample files

A set of sample files is shipped with z/OS CS that provides several functions. The first sample file provides an example of policy definitions in a Policy Agent configuration file.

/usr/lpp/tcpip/samples/pagent.conf
This file contains overall policy definition rules, syntax and semantics for defining policies in a configuration file, and examples of such policy definitions.

The next set of sample files provide sample IPSec policy definitions.

/usr/lpp/tcpip/samples/pagent_CommonIPSec.conf
This file contains sample common IPSec policy definitions. These can be referenced and reused by multiple stack-specific IPSec configuration files.

/usr/lpp/tcpip/samples/pagent_IPSec.conf
This file contains sample stack-specific IPSec policy definitions. Some of these refer to common definitions in /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf.

The following file provides sample AT-TLS policy definitions.

/usr/lpp/tcpip/samples/pagent_TTLS.conf
This file contains sample AT-TLS policy definitions. These definitions can either be in a common or stack-specific AT-TLS file. If these definitions are in a common AT-TLS file, they can be referenced and reused by multiple stack-specific AT-TLS configuration files. If these definitions are in a stack-specific AT-TLS file, they are used only by that specific stack.

The following file provides sample IDS policy definitions.

/usr/lpp/tcpip/samples/pagent_IDS.conf
This file contains sample IDS policy definitions. These definitions can either be in a common or stack-specific IDS file. If these definitions are in a common IDS file, they can be referenced and reused by multiple stack-specific IDS configuration files. If these definitions are in a stack-specific IDS file, they are used by only that specific stack.

The following file provides sample policy-based routing policy definitions.

/usr/lpp/tcpip/samples/pagent_Routing.conf
This file contains sample policy-based routing policy definitions. These definitions can either be in a common or stack-specific routing file. If these definitions are in a common routing file, they can be referenced and reused by multiple stack-specific routing configuration files. If these definitions are in a stack-specific routing file, they are used by only that specific stack.

The following files include sample C applications that can be used to develop policy performance monitoring applications.

/usr/lpp/tcpip/samples/pagent/README
This file contains instructions for compiling and running the following sample C applications.

/usr/lpp/tcpip/samples/pagent/pCollector.c
This file is a sample C application (pCollector) that uses the Policy API (PAPI) interfaces to access policy performance data. It can be used as the base for an application that provides near real-time policy performance monitoring.

/usr/lpp/tcpip/samples/pagent/pCollector.h
This file is a header file for the pCollector sample application.

/usr/lpp/tcpip/samples/pagent/pLogReader.c
This file is a sample C application (pLogReader) that reads the policy performance log file to access policy performance data. It can be used as the base for an application that provides offline policy performance monitoring.

This documentation refers to Version 1 through Version 4 when defining policies.

- Version 1 refers to policy definitions defined with the ServicePolicyRules and ServiceCategories statements or LDAP objects.
- Version 2 through Version 4 refer to policy definitions defined with other policy statements or LDAP objects.
- The primary difference between Version 2 and Version 3 is in the definition of the LDAP schema.
- Version 4 is used with configuration file IDS and Routing policies.

For information about LDAP samples and schema definition files, see Appendix F, "Using an LDAP server for policy definitions," on page 1519.

Policy types

The Policy Agent supports the following types of policies. Each policy type is referred to as a discipline.

- Quality of service (QoS) policies
  - Differentiated Services (DS) policies
  - Integrated Services (RSVP) policies
  - Sysplex distributor (SD) policies
- Intrusion Detection Services (IDS) policies
  - Scan policies
  - Attack policies
  - Traffic Regulation policies
- IP security (IPSec) policies
  - IP filtering policies
  - Key exchange policies
  - Local dynamic VPN policies
- Application Transparent Transport Layer Security (AT-TLS) policies
- Policy-based routing (Routing) policies

For information about how IPv6 affects the Policy Agent and which types of policies support IPv6, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

These policy types are defined using different policy schemas. They use a common rule, but have separate conditions and actions. None of the different policy types can be mixed in a given policy object. All policy rules can contain time-related information that indicates when the policy rule should be considered active or inactive.

For the QoS, IDS, Routing, and AT-TLS types, active policy rules are installed in the TCP/IP stack, so they can be applied as traffic filters, while inactive policy rules exist only in the Policy Agent. For the IPSec type, both active and inactive IP filtering policies are installed in the TCP/IP stack. However, only manual VPN tunnels that are active as a result of a time condition are installed in the stack. For the Routing policy type, active route tables are installed in the stack, while inactive route tables exist only in the Policy Agent. Configured route tables are active when they are referenced by an active Routing rule and its associated Routing action.

The Policy Agent supports all of the previously mentioned policy types, installing them into one or more TCP/IP stacks as configured. However, policies to be retrieved by policy clients are not installed in any stacks on the policy server.

QoS policy

Policy conditions consist of a variety of selection criteria that act as traffic filters. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol, inbound and outbound interfaces, application name, application specific data or application priority. Only packets that match the filter criteria are selected to receive the accompanying action. Policy rules can refer to

several policy actions, but only one policy action is executed per policy scope. A given policy action may be referred to by several policy rules.

The type of policy defined is in general controlled by the policy scope value defined for the policy action. SD policies are an exception. SD policies are a subset of DS policies, so use the DS scope.

Although RSVP policies are installed into the TCP/IP stack, they are only used for collecting policy statistics. For policy use and limit enforcement, these policies are requested from the Policy Agent by the RSVP Agent, to apply to RSVP reservation requests from RSVP applications.

IDS policy

Policy conditions primarily determine the portion of IDS function that is being configured. A given IDS policy rule refers to a single IDS policy action. A given IDS policy action may be referred to by several policy rules of the same IDS type. See Chapter 18, "Intrusion Detection Services," on page 897 for more details.

IPSec policy

Policy conditions consist of a variety of selection criteria that act as filters for IP filtering rules. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol, direction, routing information, and security class. For other types of IPSec policies, policy conditions contain information about dynamic key exchange filters or dynamic VPN tunnels. For more details, see Chapter 19, "IP security," on page 923.

IP filter rules and key exchange rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex IP filter rules and key exchange rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see "Policy object model overview" on page 1519.

Complex IP filter rules (rules that contain groupings, or sets, of individual conditions) are split to produce multiple simple rules to be installed in the TCP/IP stack. The conditions in the IpFilterRule statement that can make a filter rule complex are:

- IpSourceAddr

  If multiple source addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple source addresses can be specified by referencing a set or group of addresses from the rule (IpSourceAddrGroupRef).
- IpDestAddr

  If multiple destination addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple destination addresses can be specified by referencing a set or group of addresses from the rule (IpDestAddrGroupRef).
- IpService

  If multiple IpService statements are specified in a rule, the rule is considered complex. Multiple IpService statements can be specified either inline or by referencing a group of IpService statements (IpServiceGroupRef).
- IpService Direction

  If the Direction parameter in an IpService statement is configured as BiDirectional, the rule is considered complex.

Complex key exchange rules are split to produce multiple simple rules. The IKE daemon retrieves simple rules when necessary. The following conditions can make a complex key exchange rule:

- LocalSecurityEndpoint Location

  If multiple IP addresses (or address ranges) are specified in a local security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the local security endpoint (LocationGroupRef).
- RemoteSecurityEndpoint Location

  If multiple IP addresses (or address ranges) are specified in a remote security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the remote security endpoint (LocationGroupRef).

For more details on these IPSec policy configuration statements and parameters, see *z/OS Communications Server: IP Configuration Reference*.

The **pasearch** command displays IP filter rules and key exchange rules as complex rules, and not split as installed in the TCP/IP stack or retrieved by the IKE daemon.

For IP filter rules and key exchange rules, the condition level summaries are not applicable and are always displayed as all zeros.

AT-TLS policy

Policy conditions consist of a variety of selection criteria that act as filters for AT-TLS rules. Traffic can be filtered based on local addresses, remote addresses, local port range, remote port range, job name, user identification, and direction. For more details, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

AT-TLS policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex AT-TLS policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see "Policy object model overview" on page 1519.

When AT-TLS rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following TTLSRule statement:

```
TTLSRule ttlsRule1
{
  LocalAddrGroupRef    addrGroup1
  RemoteAddrGroupRef   addrGroup2
  LocalPortGroupRef    portGroup1
  RemotePortGroupRef   portGroup2
  Jobname              jobABC
  Userid               user1
  Direction            Outbound
  TTLSGroupActionRef   ttlsAction7
}

IpAddrGroup addrGroup1
{
  IpAddr
  {
    Addr 9.1.1.1
```

```
  }
  IpAddr
  {
    Addr 10.1.1.1
  }
}

IpAddrGroup addrGroup2
{
  IpAddr
  {
    Addr 200.1.1.1
  }
  IpAddr
  {
    Addr 201.1.1.1
  }
}

PortGroup portGroup1
{
  PortRange
  {
    Port 21
  }
  PortRange
  {
    Port 23
  }
}

PortGroup2
{
  PortRange
  {
    Port 10
  }
  PortRange
  {
    Port 15
  }
}
```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = local address 9.1.1.1 OR local address 10.1.1.1
- Level 2 = remote address 200.1.1.1 OR remote address 201.1.1.1
- Level 3 = local port 21 OR local port 23
- Level 4 = remote port 10 OR remote port 15
- Level 5 = job name jobABC, user ID user1, direction outbound

The **pasearch** command displays the AT-TLS policy as complex rules.

Policy-based routing policy

Policy conditions consist of a variety of selection criteria that act as filters for policy-based routing (Routing) rules. Traffic can be filtered based on source addresses, destination addresses, source port range, destination port range, protocol, job name, security zone, and security label. For more details, see "Policy-based routing" on page 337.

Routing policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, and one with more conditions is known as a complex rule. Complex routing policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details about CNF, see "Policy object model overview" on page 1519.

When routing rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following RoutingRule statement:

```
RoutingRule   rule1
{
  TrafficDescriptorGroupRef  tdGroup
  IpSourceAddrGroupRef       addrGroup
  RoutingActionRef           action1
}
TrafficDescriptor   td1
{
   SourcePortRange      1-5
   DestinationPortRange 10
   SecurityZone         zone1
   SecurityLabel        label1
   JobName              jobABC1
}
TrafficDescriptor   td2
{
   SourcePortRange      6-9
   DestinationPortRange 25
   SecurityZone         zone2
   SecurityLabel        label2
   JobName              jobABC2
}
TrafficDescriptorGroup  tdGroup
{
  TrafficDescriptorRef  td1
  TrafficDescriptorRef  td2
}
IpAddrGroup addrGroup
{
  IpAddr
  {
    Addr 9.1.1.1
  }
  IpAddr
  {
    Addr 10.1.1.1
  }
}
```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = source address 9.1.1.1 OR source address 10.1.1.1
- Level 2 = (source port range 1-5 AND destination port range 10 AND job name jobABC1 AND security zone zone1 AND security label label1) OR (source port range 6-9 AND destination port range 25 AND job name jobABC2 AND security zone zone2 AND security label label2)

The **pasearch** command displays the Routing policy as a complex rule.

Steps for configuring the Policy Agent

Before you begin: You need to understand the hierarchy and relationships of the different configuration files. A single file, the main configuration file, is specified explicitly or by default when the Policy Agent is started. This main configuration file points to other configuration files, as shown in Figure 86.

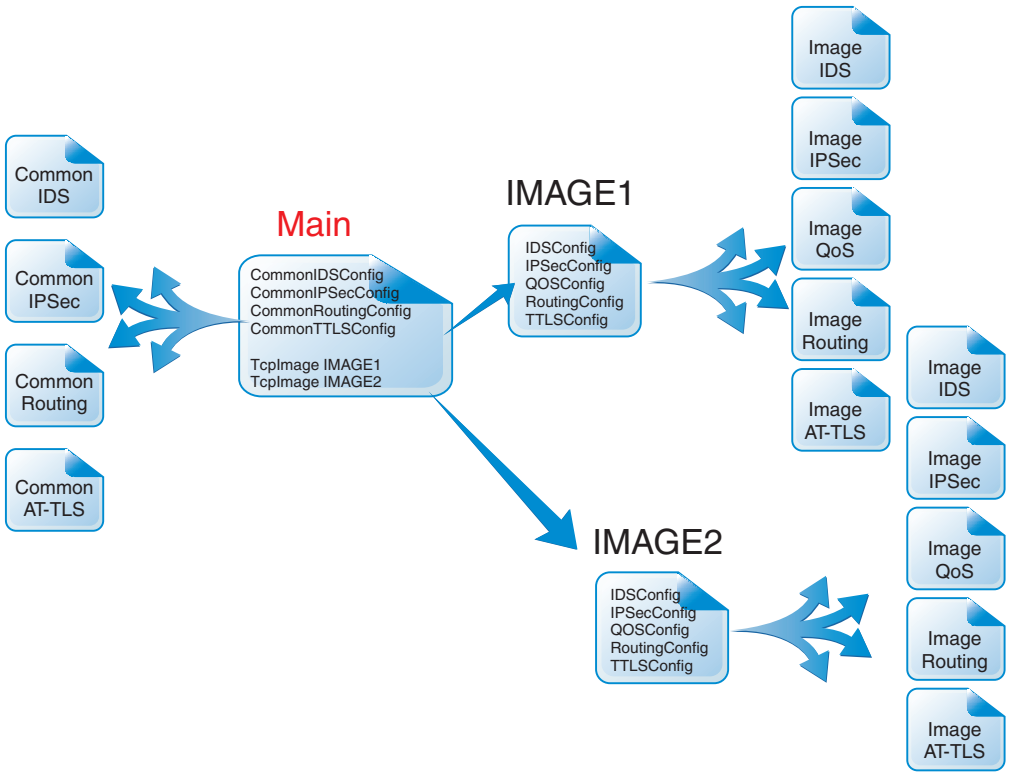

Figure 86. Policy Agent configuration files

For more information about the Policy Agent search order, see *z/OS Communications Server: IP Configuration Reference*.

You can specify statements in all configuration files using a variety of EBCDIC code pages. Use the Codepage configuration statement in the main configuration file to specify the code page to be used for all configuration files. The default code page is IBM-1047.

The main configuration file contains TcpImage or PEPInstance statements that define the TCP/IP stacks to be configured. The Policy Agent reads and installs policies for this set of stacks. Each TcpImage or PEPInstance statement can optionally specify the file name of an image-specific configuration file for that stack. If this file name is not specified, the main configuration file is also the image-specific configuration file for that stack. Thus, a single physical file can serve as two distinct logical files.

The main configuration file can also contain statements that specify the file names of one or more common configuration files for certain policy types. For example, the CommonIDSConfig statement points to a file containing IDS configuration statements that can be used for all configured stacks.

Each image-specific configuration file can contain statements that specify the file names of image-specific configuration files for different policy types. For example, the IPSecConfig statement points to a file containing IPSec configuration statements to be used for the stack that is represented by the image configuration file that contains the IPSecConfig statement. QoS policies can optionally be configured directly in the image configuration file, without using a QOSConfig statement.

The main configuration file on the policy server can also contain DynamicConfigPolicyLoad statements that determine the configuration files used when remote policy clients request policies. Each DynamicConfigPolicyLoad statement can serve a single policy client or a group of policy clients. Both common and policy client-specific configuration files can be specified for each policy type.

Perform the following steps to configure the Policy Agent:

1. Configure general information.
2. Configure Policy Agent as a policy server.
3. Configure Policy Agent as a policy client.
4. Configure policies in Policy Agent configuration files.
5. Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement.
6. Configure Policy Agent for configuration file import services.
7. Configure Policy Agent for automatic monitoring of applications.

Step 1: Configure general information

Before defining policies, some basic operational characteristics of the Policy Agent need to be configured. Follow these steps to configure these items.

1. Set the TZ and LIBPATH environment variables.

   Use the TZ environment variable to specify the correct time zone. Use the LIBPATH environment variable so that the required dynamic link library (DLL) files can be located when you start the Policy Agent. For information about how to specify these environment variables, see “Starting and stopping the Policy Agent” on page 865. You can also refer to comments in the sample start procedure that is shipped in SEZAINST(EZAPAGSP).
2. Specify the name of the main configuration file.

   You can specify the name of the main configuration file using the -c start option or the PAGENT_CONFIG_FILE environment variable, or you can use the default file name /etc/pagent.conf. For information about the search order that Policy Agent uses to locate the main configuration file, and for examples of different ways to specify the main configuration file name, see “Starting and stopping the Policy Agent” on page 865. You can also refer to comments in the sample start procedure that is shipped in SEZAINST(EZAPAGSP).
3. Define the TcpImage or PEPInstance statements in the main Policy Agent configuration file.

   The PEPInstance statement is a synonym for TcpImage, and either can be used. PEPInstance refers to policy enforcement point (PEP), the component of a policy system that enforces policies, which for z/OS is the TCP/IP stack.

   Results:

- The refresh interval used for the main configuration file will be the smallest of the values specified for the image-specific configuration files.
- When the main configuration file is an MVS data set, it is reread at each refresh interval (which is the smallest of the individual stack refresh intervals), regardless of whether it has actually been changed or not. Because Policy Agent restarts all stack-related processing when the main configuration file is reread, this effectively makes the refresh interval for all stacks the same as this smallest configured interval.
- The TcpImage or PEPInstance statement and all its parameters have no effect on policies defined for policy clients.

To install a common set of policies to a set of stacks served by a single Policy Agent, do not specify image-specific configuration files for each image. In this case, there is only one configuration file (the main one) and the policy information contained in it is installed to all of the configured stacks. Different refresh intervals can also be configured for each image, but would probably be less useful in this case.

In either case, it is possible that TCP/IP stacks configured to the Policy Agent are not started or even defined. The Policy Agent will fail when trying to connect to those stacks and log appropriate error messages.

Rule: To dynamically add a TCP/IP stack to the Policy Agent configuration and have active policies automatically installed, in addition to adding the TcpImage statement to the configuration file, further action might be necessary as follows:

- If the Policy Agent was started with the **-i** startup option, no further action is necessary. Active policies will be automatically installed to the stack when it becomes active.
- If the Policy Agent was not started with the **-i** startup option, do one of the following:
  - Issue the MODIFY REFRESH or MODIFY UPDATE command after the stack becomes active. If you issue the MODIFY REFRESH or MODIFY UPDATE command before the stack becomes active, policies will not be automatically installed.
  - Wait on the next update interval to check for configuration changes. If the stack is not active, policies will not be automatically installed.

The Policy Agent does not end when any (or all) stacks end. When the stacks are restarted, active policies are automatically reinstalled.

The TcpImage statement specifies a TCP/IP image and its associated configuration file to be installed to that image. The following example installs the policy control file */tmp/TCPCS.policy* to the *TCPCS* TCP/IP image, after flushing the existing policy control data:

```
TcpImage TCPCS /tmp/TCPCS.policy FLUSH
```

For information about the FLUSH, NOFLUSH, PURGE, and NOPURGE parameters, see "FLUSH and PURGE considerations" on page 869.

4. Define the appropriate logging level.

   The LogLevel statement is used to define the amount of information to be logged by the Policy Agent. The default is to log only event, error, console, and warning messages. This might be appropriate for a stable policy configuration, but more information might be required to understand policy processing or debug problems when first setting up policies or when making significant changes. Specify the LogLevel statement with the appropriate logging level in the main configuration file.

Note: The maximum logging level (511) can produce a significant amount of output, especially with large LDAP configurations. This is not a concern if a z/OS UNIX log file is used, because Policy Agent uses a set of log files with a finite size in a round-robin configuration (the number and size of these files is controllable with the PAGENT_LOG_FILE_CONTROL environment variable). But when using the syslog daemon as the log file, the amount of log output produced should be taken into consideration.

5. Provide the following security authorizations. Because the Policy Agent can affect system operation significantly, the following security authorizations are required.
   - A user starting Policy Agent must be a superuser.
   - Security product authority (for example, RACF(R)) is required to start the Policy Agent. For sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.
6. If Policy Agent's PAPI clients, including the **pasearch** command, are not defined as a superuser, to retrieve policies you must define security product authority in the SERVAUTH class for that client. The security product authority is always required in cases where the image name cannot be defined as a superuser. Remote policy clients are never defined as a superuser on the policy server, so security product authority is always required for them. These profiles can be defined by image name and policy type (ptype = QoS, IDS, IPSec, TTLS, or Routing). Using a wildcard for profile names is allowed.

   `EZB.PAGENT.`*`sysname`*`.`*`image`*`.`*`ptype`*

   where:
   - *sysname* - System name defined in sysplex
   - *image* - Tcp name, policy client name, or import request name for policy information that is being requested
   - *ptype* - Policy type that is being requested:
     - QOS - Policy QoS
     - IDS - Policy IDS
     - IPSec - Policy IPSec
     - TTLS - Policy AT-TLS
     - Routing - Policy Routing

   For details about the import request name, see “Configuration file import services” on page 839.

   Tip: You can specify a wildcard on segments of the profile name.

   Rules:
   - When you use policy clients, the image portion of the profile name on the policy server must match or include the name of the policy clients. Configure each policy client name using the ClientName parameter on the PolicyServer statement, or use the default value for the ClientName parameter. For information about specifying the client name on the PolicyServer statement, see *z/OS Communications Server: IP Configuration Reference*.
   - When you use import requestors, the image portion of the profile name on the policy server must match or include the import request name. If you use the IBM Configuration Assistant for z/OS Communications Server as the import requestor, configure the import request name on the Import Policy Data panel. For information about the import request name, see “Configuration file import services” on page 839.

Policy Agent checks all client requests to verify that the SERVAUTH class is active and that the profiles exist for the images and policy types in the request.

If a client's request is for multiple images or policy types, and permission is granted for only a subset of what is requested, Policy Agent returns only information for the subset for which permission is granted. However, if permission is denied for an entire request, including instances when only a single image or policy type is requested, an error is returned to the client indicating that permission is denied.

If the SERVAUTH class is not active or profiles are not active for the client's request (image, policy type), an error is returned to the client indicating that permission is denied.

See the EZARACF sample in SEZAINST for sample commands needed to create the profile name and permit users to it.

Step 2: Configure Policy Agent as a policy server

If you want to use the Policy Agent as a policy server, perform these steps:

1. Define the port to which policy clients will connect.

   If policy clients are to be used, the ClientConnection statement in the main configuration file provides the port that Policy Agent listens on for remote connections. You can use the default port (16310), but you must specify the ClientConnection statement to use Policy Agent as a policy server.

   Guideline: Reserve the port specified on the ClientConnection statement using the PORT statement in the TCP/IP profile.

   Restriction: The port value cannot match the port value that is configured on the ServicesConnection statement.

2. Define a set of policy client matching statements that select the configuration files to be used for policy clients.

   When a policy client connects to the policy server, the DynamicConfigPolicyLoad statements in the main configuration file are evaluated to determine whether there is a match. The names are case sensitive with regard to matching. When a matching statement is found, the parameters identify both common and image-specific configuration files to be used for the policy client. If no matching statement is found, a default image-specific file is used. A matching statement (or default values) is bound to a policy client for the life of that client, until one of the following events occur:

   - The policy client disconnects from the policy server.
   - The connection between the policy server and policy client ends.
   - The associated DynamicConfigPolicyLoad statement is removed. In this case, the policy client is bound to a different DynamicConfigPolicyLoad statement (or to default values).

   You can use a regular expression for the policy client name on the DynamicConfigPolicyLoad statement to cause the statement to match multiple policy clients. For a description of supported regular expressions on the DynamicConfigPolicyLoad statement, see *z/OS Communications Server: IP Configuration Reference*.

   For example, the expression (.+)_(.+) matches any client name composed of one or more characters, followed by an underscore, followed by one or more characters. The default client names configured on the PolicyServer statement on the policy client would match this expression.

   You can use two different methods to substitute all or part of the client name in parts of the image-specific file name.

- A single wildcard character (*) is replaced with the entire client name.
- If you use a regular expression as the DynamicConfigPolicyLoad statement client name, you can use the symbolic replacement values $0 through $9 in the image-specific file name. The value $0 represents the entire portion of the client name that matched, while the values $1 through $9 represent portions of the client name that match corresponding parenthesized sub-expressions in the regular expression. Using the regular expression (.+)_(.+) as an example, and a policy client name of SYS123_TCPIP2, the values of the possible replacement variables are as follows:
  - The value * is replaced with SYS123_TCPIP2
  - The value $0 is replaced with SYS123_TCPIP2
  - The value $1 is replaced with SYS123
  - The value $2 is replaced with TCPIP2

  In this example, the value $0 is the same as the value *, but this does not hold true for all regular expressions. If you want to use the entire client name as a replacement value, specify the value *.

The matching hierarchy used is as follows:

a. Exact match between the policy client name and the DynamicConfigPolicyLoad statement.
b. Regular expression match between the policy client name and the DynamicConfigPolicyLoad statement. The longest matching regular expression is chosen. If multiple statements match with the same length *clientname* parameter, the statement chosen is based on alphabetical order.
c. No matching statement. A default file is used based on the policy type, as follows:

Policy type	Default file
AT-TLS	/etc/pagent_remote.ttls
IDS	/etc/pagent_remote.ids
IPSec	/etc/pagent_remote.ipsec
QoS	/etc/pagent_remote.qos
Routing	/etc/pagent_remote.routing

The following example shows the DynamicConfigPolicyLoad statement matching by using a regular expression to simulate a simple wildcard, and the resulting configuration files that are used, using IPSec policies.

```
DynamicConfigPolicyLoad  Rem.*
{
  PolicyType             IPSec
  {
    CommonPolicyLoad     //'ETC.COMMON.IPSEC'
    PolicyLoad           //'ETC.IPSEC(*)'
  }
}

DynamicConfigPolicyLoad  Remote.*
{
  PolicyType             IPSec
  {
    PolicyLoad           /etc/*.ipsec
  }
}

DynamicConfigPolicyLoad  Remote5
{
```

```
  PolicyType             IPSec
  {
    CommonPolicyLoad     /user10/common_remote.ipsec
    PolicyLoad           /user10/pagent_remote5.ipsec
  }
}
```

The resulting configuration files used for a variety of policy clients are shown in Table 41:

Table 41. Configuration files used for various policy clients

Policy client name	Matching statement	Common IPSec configuration file	Image IPSec configuration file
Remote1	Remote.*	None	/etc/Remote1.ipsec
Remote5	Remote5	/user10/common_remote.ipsec	/user10/pagent_remote5.ipsec
Rem42	Rem.*	//'ETC.COMMON.IPSEC'	//'ETC.IPSEC(REM42)'
remote5	Not applicable	None	/etc/pagent_remote.ipsec

The following example shows the DynamicConfigPolicyLoad statement matching by using a more complex regular expression, and the resulting configuration files that are used, using IDS policies. The regular expression matches two strings separated by an underscore character. Each string must begin with an uppercase alphabetic character and end with a numeric character.

```
DynamicConfigPolicyLoad  ^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)$
{
  PolicyType             IDS
  {
    CommonPolicyLoad     //'ETC.COMMON.IDS'
    PolicyLoad           //'ETC.$1($2)'
  }
}
```

The resulting configuration files used for a variety of policy clients are shown in Table 42:

Table 42. Configuration files used for various policy clients

Policy client name	Matching statement	Common IDS configuration file	Image IDS configuration file
SYS42_TCPIP2	^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)$	//'ETC.COMMON.IDS'	//'ETC.SYS42(TCPIP2)'
Remote1_Image5	^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)$	//'ETC.COMMON.IDS'	//'ETC.REMOTE1(IMAGE5)'
SYS123_TCPIP	Not applicable	None	/etc/pagent_remote.ids

Rule: The policy client names and DynamicConfigPolicyLoad statement names are case sensitive, but MVS data set names are not. Therefore, be careful when defining MVS data set configuration files that include a wildcard that is to be substituted with the policy client name. For example, the policy client names *client42* and *Client42*, if used as a substitution variable in an MVS data set name, would result in the same configuration file being used for both policy clients.

3. Configure one or more user IDs on the policy server system to match the user IDs of the policy clients.

   Each policy client uses a unique client name, but also must present valid credentials to the policy server. Valid credentials include a user ID and password or a user ID and PassTicket (if secure signon is enabled).

Rule: The password defined for the user ID must match the password configured using the AuthBy Password parameter on the PolicyServer statement on the policy client.

A SAF user ID representing a policy client must be defined to the security product. The user ID must be defined with an OMVS segment. When RACF is used as the security product, define the SAF user ID with the following command:

```
ADDUSER client PASSWORD(password) DFLTGRP(OMVSGRP) OMVS(UID(x) HOME('/home/client'))
```

Each policy client does not need to use a unique user ID, although that is a configuration option. The user ID is used for two purposes on the policy server:

- User authentication when the policy client connects to the policy server
- Access to SERVAUTH profiles to determine which policies the client can access

4. Permit Policy Agent to the BPX.DAEMON FACILITY class profile.

   For information about the use of the BPX.DAEMON profile, see "BPX.DAEMON FACILITY class profile" on page 43. If you decide to use this profile, permit the Policy Agent user ID to it. When RACF is used as the security product, permit the user ID with the following command:

   ```
   PERMIT BPX.DAEMON CLASS(FACILITY) ID(userid) ACCESS(READ)
   ```

5. If you want to use PassTicket security for policy clients, configure PTKTDATA class profiles.

   Policy clients can be configured to use either a password or a PassTicket on the PolicyServer statement, used when they connect to the policy server. For information about the secured signon function and PassTickets, see *z/OS Security Server RACF Security Administrator's Guide*. If you choose to use PassTickets, define the appropriate profiles in the PTKTDATA class to contain the application key used to generate and validate the PassTicket. When RACF is used as the security product, define the profiles with the following command:

   ```
   RDEFINE PTKTDATA profile SSIGNON(KEYMASKED(key)) UACC(UPDATE)
   ```

   The application name used by Policy Agent is PAGENT, so you need to define a profile with this name. The application key defined in the profiles must be the same on the policy client and policy server.

6. If you want to use secure connections between policy clients and the policy server, configure AT-TLS rules on the policy server to enable SSL connections from the policy clients.

   If policy clients use SSL connections, you must define AT-TLS rules on the policy server for communications between the policy client and server to be secured using AT-TLS. AT-TLS processing for a stack is enabled by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

   Rules:

   - Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.
   - Define AT-TLS policy for each stack through which policy server and policy client communication can flow.

- If some policy clients use SSL and others do not use SSL, define AT-TLS policy to select only those policy clients that use SSL.

Result: If you choose not to use SSL for your policy client to policy server connections, sensitive information flows in the clear on the connections. Sensitive information includes, but is not limited to, the following:

- The password sent from the policy client to the policy server for authentication (if you are using password credentials)
- Policy information sent from the policy server to the policy client, such as:
  - Passwords
  - Certificate labels
  - IPSec keys for IKE tunnels that use pre-shared keys
  - IPSec keys for manual tunnels

Requirement: The policy server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the policy server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers utilizing AT-TLS, see Appendix B, "TLS/SSL security," on page 1461.

An example of the AT-TLS policy statements used to enable AT-TLS for the policy server is as follows:

```
TTLSRule                     PolicyServerRule
{
   LocalPortRange                       16310
   JobName                              PAGENT
   Direction                            Inbound
   TTLSGroupActionRef                   PolicyServerGroup
   TTLSEnvironmentActionRef             PolicyServerConn
}

TTLSGroupAction                         PolicyServerGroup
{
   TTLSEnabled                          On
}

TTLSEnvironmentAction                   PolicyServerConn
{
   TTLSKeyRingParms
   {
      Keyring                           PAGENT/keyring
   }
   TTLSCipherParmsRef                   RequireEncryption
   HandshakeRole                        SERVER
}

TTLSCipherParms                    RequireEncryption
{
   V3CipherSuites              TLS_DHE_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites              TLS_DHE_DSS_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites              TLS_DH_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites              TLS_DH_DSS_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites              TLS_RSA_WITH_3DES_EDE_CBC_SHA
   V3CipherSuites              TLS_DHE_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites              TLS_DHE_DSS_WITH_AES_256_CBC_SHA
   V3CipherSuites              TLS_DH_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites              TLS_DH_DSS_WITH_AES_256_CBC_SHA
   V3CipherSuites              TLS_RSA_WITH_AES_256_CBC_SHA
   V3CipherSuites              TLS_DHE_RSA_WITH_AES_128_CBC_SHA
   V3CipherSuites              TLS_DHE_DSS_WITH_AES_128_CBC_SHA
   V3CipherSuites              TLS_DH_RSA_WITH_AES_128_CBC_SHA
   V3CipherSuites              TLS_DH_DSS_WITH_AES_128_CBC_SHA
   V3CipherSuites              TLS_RSA_WITH_AES_128_CBC_SHA
```

```
   V3CipherSuites              TLS_DHE_RSA_WITH_DES_CBC_SHA
   V3CipherSuites              TLS_DHE_DSS_WITH_DES_CBC_SHA
   V3CipherSuites              TLS_DH_RSA_WITH_DES_CBC_SHA
   V3CipherSuites              TLS_DH_DSS_WITH_DES_CBC_SHA
   V3CipherSuites              TLS_RSA_WITH_DES_CBC_SHA
   V3CipherSuites              TLS_RSA_WITH_RC4_128_SHA
   V3CipherSuites              TLS_RSA_WITH_RC4_128_MD5
   V3CipherSuites              TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5
   V3CipherSuites              TLS_RSA_EXPORT_WITH_RC4_40_MD5
}
```

Rule: The LocalPortRange value on the TTLSRule statement must include the value specified on the ClientConnection statement in the policy server main configuration file.

7. If you use secure connections between any policy clients and the policy server, permit Policy Agent to the EZB.INITSTACK.*sysname.tcpname* SERVAUTH class profile.

   Because AT-TLS policies are used to enable SSL connections from policy clients, Policy Agent must be permitted to the EZB.INITSTACK.*sysname.tcpname* SERVAUTH class profile if any policy clients use SSL. For more details, see "TCP/IP stack initialization access control" on page 1194. When RACF is used as the security product, permit Policy Agent to the profile with the following command:

   ```
   PERMIT EZB.INITSTACK.sysname.tcpname CLASS(SERVAUTH) ID(userid) ACCESS(READ)
   ```

Step 3: Configure Policy Agent as a policy client

If you want to use the Policy Agent as a policy client, perform the following steps:

1. Define the parameters needed to connect to the policy server using the ServerConnection statement in the main configuration file:
   - Specify the host name (or IP address) and port of a primary and an optional backup server.
   - If you want to use a secure connection to the policy server, specify parameters for a secure SSL connection. For details, see "Add SSL to Policy Agent connections" on page 864.

   Requirement: Connectivity to the policy server is required for all images on the policy client that need to connect to the policy server.
2. Define the policy server parameters to be used for each image on the PolicyServer statement in the image configuration files:
   - When the policy client connects to the policy server, the policy client needs to supply a user ID and authentication information (password or PassTicket). Specify these parameters on the PolicyServer statement. The user ID must be defined on the policy server system. For information about the PTKTDATA class profiles that are needed when a PassTicket is specified on the PolicyServer statement, see step 5 on page 855 in "Step 2: Configure Policy Agent as a policy server" on page 852.
   - The policy server determines what configuration files to load based on a matching DynamicConfigPolicyLoad statement in its configuration. Specify the client name that the policy server is to use for matching. If this parameter is not specified, the default value is the policy client's system name concatenated to the image name with an intervening underscore character (_). For example, if the client's system name is SYS42 and the image name for this policy client is TCPIP2, the default client name presented to the policy server is SYS42_TCPIP2.
   - Specify the types of policies to be retrieved from the policy server. You can specify one or more policy types. You can also specify parameters for each

policy type (FLUSH, NOFLUSH, PURGE, or NOPURGE). These parameters have the same meaning as the corresponding parameters on the TcpImage or PEPInstance statement.

For each policy type specified, the corresponding *xxx*Config statement for that type is ignored in the local configuration. For example, if PolicyType IPSec is specified on the PolicyServer statement, the IPSecConfig statement is ignored. This is true even if the primary and backup policy servers cannot be reached. You can use local or remote policy for each policy type, but not both.

Step 4: Configure policies in Policy Agent configuration files

Policies can be defined in any referenced Policy Agent configuration file. For more information, see the appropriate information for each policy type:

- Policy-based routing (See "Policy-based routing" on page 337)
- Quality of Service (See Chapter 17, "Quality of service," on page 873)
- Intrusion Detection Services (See Chapter 18, "Intrusion Detection Services," on page 897)
- IP filtering, and manual and dynamic VPN tunnels, collectively referred to as IPSec policies (See Chapter 19, "IP security," on page 923)
- Application Transparent Transport Layer Security (See Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193)

Step 5: Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement

The ReadFromDirectory statement in the Policy Agent configuration file initializes the Policy Agent as an LDAP client. The policies are downloaded from the LDAP server, along with the policies specified in the Policy Agent configuration files.

When configuring the ReadFromDirectory statement, first specify the name (or IPv4 address) and port of the primary server and the same for the backup server (if one is used).

Notes:

1. The LDAP client library used to connect to the LDAP server does not support IPv6.
2. When using the z/OS LDAP server, the server listens on a separate port for SSL connections. This means that you should specify the correct port depending on whether or not SSL is used.

Next, configure other connection attributes. The Policy Agent (as an LDAP client) must log in to the LDAP server. *The userid and password for logging in must be configured on the ReadFromDirectory statement.*The userid is also known as Distinguished Name for userid, and it is in the form of an LDAP DN. If the userid and password are not specified, the Policy Agent uses anonymous login to connect to the server.

The LDAP server can be configured with only LDAP protocol version 3. To use LDAP protocol version 3, you can set LDAP_ProtocolVersion to 3 on the ReadFromDirectory statement. This is the default value. This statement also configures the version of the schema to be retrieved from the server.

Finally, configure attributes to indicate how to search the LDAP server for policies. Policy roles allow one or more roles, or role-combinations, to be assigned to policy

rules using the ibm-policyRoles attribute. These roles represent the intended usage of the policy rules. For example, a role of "East Coast WAN" might be used to represent policies for the wide area network on the US East coast for an enterprise. Policy role values are not standardized; they are simply values used to assign roles to policies. When an entity that requires policies (such as Policy Agent) requests policies from an LDAP server, it can filter out policy rules that do not match the roles that it plays. Although similar to policy keywords, which also allow search scoping, policy roles are a bit more sophisticated. Specifically, role-combinations are allowed, which take the form of a specification like "roleA && roleB", meaning both roleA AND roleB. Since the ibm-policyRoles attribute is multi-valued, a form of CNF/DNF logic can be used for policy roles: the roles in a role-combination are ANDed, and the roles or role-combinations specified on different values of this attribute are ORed.

For the Version 1 schema, a base DN to start the search, and a *selector tag* value are configured. The selector tag is used to match against the SelectorTag attribute in the policy objects. For Version 1, the Policy Agent also automatically includes the stack name when searching for policies; this value is matched against the TcpImageName attribute in the policy objects. For the Version 2 schema, a base DN to start searching is also configured. This DN can specify a single LDAP object, a policy group, or an LDAP subtree containing many objects. For filtering the search, three keywords can be configured:

- SearchPolicyKeyword matches against the ibm-policyKeywords attribute in any policy object.
- SearchPolicyGroupKeyword matches against the ibm-policyGroupKeywords attribute in policy group objects.
- SearchPolicyRuleKeyword matches against the ibm-policyRuleKeywords attribute in policy rule objects.

Optionally, specify parameters for a secure SSL connection. For details, see “Add SSL to Policy Agent connections” on page 864.

The example that follows this list does the following:

- Connects to the LDAP server at IP address 9.100.1.1, using the default port 389.
- Specifies a userid and password to log in to the server.
- Specifies LDAP protocol version 3.
- Specifies schema version 3.
- Starts searching at the DN ou=policy, o=IBM, c=US object/subtree.
- Only selects policy objects that contain either the "POLICY" or "EASTERN" keywords.

```
ReadFromDirectory
{
LDAP_Server 9.100.1.1
LDAP_DistinguishedName cn=root, o=IBM, c=US
LDAP_Password 4qr56jb
LDAP_ProtocolVersion 3
LDAP_SchemaVersion 3
SearchPolicyBaseDN ou=policy, o=IBM, c=US
SearchPolicyKeyword POLICY
SearchPolicyKeyword EASTERN
}
```

Step 6: Configure Policy Agent for configuration file import services

If you connect an import requestor to the Policy Agent to provide configuration file import services, perform the following steps:

1. Define the port and TCP/IP image name to which import requestors will connect.

   If import requestors are to be used, the ServicesConnection statement in the main configuration file provides the port and TCP/IP image name that the Policy Agent listens on for remote connections. An import requestor is one type of services requestor provided for by the ServicesConnection statement. The Policy Agent listens for services requestor connections on only one TCP/IP image. You can specify the image name to be used, or use the name specified (or specified by default) on the TCPIPUSERID statement or TCPIPJOBNAME statement in TCPIP.DATA. If the default TCP/IP image cannot be determined, the Policy Agent uses the image name INET. In any case, the image name might or might not match an image name specified on a TcpImage statement:

   - If the specified name does not match any TcpImage statement, the Policy Agent generates an internal TcpImage statement with default values to represent the TCP/IP image. This means that you can specify a maximum of only 7 (instead of 8) TcpImage or PEPInstance statements.
   - In a single stack (INET) environment, the Policy Agent uses the active TCP/IP image to listen for services connection requests.

   Rule: The ServicesConnection statement is required for any Policy Agent that accepts connections from an import requestor.

   Guideline: Reserve the port specified on the ServicesConnection statement using the PORT statement in the TCP/IP profile.

   Restriction: The port value cannot match the port value configured on the ClientConnection statement.

2. Optionally configure secure connections from the import requestors.

   By default, the ServicesConnection statement defines a basic, unsecure connection. You can define a secure connection instead, and specify the level of tracing and the TLS/SSL key ring to use. You must specify the name of a SAF key ring. Key ring files created by the System SSL gskkyman utility are not supported. When you configure a secure connection, Policy Agent automatically creates an AT-TLS policy for the connection, and the import requestor must also specify that the connection is to be secured. You must enable the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile for the generated AT-TLS policy to be effective.

   Following is an example of a ServicesConnection statement for a secure connection:

```
ServicesConnection
{
   Port       17000
   ImageName  TCPIP1
   Security   Secure
   Trace      14
   Keyring    PAGRING
}
```

   Following is the AT-TLS policy generated from this ServicesConnection statement:

```
TTLSRule                      TTLS_RULE_____________GENERATED
{
   LocalPortRange             17000
   JobName                    PAGENT
```

```
   Direction                  Inbound
   TTLSGroupActionRef         TTLS_GROUP_ACTION_______GENERATED
   TTLSEnvironmentActionRef   TTLS_ENVIRONMENT_ACTION_GENERATED
}

TTLSGroupAction               TTLS_GROUP_ACTION_______GENERATED
{
   TTLSEnabled                On
   Trace                      14
}

TTLSEnvironmentAction         TTLS_ENVIRONMENT_ACTION_GENERATED
{
   HandshakeRole              SERVER
   TTLSKeyRingParms
   {
      Keyring                 PAGRING
   }
}
```

The Policy Agent installs this generated policy in the TCP/IP image specified explicitly or by default on the ServicesConnection statement. This generated policy uses a priority value that is lower than any specified AT-TLS policies, so it is installed as the last policy in the TCP/IP image. If local or remote AT-TLS policies are configured, the Policy Agent installs those policies before installing the generated policy. If you configure AT-TLS policies on a policy server, those policies must be successfully retrieved before the Policy Agent is able to accept connections from services requestors. Accepting connections from services requestors can be affected by problems or delays in retrieving the AT-TLS policies from the policy server.

If you change the ServicesConnection statement, the generated policy is uninstalled or reinstalled as follows:

- If you change the Port, Trace or Keyring parameters, the Policy Agent regenerates and reinstalls the policy.
- If you change the ImageName parameter, the Policy Agent uninstalls the generated policy from the previous image and installs the policy on the new image.
- If you change the Security parameter value from Secure to Basic, the Policy Agent uninstalls the generated policy.

If you delete the ServicesConnection statement, the Policy Agent uninstalls the generated policy.

3. To restart the listen for services requestor connections and, if required, to reinstall the generated AT-TLS policy, issue the MODIFY SRVLSTN command. For information about when you might use the MODIFY command for Policy Agent, see *z/OS Communications Server: IP System Administrator's Commands*.

Step 7: Configuring Policy Agent to automatically monitor applications

You can use the Policy Agent to automatically start, stop, and monitor a set of related applications. Policy Agent starts the applications and monitors them to ensure that they remain active. If Policy Agent determines that any applications have not started or have stopped, it continues to try to start or restart the applications, up to a configurable retry limit within a configurable retry period.

To configure the Policy Agent for automatic monitoring, perform the following steps:

1. Decide what applications you want to monitor.

   You can use the Policy Agent to monitor any or all of the following applications:

   - Defense Manager daemon (DMD)
   - Internet Key Exchange daemon (IKED)
   - Network security services daemon (NSSD)
   - Syslog daemon (SYSLOGD)
   - Traffic Regulation Management daemon (TRMD)

   Determine which of these applications you currently use, or want to start using, in your environment, and for each application, determine whether you want the Policy Agent to start, stop, and monitor the application.

   Requirements:

   - To start the application, you must use a cataloged procedure that accepts a number of variables that are provided by the Policy Agent. A sample procedure is included in SEZAINST(EZAPOLPR).
   - If you want to manually start, restart, or stop the application, you must use MODIFY commands that are directed to the Policy Agent. If you issue the commands directly to the application itself, Policy Agent is not aware of the action and the monitoring logic will probably not produce the expected results.

   Results:

   - If you start the Policy Agent after you have already started an application to be monitored, Policy Agent starts monitoring the application if it was originally started with the same job name that is configured to the Policy Agent. If the application needs to be restarted later, it is restarted using the cataloged procedure configured to the Policy Agent. This might not be the same procedure that was originally used to start the application.
   - If you start the Policy Agent after you have already started an application to be monitored, but the application does not use the same job name that is configured to the Policy Agent, then the Policy Agent is not able to detect that the application is active. The Policy Agent will try to start another instance of the application, which is likely to fail.

   Tip: If you configure applications to be monitored by the Policy Agent, ensure those applications are not running before starting the Policy Agent. However, you probably want to start syslogd before starting the Policy Agent, so you should ensure that Policy Agent is configured with the correct syslogd job name.

2. Configure the applications that you want to monitor using the AutoMonitorApps statement.

   You can configure applications that you want to monitor that are or are not associated with a particular TCP/IP stack. You can specify the cataloged procedure used to start each application, the job name for the application, and other application-specific parameters on the AutoMonitorApps statement.

   Perform the following steps to configure the applications that you want to monitor:

   a. Specify the AutoMonitorApps statement in the main Policy Agent configuration file.

      - Use the AppName parameter to specify each application that is not associated with a particular TCP/IP stack. All supported applications except TRMD fall into this category.

- Use the TcpImageName and AppName parameters to specify each application that is associated with a particular TCP/IP stack. TRMD is the only application that falls into this category.

b. Use the ProcName parameter for each AppName parameter on the AutoMonitorApps statement to specify the cataloged procedure that is used to start each application. Because all key data is passed to the procedure as variables, you can use a single procedure for all configured applications. You can also use a unique procedure for one or more applications.

c. Use the Jobname parameter for each AppName parameter on the AutoMonitorApps statement to specify the job name for each application.

d. Use the StartParms parameter for each AppName parameter on the AutoMonitorApps statement to specify start parameters for each application.

e. Use one or more EnvVar parameters for each AppName parameter on the AutoMonitorApps statement to specify application-specific parameters, such as time zone or configuration file name. You can specify any or all environment variables that are accepted by the specific application.

Following is an example of the AutoMonitorApps statement:

```
AutoMonitorApps
{
  AppName            IKED
  {
    Procname         POLPROC
  }
  AppName            TRMD
  {
    TcpImageName     TCPIP1
    {
      Procname       POLPROC
      Jobname        TRMD1
    }
    TcpImageName     TCPIP3
    {
      Procname       POLPROC
      Jobname        TRMD3
    }
  }
}
```

This example shows how to specify parameters for two types of applications:

- An application without stack affinity, meaning that a single copy of the application runs regardless of how many TCP/IP stacks are running. This example uses IKED as such an application.
- An application with stack affinity, meaning that one instance of the application runs on each TCP/IP stack. This example uses TRMD as such an application.

3. Configure global monitoring parameters using the AutoMonitorParms statement.

   Use the AutoMonitorParms statement in the main Policy Agent configuration file to specify global monitoring parameters, such as the monitor time interval and retry limits.

   - Use the MonitorInterval parameter to specify the monitor interval in seconds.
   - Use the RetryLimitCount and RetryLimitPeriod parameters to specify how many times within a given time period Policy Agent should try to start or restart an application. If the application fails to successfully start or restart after the retry limit has been reached, Policy Agent stops trying until the

application is manually started using the MODIFY *procname*,MON,START,*application* command.

Add SSL to Policy Agent connections

The Secure Sockets Layer (SSL) protocol begins with a handshake. During the handshake, the client authenticates the server, the server optionally authenticates the client, and the client and server agree on how to encrypt and decrypt information.

Server Authentication: When using SSL to secure communications, the SSL authentication mechanism known as server authentication is used. With server authentication, the server must have a digital certificate that authenticates the server to the Policy Agent client. The server supplies the client with the certificate during the initial SSL handshake. If the client validates the server's certificate, a secure communication channel is established between the server and the Policy Agent client.

For server authentication to work, the server must have a private key and associated server certificate in the server key ring file.

To conduct commercial business on the Internet, you might use a widely known Certificate Authority (CA), such as VeriSign, to get a high assurance certificate. For a relatively small private network within your own enterprise or group, you can issue your own certificates, called self-signed certificates, for your own use.

Client Authentication: When using SSL Client Authentication, the client passes a digital certificate to the server as part of the SSL handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server.

Self-signed Server Certificates: Normally, a server certificate should be obtained from a known CA. However, for testing, an installation might use a self-signed server certificate. Because the clients will not know about the issuer of the self-signed server certificate, in most cases it is necessary to add the server's self-signed certificate to the client's signer certificates.

The gskkyman utility is used to create public/private key pairs and certificate requests, receive certificate requests into a key ring, and manage keys in a key ring. The gskkyman utility is documented in *z/OS Cryptographic Services System SSL Programming*. The gskkyman utility is shipped with z/OS in System SSL, which is part of the cryptographic services base element of z/OS. For detailed instructions on setting up certificates and key rings, see Appendix B, “TLS/SSL security,” on page 1461.

The set of SSL protocol cipher specifications to be allowed for the secure session can be set for the policy server connection.

Rule: Define AT-TLS policy on the policy server such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.

For the list of cipher suites supported and the default order used if none is specified, see *z/OS Cryptographic Services System SSL Programming*.

The Policy Agent connection to LDAP can be secured using SSL by tailoring the following parameters on the ReadFromDirectory statement. This allows for protection of policy retrieval from an LDAP server.

- LDAP_SSLKeyringFile
- LDAP_SSLKeyringPassword
- LDAP_SSLName

The policy client connection to the policy server can be secured using SSL by tailoring the following parameters on the ServerConnection statement. This allows for protection of policy retrieval from the policy server.

- ServerSSLKeyring
- ServerSSLKeyringPassword
- ServerSSLKeyringStashFile
- ServerSSLName
- ServerSSLV3CipherSuites

You can secure the connection used by services requestors by tailoring the following parameters on the ServicesConnection statement. This provides protection of policy retrieval by import requestors, such as the IBM Configuration Assistant.

- Security Secure
- Keyring

For more detail about these parameters, see *z/OS Communications Server: IP Configuration Reference*. Additional information about the concepts of cryptography and SSL can be found at the following Web sites:

- http://httpd.apache.org/docs/2.0/ssl/ssl_intro.html
- http://www.verisign.com/repository/crptintr.html

Starting and stopping the Policy Agent

You can start the Policy Agent from the z/OS shell, as a started task, or in some cases by using the TCP/IP AUTOLOG statement (see "AUTOLOG considerations"). If you use the shell, the Policy Agent should be started in a background shell session, by specifying a trailing & on the command line.

AUTOLOG considerations

If a procedure in the AUTOLOG list also has a PORT statement reserving a TCP or UDP port but does not have a listening connection on that port, TCP/IP periodically attempts to cancel that procedure and start it again.

Guideline: Do not use AUTOLOG to start the Policy Agent if any listening connections are used. The Policy Agent is unlike typical servers, and performs functions outside the realm of listening for connections from other applications. Sometimes during normal operation of the Policy Agent, listening connections are unavailable for short periods of time. When listening connections are unavailable, it is possible that the AUTOLOG timer could restart the Policy Agent.

Policy Agent optionally listens on one or more of the following ports:

- The pagentQosListener port (usually defined in the /etc/services file as port 1700). This happens only when the PolicyPerfMonitorForSDR statement is configured for a given TCP/IP stack.

- The port defined or specified by default on the ClientConnection statement, which is used to listen for remote policy client connections on all TCP/IP stacks.
- The port defined or specified by default on the ServicesConnection statement, which is used to listen for services requestor connections on a single TCP/IP stack. For information about the ServicesConnection statement and specifying which stack to use to listen for these connections, see *z/OS Communications Server: IP Configuration Reference*.

If you want to start Policy Agent with AUTOLOG, you must do one of the following:

- Ensure that none of the listening ports used by Policy Agent are reserved by the PORT statement in the TCP/IP profile.
- Add the NOAUTOLOG parameter to the PORT statement in the TCP/IP profile. For example:

```
PORT
 1700  TCP PAGENT NOAUTOLOG
 16310 TCP PAGENT NOAUTOLOG
 16311 TCP PAGENT NOAUTOLOG
```

In addition, when the PolicyPerfMonitorForSDR statement is being used, if the pagentQosCollector port (usually defined in the /etc/services file as port 1701) is reserved in the PORT list it should always be specified with the NOAUTOLOG parameter, because this port is never used as a listening port. For example:

```
PORT
 1701 TCP PAGENT NOAUTOLOG
```

Tip: When Policy Agent is not listening on any ports, you can use the autostart feature of AUTOLOG as previously described. However, the monitoring and automatic restart features of AUTOLOG are unavailable because AUTOLOG must listen to a TCP or UDP connection.

If you fail to take one of the above actions, Policy Agent will be periodically canceled and restarted by TCP/IP.

Specifying environment variables

The Policy Agent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

For policy time specifications to be properly acted upon, the TZ environment variable needs to be set to local time. You can set the LIBPATH and TZ environment variables as follows:

- When starting from the z/OS shell:

  Export the LIBPATH and TZ environment variables before starting the Policy Agent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

  ```
  export LIBPATH=/usr/lib
  export TZ=EST5EDT
  ```

- When starting as a started task, use either of the following methods:
  - Specify LIBPATH and TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

    ```
    // PARM=('ENVAR("LIBPATH=/usr/lib","TZ=EST5EDT")/')
    ```

  - Export the LIBPATH and TZ environment variables in a file specified with the STDENV DD statement. For example:

```
// PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//STDENV DD PATH='/etc/pagent.env',PATHOPTS=(ORDONLY)
```

In the /etc/pagent.env file:

```
LIBPATH=/usr/lib
TZ=EST5EDT
```

The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRM*xx* PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
```

For more information on specifying run-time options, see *z/OS Language Environment Programming Guide*. For details on setting the LIBPATH and TZ environment variables, see *z/OS UNIX System Services Command Reference*.

Main configuration file search order

Although the /etc/pagent.conf is the default configuration file, a specific search order is used when starting the Policy Agent. The following order is used:

1. File or data set specified with the **-c** startup option
2. File or data set specified with the PAGENT_CONFIG_FILE environment variable
3. /etc/pagent.conf

The syntax for a z/OS UNIX file is different than the syntax for an MVS data set. The following examples use the PAGENT_CONFIG_FILE environment variable:

- PAGENT_CONFIG_FILE=*/dir/file*
- PAGENT_CONFIG_FILE=//'*mvs.dataset.name*'

Other considerations when starting the Policy Agent

If the Policy Agent cannot successfully parse the start options, log output is written to the syslog daemon (syslogd).

At initialization, the Policy Agent creates a z/OS UNIX file called /tmp/*tcpname*.Pagent.tmp. This occurs for every TCP/IP stack defined on a TcpImage statement.

In this z/OS UNIX file, *tcpname* is the name of a TCP/IP stack from a TcpImage statement. During TCP/IP stack initialization, the TCP/IP stack will attempt to modify a file by this name to notify the Policy Agent that the stack has been reactivated. This causes the Policy Agent to automatically attempt to reinstall the existing policies to this stack.

To ensure that only one Policy Agent is started, the Policy Agent uses the following enqueue:

- Enqueue name is TCP_TCPI
- Resource name is TCPIP.PAGENT

When starting from the shell, note that the Policy Agent executable file resides in the /usr/lpp/tcpip/sbin directory. There is also a link from the /usr/sbin directory. Make sure your PATH statement contains either the /usr/sbin or /usr/lpp/tcpip/sbin directory.

For example, the following command starts Policy Agent with these characteristics:

```
pagent -c /u/user10/pldap.conf -l SYSLOGD &
```

- Policy Agent uses the configuration file /u/user10/pldap.conf
- Policy Agent logs output to the syslog daemon (SYSLOGD). Note that "SYSLOGD" must be specified in uppercase to obtain this behavior

Use the S PAGENT command on an MVS console or SDSF to start the Policy Agent as a started task. A sample procedure is shipped in member EZAPAGSP in SEZAINST.

Stopping the Policy Agent

You can stop the Policy Agent by:

- Using the operator command STOP
- Using the kill command in the z/OS shell
- Using the operator command CANCEL. Use the CANCEL command only as a last resort if the STOP or kill commands do not completely stop the Policy Agent.

Result: When the Policy Agent is shut down normally (KILL or STOP), if the PURGE option is configured, all QoS, IDS, and AT-TLS policies are purged from this stack. IPSec and Routing policies are not automatically purged.

The following kill command with the TERM signal will enable Policy Agent to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

where pid is the Policy Agent process ID.

The Policy Agent process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

It can also be obtained from the /tmp/pagent.pid file. The /tmp/pagent.pid file is a temporary file created by the Policy Agent. It contains the process ID of the current invocation of the Policy Agent. This temporary file is deleted when the Policy Agent is stopped.

Refreshing policies

The MODIFY command may be used to interactively cause the Policy Agent to reread the configuration information and, if requested, download objects from the LDAP server. In addition to this, the Policy Agent will also accept SIGHUP signals to perform the refresh function. See the *z/OS Communications Server: IP System Administrator's Commands* for more detailed information on the MODIFY command.

Restriction: The import configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the MODIFY REFRESH and MODIFY UPDATE commands do not apply to these files.

FLUSH and PURGE considerations

The FLUSH/NOFLUSH and PURGE/NOPURGE parameters can be configured for each policy type supported by the Policy Agent.

Restriction: The import configuration files are parsed only once. The import policies are not installed in the TCP/IP stack, so the FLUSH and PURGE parameters do not apply to these files.

These parameters determine whether or not policies are deleted from the associated TCP/IP stack under certain conditions, as detailed in Table 44 on page 870.

Table 43 shows where you configure these parameters for each type of local or remote policy.

Table 43. Where Policy Agent FLUSH and PURGE are configured

Policy type	Statement where configured
Local Routing policies	Not configurable (always support FLUSH and NOPURGE)
Local IDS policies	IDSConfig or TcpImage/PEPInstance
Local IPSec policies	Not supported
Local QoS policies	TcpImage/PEPInstance
Local AT-TLS policies	TTLSConfig or TcpImage/PEPInstance
Remote policies (all types except IPSec and Routing)	PolicyServer or TcpImage/PEPInstance
Import policies	Not supported

Results:

- IPSec policies do not use these parameters. Instead, IPSec functions as though the FLUSH and NOPURGE parameters are always specified, with the exception that the FLUSH parameter has no effect when the MODIFY REFRESH command is entered.
- Parameters specified on the TcpImage/PEPInstance statement are overridden by parameters configured on other statements.

Table 44 on page 870 shows the results of using the FLUSH and PURGE parameters.

Table 44. How Policy Agent FLUSH and PURGE are used

Event	IPSec policies	Routing policies	Other policies
Policy Agent start (FLUSH defined)	All policies are replaced in the TCP/IP stack.	All policies are deleted and reloaded into the TCP/IP stack.	All policies are deleted and reloaded into the TCP/IP stack.
Policy Agent start (NOFLUSH defined)	All policies are replaced in the TCP/IP stack.	All policies are deleted and reloaded into the TCP/IP stack.	All changed policies are updated in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.
Policy Agent termination (PURGE defined)	TCP/IP stack policies are unchanged.	TCP/IP stack policies are unchanged.	All policies are removed from the TCP/IP stack.
Policy Agent termination (NOPURGE defined)	TCP/IP stack policies are unchanged.	TCP/IP stack policies are unchanged.	TCP/IP stack policies are unchanged. Deleted policies are not removed from the TCP/IP stack.
Policy Agent update (FLUSH defined)	If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.	Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.	Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.
Policy Agent update (NOFLUSH defined)	If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.	Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack.	Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.
Policy Agent refresh (FLUSH defined)	If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.	If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.	If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.
Policy Agent refresh (NOFLUSH defined)	If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack.	If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.	Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.

Rules:

- The TCP/IP stack results do not apply for policy client or import requestor policies configured on the policy server.
- The PURGE and NOPURGE parameters have no effect on policy client or import requestor policies configured on the policy server.

Result: When a TCP/IP stack is recycled, the result is the same as if the FLUSH parameter was specified; all active policies are reinstalled into the stack.

Switching between local and remote policies

If you dynamically switch from local policies to remote policies by adding the PolicyServer statement or a new PolicyType parameter within that statement, the FLUSH and PURGE parameters that are specified on the PolicyServer statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

Likewise, if you dynamically switch from remote policies to local policies by removing the PolicyServer statement or a PolicyType parameter from within that statement, the FLUSH and PURGE parameters that are specified on the *xxx*Config statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

When the NOFLUSH parameter is used due to one of these dynamic switches, the result is that both the local and remote policies exist in the configuration; existing policies are not deleted when NOFLUSH is in effect, as shown in Table 44 on page 870.

The following examples show how switching between local and remote policies works:

- Switching from local IDS to remote IDS policies:
  1. The TcpImage statement is configured with the FLUSH parameter.
  2. The IDSConfig statement is not configured with the FLUSH or NOFLUSH parameters, so the TcpImage FLUSH value is used.
  3. The local IDS policies are read and installed.
  4. The PolicyServer statement is added with a PolicyType parameter for IDS that specifies the NOFLUSH value.
  5. The remote IDS policies are retrieved and installed.
  6. Because the NOFLUSH parameter is in effect (from the PolicyServer statement), the local IDS policies are not deleted; both the local and remote IDS policies exist.
- Switching from remote AT-TLS to local AT-TLS policies:
  1. The TcpImage statement is configured with the NOFLUSH parameter.
  2. The TTLSConfig statement is configured with the FLUSH parameter.
  3. The PolicyServer statement is configured with a PolicyType parameter for AT-TLS that specifies the FLUSH value.
  4. The remote AT-TLS policies are retrieved and installed.
  5. The PolicyType parameter for AT-TLS is removed from the PolicyServer statement.
  6. The local IDS policies are read and installed.
  7. Because the FLUSH parameter is in effect (from the TTLSConfig statement), the remote AT-TLS policies are deleted; only the local policies exist.

Result: Because the IPSec and Routing policy types always use the FLUSH value, the local and remote policies never exist at the same time.

Verifying that policies are correctly defined and functioning properly

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies defined correctly to the LDAP server?

  See the documentation appropriate for the LDAP server which you are using. LDAP servers usually allow you to install multiple files (LDIF), each containing different objects in the LDAP hierarchy. Structural objects higher in the directory tree must be installed before objects that are contained below them. Check for any error messages as each LDIF is installed. Some LDAP servers interpret two consecutive blank lines as end of file. Ensure that all of the objects in the LDIF have been installed by the LDAP server.

- Are the policies defined correctly to the Policy Agent?

  When starting the Policy Agent, first check for any error messages issued to the console. Message EZZ8434I indicates something is wrong with the Policy Agent environment. Message EZZ8438I indicates a syntax or semantic error in the policy definitions. Messages EZZ8439I and EZZ8440I indicate a problem with the LDAP server configuration or the server itself. For more information on diagnosing Policy Agent problems, see *z/OS Communications Server: IP Diagnosis Guide*. Use the UNIX **pasearch** command to display policy definitions. The output from this command indicates whether or not policy rules are active, and shows the parsed results of the policy definition attributes. One thing to note is that the Policy Agent is designed to ignore unknown attributes, so misspelled attributes will result in default values being used. The **pasearch** output can be used to verify that policies are correctly defined.

- Are the import policies defined correctly for configuration file import services?

  The import configuration files are parsed only once and always start with new policies. Any syntax or semantic errors in the import policy definitions are reported to the import requestor, and result in message EZZ8438I being issued. For more information about diagnosing Policy Agent problems, see *z/OS Communications Server: IP Diagnosis Guide*.

Chapter 17. Quality of service

Applications and users of TCP/IP networks have different requirements for the service they receive from those networks. A network that treats all traffic as best effort does not meet the needs of such users. *Service differentiation* is a mechanism to provide different service levels to different traffic types based on their requirements and importance in an enterprise network. For example, it might be critical to provide Enterprise Resource Planning (ERP) traffic better service during peak hours than that of FTP or web traffic. The overall service provided to applications or users, in terms of elements such as throughput and delay, is termed *Quality of service* (QoS). Network service providers that need to provide different QoS levels express their business goals in *Service Level Agreements* (SLAs). There are two types of service in TCP/IP networks that relate to QoS. The first is *Differentiated Services*, which provides QoS to broad classes of traffic or users, for example all outbound web traffic accessed by a particular subnet. The second is *Integrated Services*, which provides end-to-end QoS to an application, by reserving resources along a data path. For z/OS Communications Server, Integrated Services is largely provided by the RSVP Agent, which implements the Resource ReserVation Protocol.

Workload distribution also relates to QoS, in terms of the throughput and delay characteristics of a given server in a sysplex. The ability to dynamically monitor server performance and affect sysplex workload distribution is an important part of the overall QoS of a sysplex. Also important is the ability to limit the set of target systems considered for sysplex routing based on network selection criteria, such as source subnet.

Differentiated Services policies

Policies for Differentiated Services (DS) are used to select and control DS traffic for selected IP servers, such as FTP server traffic. The policy administrator selects the IP traffic to be controlled by defining policy rules. These policy rules include several attributes that can be specified to identify the traffic to be managed. These attributes fall into 2 categories, general attributes and application specified attributes. General attributes can be used to identify the IP traffic of most IP applications using a variety of information, such as:

- The source or destination IPv4 or IPv6 addresses or subnets
- The source and destination ports used by the application
- The IP protocol the application is using (TCP or UDP)
- The network interface selected for the outgoing traffic
- The jobname of the application

Application specified attributes allow policy administrators to identify outgoing application IP traffic based on information that is provided and defined by an application. For example, the IBM HTTP Server provides the TCP/IP stack with the URI (Universal Resource Identifier) associated with any outgoing data being sent to a client. This allows the policy administrator to define rules that identify traffic related to specific URIs and policy actions with unique DS controls for this traffic. For example, an installation can define a policy that specifies preferential treatment of outgoing traffic related to the servicing of any URIs beginning with */product/placeorder*. For more information on defining policy rules for the IBM HTTP

Server based on URIs, see *z/OS HTTP Server Planning, Installing, and Using* and the policy configuration file topic in *z/OS Communications Server: IP Configuration Reference*.

Any IP application using the TCP protocol can provide application specified attributes using extensions to the sendmsg() socket API. For more information, see the programming interfaces appendix in the *z/OS Communications Server: IP Programmer's Guide and Reference*. Application provided attributes can be specified in 2 forms:

- Application defined data: This allows applications to provide free-form text data that can be used to classify the application's outgoing traffic in terms that should be familiar to the application's administrator (for example, URIs are provided by the IBM HTTP server).
- Application specified priority: This allows applications to associate an application priority on the outgoing IP traffic. This application priority in itself does not automatically cause the application's traffic to get preferential treatment. In order to make use of these application specified priorities the policy administrator needs to define policy rules that map these priorities to policy actions that will govern the outgoing traffic of each priority level.

Applications can pass both application defined data and application specified priorities to the TCP/IP stack. When both are specified, the administrator is free to use either or both criteria in their service policy rules. However, it is strongly recommended that any policy rules defined using the application specified attributes should also include at least one general attribute that uniquely identifies the application instance. For example, when defining rules for the HTTP server using URIs, you can help further identify the application by specifying the source port for the server or the HTTP Server's jobname. This will help insure that unauthorized applications cannot exploit policy actions intended for the HTTP Server.

Several aspects of connection and throughput control can be specified with DS policies, including the following:

- TCP connection limits
- Maximum and minimum TCP connection rates, TCP maximum delay
- Committed access bandwidth (mean rate and peak rate) control/enforcement, also known as token bucket traffic shaping
- IPv4 type of service (ToS) byte or IPv6 traffic class setting, and mapping to zSeries Queued Direct I/O (QDIO) device priorities and VLAN user priorities.

The above DS service attributes are enforced by the TCP/IP stack in which the DS policies are installed. For additional information on the enforcement of these attributes, see *z/OS Communications Server: IP Configuration Reference*.

Token bucket traffic shaping is defined using the following parameters:

- DiffServInProfileRate is the average or mean rate that is desired to be transmitted over time. For example, 256 kilobits per second.
- DiffServInProfileTokenBucket is the *burst* size. This is how much data is allowed to be sent from the application to TCP/IP and still be allowed to be transmitted at the mean rate. It is suggested, if the application is not policing itself, that this burst size be at least one second's worth of data. Otherwise, if the application is sending large amounts of data at one time to TCP/IP, TCP/IP will slow that application down via congestion windows, and the mean rate may not be achieved.

- DiffServInProfilePeakRate is the highest rate that is allowed to be transmitted for a shorter interval of time. For example, though a customer may only want on average 256 Kb of data per second, they may allow a peak of 512 Kb of data for 1/4 second. The peak rate is used to control the spacing of outbound packets on the transmission line. By having a smaller peak rate, there will be longer spacing between packets, and thus less burstiness of traffic and increased efficiency. Higher peak rates result in shorter spacing and increased burstiness, which can result in lower link utilization. However, some applications may require it, such as real time or video data.
- DiffServInProfileMaxPacketSize is the amount of data that will be policed at the peak cell rate. For example, if the peak rate is 512 Kb per second, and the maximum packet size is 120 Kb, TCP/IP will only allow about 10 packets of size 1492 bytes to be transmitted every .23 seconds. Again, if an application is sending large amounts of data at one time to TCP/IP, TCP/IP will enforce the peak rate, and anytime more than 10 packets are sent within .25 seconds, TCP/IP will begin to slow this TCP connection. The peak rate can be achieved over a longer period of time if the maximum packet size is entered in larger multiples of packets. However, this will cause greater burstiness as described above. For example, if the maximum packet size is entered as 240 Kb, TCP/IP will allow 20 packets in a .23 second range before enforcing slowdown.

  Note that the peak rate cannot be enforced without mean rate policing. However, you can enforce mean rate without peak rate. Also, setting of these parameters depends on the type of applications and the network that carries it.

Integrated Services policies

Integrated Services (RSVP) policies are used to set limits on certain parameters requested by RSVP applications. These applications interact with the RSVP Agent to establish resource reservations along a network path, using the RSVP API (RAPI). The reservation requests are in the form of an entity known as a Traffic Specification, or Tspec, which consists of the following values:

- Token bucket mean rate (r)
- Token bucket depth (b)
- Peak rate (p)
- Minimum policed unit (m)
- Maximum packet size (M)

RSVP policies can be used to limit the values requested for (r) and (b), as well as limiting the total number of RSVP reserved flows. The RSVP service attributes are enforced by the RSVP agent which gets RSVP policies from the Policy Agent. For additional information on the enforcement, see *z/OS Communications Server: IP Configuration Reference* or RFC 1363.

Sysplex distributor policies

Sysplex distributor (SD) policies are used to specify a set of SD target nodes for a given set of traffic. For example, all traffic destined to a given port or application from a specified subnet can be assigned one group of SD target nodes, while traffic for the same port or application from another subnet can be assigned to a different group of target stacks. These policies be can used in conjunction with other sysplex distributor controls to assist in load balancing. For more information, see "Policy interactions" on page 481.

QoS-specific Policy Agent functions

In addition to supporting the various types of policies, the Policy Agent performs functions related to the sysplex distributor. The Policy Agent can be configured to collect network QoS performance data relevant to SD on behalf of policies defined for a target port or application, and assign a default QoS weight fraction to such policy traffic. This weight is then used by SD (in conjunction with weights assigned by the Workload Manager) to assist in load balancing decisions. This function is performed by the Policy Agent on SD target nodes within the sysplex.

The Policy Agent also supports load distribution by service level. Performance data is kept for each Policy Action (service level) that a target's DVIPA port or application supports. A Policy Action weight fraction is generated. If available, this weight is used (instead of the default QoS weight fraction) in conjunction with the Workload Manager weight to assist in load distribution decisions for traffic assigned to this service level. If the Policy Action weight fraction is unavailable, the sysplex distributor will continue to use the default QoS weight fraction.

Another function related to policy performance is the performance collection function. When so configured, the Policy Agent collects policy performance data from the stack and caches it. This performance data is then made available to user applications through the Policy API (PAPI), for near real-time performance monitoring applications. The data are also optionally logged to a performance log file for offline performance monitoring. Sample C applications are provided to show how to use the PAPI interfaces to access performance data, and how to access and read the performance log file.

Policy performance data collected is affected by the FLUSH or NOFLUSH parameter on the Policy Agent TcpImage statement that defines the corresponding stack that is collecting the data. When FLUSH is specified, policies are deleted at the following times:

- When a new TcpImage statement is processed for the first time, including Policy Agent starting. This should not be a concern in most cases.
- When a MODIFY REFRESH command is entered.

As a result, all previously collected metrics start again from 0 when the policies are reinstalled. Conversely, policies are never deleted when NOFLUSH is specified, so performance metrics are never reset to 0.

Sysplex distributor policy performance monitoring and policy performance collection are similar in some respects but distinctly different in others:

- Sysplex distributor policy performance monitoring is actively performed by the Policy Agent. This performance monitoring is only used to assist with load balancing in a sysplex distributor environment.
- Policy performance collection is performed without regard to whether or not the Policy Agent is running in a sysplex distributor environment. Also, the Policy Agent does not actively participate in performance monitoring, only making the performance data available to user applications that perform the actual monitoring.

Policy performance data might not immediately change when changes are made to policy definitions. Some of the performance metrics are average values, and some are smoothed over several sampling intervals. As a result, when making changes to policies, some period of time will need to elapse before a new steady state is achieved.

Another function supported by the Policy Agent is to map IPv4 type of service (ToS) byte or IPv6 traffic class values to outbound interface priority values for outbound traffic. The ToS byte is also referred to as the Differentiated Services (DS) byte as an alternative definition (see RFC 2474). Note that outbound interface priority values are only meaningful for QDIO interfaces. A set of mappings can be defined to cover various ToS byte or traffic class values and map them to an appropriate interface priority. All outbound packets over the associated interfaces with a given ToS byte or traffic class value will then be assigned the corresponding priority value. ToS byte or traffic class values can also be mapped to Virtual LAN (VLAN) user priorities for propagation over LANs directly connected through the OSA-Express feature.

Note: Coding the virtual LAN (VLAN) user priority causes a frame to be sent out based on the IEEE 802.1Q specification, which establishes a standard method for tagging Ethernet frames with VLAN priority and membership information. Specifically, a VLAN priority-tagged frame is used to convey packet priority to the switches; it has a value of NULL for VLANID. A full VLAN-tagged frame contains both the priority and non-null VLANID. If you have switches in your network that do not support the IEEE 802.1Q standard or that are not properly configured for these types of frames, the frames might be dropped by the switch.

Sysplex distributor policy performance monitoring configuration

Before activating the sysplex distributor policy performance monitoring function, see "Policy interactions" on page 481 for information on workload balancing and policy interactions with sysplex distributor.

The following example illustrates how to activate the policy performance monitoring function for sysplex distributor.

Note: This function is activated on SD target servers and is used to monitor the performance of outbound traffic being serviced by the target servers. The goal is to detect TCP traffic that exceeds defined thresholds for dropped packets or time-outs, and derive a default QoS weight fraction for the target server. This default QoS weight fraction is then used to reduce the WLM weight assigned to the target servers, so that the SD distributing stack can take QoS performance into account.

The following statements apply to the example in this topic:

- The policy performance monitoring sampling interval is 60 seconds.
- Policy Agent assigns a loss ratio weight fraction of 25% when the TCP loss ratio (dropped packets to total packets) starts to exceed 2%.
- The loss ratio weight fraction is increased to 50% when the loss ratio starts to exceed 4%, continuing in this manner up to the maximum loss ratio weight fraction of 95%.
- In a similar manner, a TCP timeout weight fraction of 50% is assigned when the timeout ratio starts to exceed 5%, increasing up to a maximum timeout weight fraction of 100%.
- The loss ratio weight fraction and TCP timeout weight fraction are added together to form a single default QoS weight fraction for the target server, up to a maximum of 100%. When the Traffic Regulation policy connection limit

reaches constrained threshold (90%), the default QoS weight fraction is set to 100% and forces SD to route requests to other target nodes with better routing weights.

- The default QoS weight fraction is used at the SD distributing stack to reduce the WLM weight. For example, if the WLM weight is 40, a weight fraction of 50% results in the weight being reduced to 20.
- The traffic to be monitored must be represented by at least one Differentiated Services policy defined for the target application (in this example a policy is defined for Telnet).
- An additional Policy Action weight fraction is calculated for a target's DVIPA/Port if there are any active connections to the target using that service level.

  The Policy Action weight fraction is calculated as the largest of three fractions:

  – The number of active connections to this target DVIPA/Port will be compared with the maximum connections allowed for this Policy action.
    - When the number of active connections reaches 50% of maximum connections, then the Policy Action weight fraction will be set to MAX (50%, current calculated value).
    - When the number of active connections reaches 65% of maximum connections, then the Policy Action weight fraction will be set to MAX (85%, current calculated value).
    - When the number of active connections reaches 80% of maximum connections, then the Policy Action weight fraction will be set to 100%.
  – The throughput rate for this timer interval will be calculated and compared to the DiffServ mean rate of this Policy action. If the throughput rate is greater than 85% of the DiffServ mean rate, the average throughput rate per connection will be calculated. If the throughput rate per connection is less than the DiffServ min rate, the minimum throughput requirement per connection is not being met and the Policy Action weight fraction will be set to 100%.
  – The default QoS weight fraction.
- Only one policy rule and policy action are defined here.

  As a result, only Telnet QoS performance information is monitored by the Policy Agent for sysplex distributor to route incoming Telnet connections to this target node relative to other target nodes which presumably can also accept Telnet requests.

```
PolicyPerfMonitorForSDR  enable
{
   samplinginterval 60
   LossRatioAndWeightFr 20 25
   TimeoutRatioAndWeightFr 50 50
   LossMaxWeightFr 95
   TimeoutMaxWeightFr 100
   MaxConnWeightFr 50 65 80
}
policyAction telnetGold
{
MinRate 500 # Provide minimum rate of 500 Kbps.
OutgoingTOS 10100000 # the TOS value of outgoing telnet packets.
}

policyRule targetelnet
{
```

```
ProtocolNumberRange 6
SourcePortRange 23
policyactionreference telnetGold
}
```

Policy performance collection configuration

The following example shows how to activate the policy performance collection function. Policy performance data for all active policies is maintained by the TCP/IP stack. This function allows this data to be collected and made available for policy performance monitoring applications. The following statements apply to the example in this topic:

- Performance data is collected for both rules and actions. Action data is an aggregate of the data for the rules that refer to the action. For policies that have a single action per rule, the performance data will be the same for both the rule and action.
- The default minimum sampling interval is 30 seconds. This is the minimum value accepted for the acceptableCachedTime parameter on the PAPI papi_get_perf_data() function that gets performance data.
- Performance data will be logged to the file /u/user10/perflog, based on a sampling interval of 60 seconds.
- The number of performance log files maintained is 10, each of which is the default 300 kilobytes in size. In this example, the log files will be named assuming a stack name of TCPCS:

  ```
  /u/user10/perflog.TCPCS
  /u/user10/perflog.TCPCS.1
  /u/user10/perflog.TCPCS.2
  ⋮
  /u/user10/perflog.TCPCS.9
  ```

- Each performance data record is 232 bytes, so a file size of 300 kilobytes can contain 1324 records. Since 10 files are maintained, the total set of log files can contain 13240 records. Assuming that 50 policy rules and actions exist in the configuration, this means that the set of log files will wrap in approximately 4.4 hours, according to the following formula:

  ```
  number of records (13240) / number of policies (50) = number of refresh cycles (264)

  number of refresh cycles (264) * refresh interval in minutes (1) = 264 minutes worth of data
  ```

```
PolicyPerformanceCollection Enable
{
DataCollection           Rule Action
LogSamplingInterval      60
PerformanceLogFile       /u/user10/perflog
NumberOfLogFiles         10
}
```

IPv4 type of service or IPv6 traffic class mapping configuration

There are two mappings provided by the SetSubnetPrioTosMask statement:

- IPv4 type of service (ToS) or IPv6 traffic class to device priority

  Quality of service (QoS) support in z/OS Communications Server allows the IPv4 ToS byte, also known as the Differentiated Services (DS) field, or the IPv6 traffic class to be set for outbound IP packets according to defined policies managed by the z/OS Communications Server UNIX Policy Agent. When IP packets are sent out over QDIO devices, the ToS/DS or traffic class value is mapped to a QDIO priority value. Device priority values are 1-4, where 1 is the highest priority.

- IPv4 ToS or IPv6 traffic class to VLAN user priority

  ToS/DS or traffic class values can be mapped to user priorities for directly attached LANs using the OSA-Express feature in QDIO mode. VLAN user priority values are 0-7, where 7 is the highest priority. This allows assigned user priorities to be propagated through such networks, resulting in no loss of priority information for data being served by z/OS.

See *z/OS Communications Server: IP Configuration Reference* for more detail on these statements.

The following example shows a mapping of various ToS byte or traffic class values to associated interface priority values. Note that the mapping can be applied to individual interfaces or all interfaces:

- The first example defines a mapping for a specific interface. Note that the specified interface must be a valid interface specified in the HOME list. The second example shows a different mapping for all other interfaces.
- The subnet mask defines the bits in the ToS byte or traffic class that are significant. These examples use the leftmost 3 bits.
- The first example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device and VLAN user priorities to be assigned for each value.
- The second example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device priority to be assigned for each value.

```
SetSubnetPrioTosMask
{
  SubnetAddr         10.10.1.5
  SubnetTosMask      11100000
  PriorityTosMapping 1 11100000 7
  PriorityTosMapping 1 11000000 7
  PriorityTosMapping 2 10100000 6
  PriorityTosMapping 2 10000000 5
  PriorityTosMapping 2 01100000 5
  PriorityTosMapping 3 01000000 3
  PriorityTosMapping 4 00100000 2
  PriorityTosMapping 4 00000000 0
}
SetSubnetPrioTosMask
{
  SubnetTosMask      11100000
  PriorityTosMapping 1 11100000
  PriorityTosMapping 1 11000000
  PriorityTosMapping 1 10100000
  PriorityTosMapping 1 10000000
  PriorityTosMapping 2 01100000
  PriorityTosMapping 2 01000000
  PriorityTosMapping 3 00100000
  PriorityTosMapping 4 00000000
}
```

Options for configuring QoS

You configure QoS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the QoS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF)

  z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.
- As a standalone application that you can run on your workstation

  You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

Through a series of wizards and online help panels, you can use the Configuration Assistant to create QoS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the Configuration Assistant, there are four types of reusable objects:

- Traffic descriptors that define the local application by describing the TCP traffic with ports or identifying the application using its job name.
- Priority levels that define the level of network priority or type of service (ToS).
- Traffic shaping levels that define settings to enforce specific traffic thresholds.
- Requirement maps that map traffic descriptors to priority levels and traffic shaping levels. A single requirement map should contain a complete set of QoS requirements that will govern the level of service for multiple IP traffic types.

For each TCP/IP stack, you select a requirement map that provides QoS for the stack.

The Configuration Assistant comes with a number of IBM-supplied traffic descriptors, priority levels, traffic shaping levels and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The Configuration Assistant can dramatically reduce the amount of time that is required to create QoS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing QoS.

This information primarily describes option 2, manual configuration. However, if you are using the Configuration Assistant, reading this information will help you understand security concepts and the relationship between Policy Agent and QoS function.

Option 2: Manual configuration

You can manually create the QoS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by QoS policy statements that permit advanced users to carefully fine-tune QoS policy on a per-stack basis. This information describes the procedure for creating a QoS policy by manually creating and editing the configuration files. For details about the QoS policy statements, see *z/OS Communications Server: IP Configuration Reference*.

Specifying the QoS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see "Policy types and infrastructure overview" on page 829. Regardless of which option is used to configure QoS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves QoS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve QoS policies from the policy server, specify the configuration files using the QOSConfig statement on the policy client, or configure the QoS policies directly in the image file specified on the TcpImage statement.
- If you are not using a policy client/policy server environment, specify the configuration files using the QOSConfig statement on the single Policy Agent, or configure the QoS policies directly in the image file specified on the TcpImage statement.

When specifying configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

Defining policies in a Policy Agent configuration file

Configure the following statements in the configuration file to define policies:

- PolicyAction
- PolicyRule

See *z/OS Communications Server: IP Configuration Reference* for more information about these statements.

The following subtopics contain examples of these tasks.

Note: These examples are for illustrative purposes only. The policies deliberately use a wide variety of attributes, and they do not necessarily represent real-world usage. Some examples show continued and indented statements that were modified to fit within the margin and therefore are not an actual representation of proper syntax.

Differentiated Services policy examples

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the PolicyScope DataTraffic attribute on the PolicyAction statement, as well as the use of several DS-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005..
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
- The action establishes a *token bucket* traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as *best effort*, with an accompanying ToS byte of '00000000'.

```
PolicyRule                              diffServ
    {
       ProtocolNumberRange                  6
       SourceAddressRange                   200.50.23.11
       SourcePortRange                      20-21
       PolicyActionReference                tokenbucket
       PolicyRulePriority                   10
       ConditionTimeRange                   20000701000000:20050630235959
       DayOfMonthMask                       11111111111111111111111111111111
       DayOfWeekMask                        0111110
       TimeOfDayRange                       06:00-22:00
    }
    PolicyAction                            tokenbucket
    {
       PolicyScope                          DataTraffic
       OutgoingTOS                          10000000
       DiffServInProfileRate                256       # 256 Kbps
       DiffServInProfileTokenBucket         512       # 512 Kbits
       DiffServInProfilePeakRate            512       # 512 Kbps
       DiffServInProfileMaxPacketSize       120       # 120 Kbits
       DiffServOutProfileTransmittedTOSByte 00000000
       DiffServExcessTrafficTreatment       BestEffort
    }
```

The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will only match traffic on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".
- Since we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

```
PolicyRule          web-catalog       # web catalog traffic
{
     protocolNumberRange  6
     SourcePortRange    80
     ApplicationData /catalog
     policyActionReference  interactive1

}

PolicyAction      interactive1
```

```
{
    policyScope DataTraffic
    outgoingTOS 10000000
}
```

RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the PolicyScope attribute on the PolicyAction statement, as well as the use of RSVP-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- The DataTraffic policy action specifies that the ToS byte be set to 01100000 for differentiated services traffic that conforms to this policy. Essentially, any traffic sent by the target application without an RSVP reservation in place will use this policy action. Once an RSVP reservation is in place, the RSVP action gets used.
- The RSVP policy action specifies that the ToS byte be set to 01100000 while an RSVP reservation is in place. It also limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.
- The action also limits the number of active RSVP flows that map to this policy to 10.

```
PolicyRule                              intserv
     {
        SourcePortRange                      8000 8001
        ProtocolNumberRange                  6
        PolicyActionReference                intserv1
        PolicyActionReference                intserv2
     }
     PolicyAction                            intserv1
     {
        PolicyScope                          DataTraffic
        OutgoingTOS                          01100000
     }
     PolicyAction                            intserv2
     {
        PolicyScope                          RSVP
        OutgoingTOS                          01100000
        FlowServiceType                      ControlledLoad
        MaxRatePerFlow                       400    # 50000 bytes/second
        MaxTokenBucketPerFlow                48     # 6000  bytes
        MaxFlows                             10
     }
```

Sysplex distributor policy example

The goal of this sysplex distributor policy is to limit the number of SD target stacks for inbound Telnet traffic. The policies are identified as SD policies by the ForLoadDistribution TRUE attribute on the PolicyRule statement. The corresponding policy on the target is also shown.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target stacks.
- The policy rules select incoming Telnet connection requests.
- The selected target stack will be based on WLM information and QoS information if activated at the target stacks.
- The rule (disttelnet) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (targtelnet) is coded on the target stack to select outbound data from the Telnet server.
- If none of the specified target stacks is available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target stack.

  Result: If the OutboundInterface 0.0.0.0 statement (for IPv4) and the OutboundInterface :: statement (for IPv6) are not present, and the defined target stacks are not available, sysplex distributor rejects the request.

```
policyAction        telnetGold
    {
        MinRate         500       # Provide minimum rate of 500 Kbps.
        OutgoingTOS     10100000  # the TOS value of outgoing telnet packets.
        outboundinterface  129.100.11.1
        outboundinterface  129.100.21.1
        outboundinterface  129.200.12.1
        outboundinterface  129::1B0D:13F0
        outboundinterface  0.0.0.0
        outboundinterface  ::
    }

    policyRule           disttelnet
    {
        ProtocolNumberRange     6
        DestinationPortRange    23
        PolicyRulePriority      20
        policyactionreference   telnetGold
        ForLoadDistribution     TRUE
    }

    policyRule           targtelnet
    {
        ProtocolNumberRange     6
        SourcePortRange         23
        PolicyRulePriority      20
        policyactionreference   telnetGold
        ForLoadDistribution     FALSE
    }
```

Notes:

1. The ApplicationName attribute is only valid for a target rule and should not be coded on a distributor rule because the application name determined for inbound traffic (which is always the case on a distributor) will always be the stack's TCP jobname.
2. If you are using Telnet with multiple stacks in conjunction with the sysplex distributor, see Chapter 11, “Accessing remote hosts using Telnet,” on page 549 for more information.

Defining policies using LDAP

For information about defining QoS policies using LDAP, see “Defining QoS policies using LDAP” on page 1533.

RSVP

Resource ReSerVation Protocol (RSVP) is a protocol that provides a mechanism to reserve resources in support of Integrated Services. The z/OS UNIX RSVP agent provides the following services on behalf of applications that want to use Integrated Services:

- An RSVP API (RAPI) that allows applications to explicitly request RSVP services. Using RAPI, applications indicate their intent to send or receive data, describe the characteristics of the data traffic and request that RSVP reserve resources along the data path to provide a given QoS to one or more traffic flows. For more information about RAPI, see *z/OS Communications Server: IP Programmer's Guide and Reference*.
- Mapping of IP ToS settings to RSVP traffic, using policies defined for RSVP.
- Establishment of resource reservations on ATM interfaces by use of reserved SVC connections.

  Note: Resource reservations cannot be made on interfaces other than ATM for outbound traffic on z/OS. However, RSVP-capable routers in the network can still reserve resources, and the ToS byte can be set for RSVP traffic to provide further means of prioritizing traffic.
- Support for VIPA addresses as well as real IP addresses.
- Communication with other RSVP agents on hosts and routers in the network to communicate application resource reservation requests.

Network administrators can use the z/OS UNIX Policy Agent to define RSVP-specific policies. These policies can be used to limit the parameters of application-requested resource reservations, provide ToS mappings for RSVP traffic, and limit the number of traffic flows that can use RSVP services simultaneously.

RSVP is designed to be implemented on both end systems (hosts) and routers. Different functions are provided by RSVP in these two environments. The z/OS RSVP agent is supported as a host RSVP implementation only. It can communicate with router RSVP implementations, but is not itself supported as such. For more information about RSVP, see RFC 2205.

Configuring the RSVP agent

To configure the RSVP agent, update the configuration file to specify RSVP agent operational parameters using the LogLevel, TcpImage, Interface and RSVP statements. See *z/OS Communications Server: IP Configuration Reference* for detailed information about the statements.

To start the RSVP agent, you must first authorize the RSVP Agent using the security product. See SEZAINST(EZARACF) for SAF considerations for started tasks.

The following is an example of an RSVP configuration file.

This example:

- Runs the RSVP Agent on the stack selected using the standard resolver search order, because a TcpImage statement is not configured.
- Disables RSVP processing on interface 10.11.12.13, while enabling it for all other interfaces.

- Disables traffic control on interface 200.1.1.1. This means that no reservations will be made on this interface.
- Allows a maximum of 50 active RSVP flows per interface.

```
Interface 10.11.12.13 Disabled
{}
Interface 200.1.1.1 Enabled
{
TrafficControl Disabled
}
Interface Others Enabled
{}
Rsvp All Enabled
{
MaxFlows 50
}
```

Starting and stopping RSVP

RSVP can be started from the z/OS shell or as a started task.

The RSVP agent uses the following search order to locate the configuration file (highest priority is listed first):

- z/OS UNIX file or MVS data set specified by the **-c** startup option. The syntax for a z/OS UNIX file is '/dir/file', and the syntax for an MVS data set is "//'MVS.DATASET.NAME'".
- z/OS UNIX file or MVS data set specified with the RSVPD_CONFIG_FILE enviroment variable.
- /etc/rsvpd.conf z/OS UNIX file.
- 'hlq.RSVPD.CONF' MVS data set.

  Note: If this file is not present, RSVP is enabled on all network interfaces with default parameters.

When starting from the shell, note that the RSVP executable file resides in the /usr/lpp/tcpip/sbin directory. There is also a link from the /usr/sbin directory. Make sure your path statement (in the profile) contains either the /usr/sbin or /usr/lpp/tcpip/sbin directory.

Use the S RSVPD command on an MVS console or SDSF to start RSVP as a started task. A sample procedure is shipped in member EZARSVPP in SEZAINST.

RSVP can be stopped using the cancel command (C RSVPD) or using the kill command in the z/OS shell. The following kill command with the TERM signal will enable RSVP to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

where *pid* is the RSVP process ID.

The RSVP process ID can be obtained using the following z/OS UNIX command:

```
ps  -A
```

It can also be obtained from the /tmp/rsvpd.pid.imagename file. See *z/OS Communications Server: IP Configuration Reference* for more information.

SNMP Network SLAPM2 (nslapm2) performance monitor

The SLAPM2 subagent provides information about defined service policies and performance data for applications that are mapped to those policies. Statistics are retrieved by this subagent and monitored for possible Network SLAPM2 performance deviations. For more information about the Network-SLAPM2 MIB, see usr/lpp/tcpip/samples/slapm2.mi2.

Configuring the Network SLAPM2 subagent

The z/OS CS Network SLAPM2 subagent allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. Before starting the Network SLAPM2 subagent, some basic operational characteristics of the Network SLAPM2 subagent need to be configured using the following steps:

1. Configure the Network SLAPM2 subagent security authorization.

   For the subagent to retrieve performance monitor data from the Policy Agent, the Network SLAPM2 subagent must have superuser authority or security product authority in the SERVAUTH class.

   These profiles can be defined by TCP/IP stack and policy type as follows, where *sysname* is the system name defined in the sysplex, *TcpImage* is the TCP name for policy information that is being requested, and *ptype* is the policy type (*QOS*) that is being requested:

   ```
   EZB.PAGENT.sysname.TcpImage.ptype
   ```

   Wildcarding is allowed on segments of the profile name.

   If SERVAUTH class is absent (not RACLIST) or profiles are absent for the subagent's request (TcpImage and policy type), permission is denied and data is not returned.

   If SERVAUTH class is active, profiles are present for the subagent's request (TcpImage and policy type), and an MVS user is defined for all profiles, permission is granted and data is returned.

   If SERVAUTH class is active, profiles are present for the subagent's request (TcpImage and policy type), and an MVS user is not defined for all profiles, permission is refused and data is not returned.

   For the sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.

2. Configure the Policy Agent as follows:
   - Configure QoS policy rules and QoS policy actions in Policy Agent. The Network SLAPM2 subagent only keeps statistics for active QoS policies. For details, see “Steps for configuring the Policy Agent” on page 848.
   - Configure PolicyPerformanceCollection in Policy Agent. The PolicyPerformanceCollection statement for rules needs to be enabled to retrieve performance monitoring information from Policy Agent for the Network SLAPM2 Subagent. For details on the PolicyPerformanceCollection statement, see “Policy performance collection configuration” on page 879.
3. Configure and start the SNMP agent. For details, see “Step 1: Configure the SNMP agent” on page 1334.

Starting and stopping the Network SLAPM2 subagent

Before you start the Network SLAPM2 subagent, the following applications need to be be started and initialized:

- Policy Agent - For details, see “Starting and stopping the Policy Agent” on page 865.
- SNMP agent - For details, see “Start the SNMP agent” on page 1345.

The Network SLAPM2 subagent can be started from the z/OS shell or as a started task.

- When starting from the shell:

  The Network SLAPM2 subagent executable file (nslapm2) resides in /usr/lpp/tcpip/bin. There is also a link from /bin. Make sure your PATH statement (in the profile) contains either /bin or /usr/lpp/tcpip/bin.

  The Network SLAPM2 subagent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

  Export the LIBPATH environment variable before starting the subagent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example:

  ```
  export LIBPATH=/usr/lib
  ```

  Following is an example command:

  ```
  nslapm2 -d 3 -t 1800 -c special -P 5000
  ```

  The command above starts the Network SLAPM2 subagent with the following characteristics:

  – Connect to the SNMP agent using a community name of *special* and a port of *5000*.
  – The debugging level is set to *3*, to log the following debugging messages to syslogd:
    - Trace Network SLAPM2 subagent error and system console messages
    - Trace Network SLAPM2 subagent warning messages
  – The MIB table cache time is set to 30 minutes.
- When starting as a started task:

  Use the S NSLAPM2 command on an MVS console or SDSF. A sample procedure is shipped in member EZAPAGSB in SEZAINST.

  – Specify LIBPATH using the ENVAR parameter on the PARM statement in the started procedure. For example:

    ```
    // PARM=('POSIX(ON) ALL31(ON)',
    // 'ENVAR("LIBPATH=/usr/lib")/')
    ```

  – Export the LIBPATH environment variable in a file specified with the STDENV DD statement. For example:

    ```
    //STDENV DD PATH='/etc/nslapm2.env',PATHOPTS=(ORDONLY)
    ```

    In the /etc/nslapm2.env file:

    ```
    LIBPATH=/usr/lib
    ```

For more information on specifying run-time options, see *z/OS Language Environment Programming Guide*. For details on setting the LIBPATH environment variable, also see *z/OS UNIX System Services Command Reference*.

The Network SLAPM2 subagent can be stopped using the stop command (P NSLAPM2), or using the kill command in the z/OS shell. For example, the following kill command with the TERM signal, where *pid* is the nslapm2 process ID, enables the Network SLAPM2 subagent to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

The nslapm2 process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

Verification

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies installed in the TCP/IP stacks?
- Is the expected traffic mapping to the correct policies?
- Are the sysplex distributor policy functions working correctly?
- Does anything need to be tuned?

The following subtopics provide more details about these considerations.

Verifying that the policies are installed in the TCP/IP stacks

Use the Netstat SLAP/-j command to display QoS policy statistics. This command displays statistics for only active (installed) QoS policies, so it can be used to verify the correct policies are installed, even if all the statistics are 0. Since the Policy Agent can install policies on multiple stacks, issue this command on each stack to verify the correct set of QoS policies is installed.

Verifying that the expected traffic is mapping to the correct QoS policies

While connections are active, use the Netstat ALL/-A command to display details about the active connections. One piece of information displayed is the policy rule name. If this name is blank, then the traffic is not mapped to any active rule. Also, use the Netstat SLAP/-j command to display QoS policy statistics. The output shows the time that each policy was last mapped to traffic, and accumulated statistics for each policy. Monitor these values over time to verify that new traffic is mapping as expected.

Note: The values displayed by the Netstat SLAP/-j commands can wrap around to 0. If some of the values do not seem correct (for example, total out bytes less than total out bytes in profile), then wrapping has probably occurred.

Verifying that the sysplex distributor policy functions are working correctly

To verify that the distributor is using the expected service levels when deciding how to distribute traffic to each DVIPA/Port target, use the Netstat VDPT/-O DETAIL command on the distributing stack. The following QoS related information will be displayed for each DVIPA/Port target:

- WLM weight unmodified by QoS
- Modified WLM/QoS aggregate weight, identified by *DEFAULT*
- Modified WLM/QoS service level weights, identified by service level name

To verify that active connections distributed to DVIPA/Port targets are using the expected service level, use the Netstat VCRT DETAIL command on the distributing stack. This will display the following policy related information:

- PolicyRule: the policy rule that the distributor used in selecting the policy action for this connection.

- PolicyAction: the policy action that this connection is currently using. If PolicyAction is specified by *NONE*, then the distributor is using the *DEFAULT* fraction to distribute this connection.

See *z/OS Communications Server: IP Diagnosis Guide* for more information.

Monitoring performance and tuning policies

Poor performance, such as low throughput, long response times, and so on, might be suddenly and consistently experienced by a certain set of users or applications. Also, traps might be generated by the Network SLAPM2 subagent. When this happens, the problem might be the way the QoS policy is defined for the corresponding set of users or applications.

For example, the IPv4 ToS/DS or IPv6 traffic class value might be set incorrectly to a lower QoS level than is intended, for example, medium or low priority instead of high priority. It is important to remember that given a fixed amount of network resources, changing some traffic demand from a lower to higher QoS level will mean that other traffic demands will be affected. Therefore, use care to ensure that in attempting to meet one set of QoS requirements, different or worse problems do not result.

Another cause for poor performance might be in the way the bandwidth allocation defined via the DiffServ token bucket parameters, or TCP maxrate or minrate, is not adequate to accommodate the traffic demand. Yet another possibility might be that either network or the server capacity is not adequate to handle the traffic demand. This is evident when a majority of users or applications do not have their QoS requirements met. When this happens, the network planning process must be revisited.

For more information, see "Using the Network SLAPM2 MIB to monitor policies."

Using pasearch

Use the **pasearch** command to display policy details. This command displays both active (installed in the stack) and inactive policies. Various parameters can be specified to filter the results, for example to display only policies for certain stacks, only QoS policies, only policy names, or only a single policy specified by name. See *z/OS Communications Server: IP System Administrator's Commands* for the complete syntax and sample output for **pasearch**.

Using the Network SLAPM2 MIB to monitor policies

The Network SLAPM2 subagent provides information about service policies and performance data for applications mapped to those policies through the slapm2PolicyRuleStatsTable.

Note: The Network SLAPM2 subagent can be used to monitor Differentiated Services policies.

slapm2PolicyRuleStatsTable
Provides statistics on a per policy rule basis.

The Network SLAPM2 subagent also supports performance monitoring using the slapm2PRMonTable object. Entries are created in the monitor table to establish the desired criteria for monitoring. The following level of monitoring is provided:

Aggregate
Monitoring is performed based on the aggregate of all TCP or UDP applications that are mapped to one or more service policies.

Three types of monitoring are provided for measuring application performance:

TCP round-trip time
The current TCP round-trip time of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

TCP packets retransmit ratio
The current TCP packets retransmit ratios of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

Average accept queue delay
The current average accept queue delay of applications are compared to threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

For more details about how to make the various monitoring calculations, see the NETWORK-SLAPM2-MIB in the sample file slapm2.mi2 in the /usr/lpp/tcpip/samples directory.

When SNMP traps are enabled, and a *not achieved* trap is sent as described above, a corresponding *okay* trap is sent when the traffic once again conforms to the boundaries established in the monitor table entry.

For example, suppose the slapm2PRMonTcpRttDelayHigh value is set to 2 seconds and the slapm2PRMonTcpRttDelayLow value is set to 1 second. If the TCP round-trip delay rises above 2 seconds, a *not achieved* trap is sent. If the TCP round-trip delay then drops below 1 second, an *okay* trap is sent to indicate the problem has been resolved. However, if the row becomes inactive before conforming to the established boundaries, an *okay* trap is never sent, since this removes monitoring for this entry.

The following traps are used to monitor table administration:

Policy deleted
A slapm2PolicyRuleDeleted trap is sent when an entry is deleted from the slapm2PolicyRuleStatsTable, if slapm2PolicyDeletedTrapEnabled is enabled(1).

Monitor deleted
A slapm2PolicyRuleMonDeleted trap is sent when a slapm2PRMonEntry is deleted, if the value of slapm2PolicyDeletedTrapEnabled is enabled(1).

Creating monitor table entries and enabling SNMP traps

Several MIB objects are used when establishing monitor table entries and when configuring whether and how often traps are sent. To establish monitor table entries, set the following MIB object variables. Most of these objects have default values, so you might be able to achieve the desired monitoring using only a subset of the objects.

slapm2PRMonTcpRttDelayHigh, slapm2PRMonTcpRttDelayLow
Establishes the threshold values for the average TCP round-trip time. The minimum and maximum rates are in units of milliseconds.

slapm2PRMonTcpReXmitHigh, slapm2PRMonReXmitLow
Establishes the threshold values for the TCP packets retransmit ratio. The minimum and maximum rates are in tenths of a percent units.

slapm2PRMonTcpAcceptQDelayHigh, slapm2PRMonTcpAcceptQDelayLow
Establishes the threshold values for the average accept queue delay. The minimum and maximum rates are in units of milliseconds.

slapm2PRMonRowStatus
This object allows entries to be created and deleted in the slapm2PRMonTable.

In addition, the following MIB objects are used to control the generation of traps:

slapm2PRMonTrapEnable
Indicates whether slapm2PolicyRuleMonNotOkay and slapm2PolicyRuleMonOkay notifications should be generated for this conceptual row.

slapm2PRMonTrapFilter
The purpose of this object is to suppress excessive slapm2PolicyRuleMonNotOkay notifications. A monitored quantity must exceed its high threshold for the number of consecutive intervals indicated by this object for a notification to be generated. The length of the intervals is specified by the slapm2PolicyMonInterval object.

Creating the monitor table index

When you create monitor table entries, specify the appropriate index value. The index is composed of the following:

- slapm2PRMonOwnerIndex
- slapm2PolicyRuleIndex

The OwnerIndex is expressed in the following format, where *character* is in ASCII decimal form:

```
length.character.character...
```

For example, the value *u1* is expressed as 2.117.31. The PolicyRuleIndex that maps to the policy name value is the index into the slapm2PolicyRuleTable.

The Network SLAPM2 subagent creates an entry in the slapm2PolicyRuleTable to represent a policy rule. The index value for this entry is arbitrary and assigned by the subagent. Corresponding entries in the other MIB tables, including the monitor table, contain the index value that maps to the entry in the name table.

To assist you in creating the index for the monitor table entries, note that the index value used in the slapm2PolicyRuleStatsTable entries consist of the last value used in the monitor table index, namely the PolicyRuleIndex. Thus, you can walk through the policy statistics table using the following command:

```
osnmp -v walk slapm2PolicyRuleStatsTable
```

Then, cut and paste the index value from the PolicyRuleStatsTable and add an OwnerIndex of your choosing at the beginning of the index.

For the above example, the complete index using an OwnerIndex of *u1* is:

```
2.117.31.3
 |       +--- name table index value (PolicyRuleIndex)
 +----------- length + "u1" (OwnerIndex)
```

Monitor table examples

If you are going to change any of the monitor table object values for an existing table entry or row, you must take the row out of service to make the changes. To do this, set the value of slapm2PRMonRowStatus to 2. After your changes are made, set the row status to a value of 1 to put it back in service.

The following examples show how to create monitor table entries to monitor.

- This example assumes SNMP version 1 security and no SNMPD.CONF file.
  1. Enable traps. The snmptrap.dest file should contain the IP address and protocol of an entity to receive traps:

     ```
     /etc/snmptrap.dest   contains: 9.67.191.5        UDP
     /etc/pw.src          contains: public 0.0.0.0    0.0.0.0
     ```

     In this example, use the osnmp command running in the background to receive traps:

     ```
     osnmp trap > /tmp/trap.output &
     ```
  2. Change status to notInService:

     ```
     osnmp set slapm2PRMonRowStatus.index 2
     ```
  3. Enable monitoring for slapm2PolicyRuleMonNotOkay and slapm2PolicyRuleMonOkay (traps):

     ```
     osnmp set slapm2PRMonTrapEnable.index 1
     ```
  4. If desired, change default thresholds:
     - TCP round-trip, where *l* is the lower boundary and *h* is the upper boundary:

       ```
       osnmp set slapm2PRMonTcpRttDelayLow.index l
       osnmp set slapm2PRMonTcpRttDelayHigh.index h
       ```
     - TCP retransmit ratio, where *l* is the lower boundary and *h* is the upper boundary:

       ```
       osnmp set slapm2PRMonTcpReXmitDelayLow.index l
       osnmp set slapm2PRMonTcpReXmitDelayHigh.index h
       ```
     - Accept Queue delay ratio, where *l* is the lower boundary and *h* is the upper boundary:

       ```
       osnmp set slapm2PRMonAcceptQDelayLow.index l
       osnmp set slapm2PRMonAcceptQDelayHigh.index h
       ```
  5. Make row active:

     ```
     osnmp set slapm2PRMonRowStatus.index 1
     ```
- Evaluate the following fields to determine why the slapm2PolicyRuleMonNotOkay trap was generated:
  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates

that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.

- If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.

- Evaluate the following fields to determine why the slapm2PolicyRuleMonOkay trap was generated:
  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.

Chapter 18. Intrusion Detection Services

It is becoming increasingly important to not just protect systems from attacks but to detect patterns of usage that might indicate impending attacks. Many attacks follow a sequence of information gathering, unauthorized access to resources (information, applications, storage) and denial of service. It can be difficult, or at times, impossible to determine the originator of denial of service attacks. Correlating information gathering activities with access violation may help identify an intruder before they succeed.

Intrusion Detection Services provides support for:

- Scan detection and reporting
- Attack detection, reporting and prevention
- Traffic regulation for TCP connections and UDP receive queues

Each of these is described in detail.

Intrusion Detection Services (IDS) policies are used to specify what events are to be detected under what circumstances and what action to take. All IDS policies support logging events to a specified message priority level in syslogd and/or the system console. Most IDS policies support discarding packets when a specified limit is reached. Most IDS policies support writing statistics records to the INFO message level of Syslogd on a specified time interval, optionally only if exceptional events have occurred. All IDS policies support tracing all or part of the triggering packet to an IDS specific CTRACE facility, SYSTCPIS. IDS assigns a correlator value to each event. Messages written to the system console and syslogd and records written to the IDS trace all use this correlator. A single detected event may involve multiple packets. The correlator value identifies which messages and packets are related to each other. Each IDS policy has additional attributes that are specified either in conditions or in the action.

Scan policies

Scans are recognized as the result of multiple information gathering events from a single source IP within a defined period of time. Scanning in and of itself is not harmful. However, many serious attacks, especially access violation attacks, are preceded by information gathering scans. Because scans by their nature must use reliable source IP addresses, they can be interesting events to monitor.

The IDS support defines a scanner as a source host that accesses multiple unique resources (ports or interfaces) over a specified period of time. The number of unique resources (Threshold) and the time period (Interval) can be specified via policy. Two categories of scans are supported:

- Fast scan
  - many resources rapidly accessed in a short time period (usually less than 5 minutes and program driven)
- Slow scan
  - different resources intermittently accessed over a longer period of time (many hours). This could be a scanner trying to avoid detection.

Sample scanners:

- Source host A has a program that loops through all low ports and tries to connect to each port on target host X (fast scan). Note: each port is considered a unique resource.
- Source host B manually does pings to each interface on target host X and then tries to access well-known ports on target host X (most likely a slow scan) . Note: each interface accessed by the ping is considered a unique resource and each port accessed is considered a unique resource.

Not a scanner:

- Source host C starts 20 connections to port 23 . Since these connections are to the same port, only one unique resource has been accessed. Therefore, host C is not considered a scanner.

Certain scans may not be detected by IDS:

- source host E issues pings to addresses 9.1.1.1 through 9.255.255.255. Since host X only collects data for the pings directed to X's interfaces, this is not detected by host X as a scan. Network IDS may detect this as wide scan.

Scan policy provides the ability to:

- Control the parameters that define a scan:
  - Fast scan time interval
  - Slow scan time interval
  - Fast scan threshold
  - Slow scan threshold
  - Exclude well-known legitimate scanners via an exclusion list
  - Specify a sensitivity level by port or portrange (to reduce performance impacts)
  - Notify the installation of a detected scan via console message or syslogd message
  - Trace potential scan packets

The individual packets used in a scan can be categorized as normal, possibly suspicious or very suspicious. To control the performance impact and analysis load of scan monitoring, it will be useful to have a mechanism for adjusting our interest level in potential scan events. For information gathering we will provide sensitivity levels of High, Medium and Low to control recognizing countable events for normal, possibly suspicious and very suspicious packets.

The following table shows how the policy-specified sensitivity affects the counting of scan events. The event suspicion level is determined by the stack.

Sensitivity (from policy)	Normal event	Possibly suspicious event	Very suspicious event
Low			count
Medium		count	count
High	count	count	count

To help reduce or eliminate false positives, IDS will allow policy-specified source IP addresses, subnet masks, and (optionally) source port numbers to be excluded

from scan detection. For UDP and TCP port scans, scan detection can be limited to specified destination port ranges. The sensitivity (high, medium and low) may be specified by these port ranges.

Another way IDS will reduce false positives is by counting only unique events from a specific source IP address within a scan interval. An event is considered unique if the IP Protocol, Destination IP Address and Destination Port (UDP, TCP) or Type (ICMP) have not been seen before within this scan interval.

IDS scan policy supports a fast scan interval and threshold and a slow scan interval and threshold. A fast scan will be recognized if more than the fast scan threshold-specified unique events are received. A slow scan will be recognized if more than the slow scan threshold-specified unique events are received. Counting of scan events will be done on an internal interval no greater than half of the fast scan interval to avoid missing scans that occur within the fast scan interval but spread across two reporting intervals. Within an internal interval, once the number of unique events reaches the slow scan threshold, IDS knows that a scan has been detected and it is not necessary to continue to save information about additional related events in storage. This saves both storage and processing overhead. These events, however, are traced if requested by policy using the trace data parameter in the action.

Note: When system resources are constrained, IDS might temporarily suspend scan detection.

Scan events come from the categories listed below. Any countable scan event will count against an origin source IP address. The total number of countable events from all categories is compared to the policy thresholds. When an origin source IP address has exceeded the policy-defined fast or slow threshold an event may be sent to the TRMD for logging to SYSLOG. Additionally, a console message may be issued and the packet may be logged to the IDS packet trace depending on the notification options in the action. When an origin source IP address has exceeded the policy-defined fast or slow threshold an event will be sent to the TRMD for logging to SYSLOG or console. Once a scan event is logged for a particular source IP address, no further scan events will be reportable within the specified fast interval. The intervals and thresholds for fast and slow scan are global, that is, only one definition of them is allowed across all event categories.

- ICMP Scans

  ICMP requests (Echo, Information, Timestamp, Subnet Mask) are used to map network topology. Any request sent to a subnet base or broadcast address will be treated as a very suspicious event. Echo Requests (ping) and Timestamp Requests are very common and will be treated as normal events when they do not include the IP Options for Record Packet Route or Record Timestamp. These options are intended to be used only with ICMP Echo Request packets. The stack ignores them on any other type of packet. The other types of requests are uncommon and will be treated as possibly suspicious events.

Request type	Destination address	Event classification
any	subnet base or broadcast	very suspicious
Information or Subnet Mask	single host	possibly suspicious
Echo with IP Option Record Route or Record Timestamp	single host	possibly suspicious
Echo or Timestamp	single host	normal

- UDP Port Scans

  Because UDP is stateless, the stack is unable to differentiate between a client port and a server port. A scanner sending messages to many ephemeral ports looks very similar to a DNS server sending replies to many clients on ephemeral ports. TCP/IP configuration allows UDP ports to be RESERVED, therefore restricting a port so that it cannot be used. Any datagram received for a restricted port will be treated as a highly suspicious event. Datagrams received for unbound but unrestricted ports will be treated as possibly suspicious events and datagrams received for bound ports will be treated as normal events. Event generation can also be scoped to specific port ranges.

Socket state	Event	Event classification
Restricted (RESERVED to no one)	recv any packet	very suspicious
Unbound, not restricted	recv any packet	possibly suspicious scanner or application temporarily down
Bound	recv any packet	normal

- TCP Port Scans

  Because TCP is a stateful protocol, there are many different events that may be classified as normal, possibly suspicious or highly suspicious. The identified conditions are listed in the table that follows. TCP/IP configuration allow TCP ports to be RESERVED, therefore restricting a port so that it cannot be used. Event generation can also be scoped to specific port ranges.

Socket state	Event	Event classification
Any state	recv unexpected flags (that is, SYN+FIN)	very suspicious
Restricted (RESERVED to no one)	recv any packet	very suspicious
Unbound, not restricted	recv any packet	possibly suspicious scanner or application temporarily down
Listen	recv standalone SYN	no event (classification deferred)
Half open connection	recv ACK	normal - connection handshake completed
Half open connection	recv RST	possibly suspicious peer covering tracks
Half open connection	final time out	very suspicious peer abandoned handshake
Any connected state	seq# out of window	normal perhaps duplicate packet
Any connected state	recv standalone SYN	normal perhaps peer reboot
Any connected state	final timeout	possibly suspicious peer abandoned connection

Attack policies

An attack can be a single packet designed to crash or hang a system. An attack can also consist of multiple packets designed to consume a limited resource causing a network, system or application to be unavailable to its intended users (that is, denial of service). IDS attack policy allows you to turn on attack detection for one or more categories of attacks independently of each other. In general, the types of actions that can be specified for an attack policy are event logging, statistics gathering, packet tracing and discarding of the attack packets.

Most attack checking is done for inbound packets destined for this stack. The IDS categories of attacks are:

- Malformed packets events

  There are numerous attacks designed to crash a system's protocol stack by providing incorrect or partial header information. These packets are always discarded when received regardless of IDS policy. The source IP address is rarely reliable for these attacks.

  You can use IDS policy to provide notification of malformed packet attacks.

- Inbound fragment restrictions

  Many attacks are the result of fragment overlays in the IP or transport header. This support allows you to protect your system against future attacks by detecting fragmentation within the first 88 bytes of a datagram.

  Guideline: Examine packets flagged by this attack type to determine whether the packets are legitimate traffic. Although fragmentation within the first 88 bytes of a datagram is suspicious, it is does not violate any RFC specifications.

  You can use IDS policy to provide notification of a packet that results from a datagram being fragmented in the first 88 bytes, as well as to discard the packet.

  Tip: Initially use the NoDiscard action and evaluate any packets flagged by this attack type. If legitimate traffic in your network is being flagged as suspicious because it is fragmented in the first 88 bytes, you should not use the Discard action.

- IP protocol restrictions

  While there are 256 possible valid IP protocols, only a handful are in common usage today. This support allows you to protect your system against future attacks by prohibiting those protocols that you are not actively and intentionally using.

  You can use IDS policy to provide notification of a packet with a restricted IP protocol, as well as to discard the packet.

- IP option restrictions

  As with IP protocols, there are 256 possible IP options, with only a small number currently in common use. This support allows you to prevent misuse of options you are not intentionally using. Note that checking for restricted IP options is performed on all inbound packets, even those forwarded to another system.

  You can use IDS policy to provide notification of a packet with a restricted IP option, as well as to discard the packet.

- UDP perpetual echo

  Some UDP applications unconditionally respond to every datagram received. In some cases, such as Echo, CharGen or TimeOfDay, this is a useful network management or network diagnosis tool. In other cases it may be polite application behavior to send error messages in response to incorrectly formed requests. If a datagram is inserted into the network with one of these

applications as the destination and another of these applications spoofed as the source, the two applications will respond to each other continually. Each inserted datagram will result in another perpetual echo conversation between them. This support allows you to define the application ports that exhibit this behavior.

You can use IDS policy to provide notification of a perpetual echo packet, as well as to discard the packet.

- ICMP redirect restrictions

  ICMP redirect packets can be used to modify your routing tables. The IGNOREREDIRECT statement in the TCPIP profile disables ICMP Redirects. You can use IDS policy to provide notification of attempts to modify your routing tables in this manner.

  You can also use IDS policy to disable ICMP Redirects. ICMP Redirect packets will be ignored or discarded if either IGNOREREDIRECT is specified in the TCPIP profile or if IDS policy is active for ICMP redirect attacks and the associated policy action requests that the packet be discarded.

- Outbound raw restrictions

  Most network attacks require the ability to craft packets that would not normally be built by a proper protocol stack implementation. This support allows you to detect and prevent many of these crafting attempts so that your system is not used as the source of attacks on other systems. As part of this checking, you can restrict the IP protocols allowed in an outbound RAW packet. It is recommended that you restrict the TCP protocol (6) on the outbound raw rule.

  You can use IDS policy to provide notification of an outbound raw packet that is considered an attack, as well as to discard the packet.

- Flood events

  Two types of floods are currently detected:

  – TCP SYN floods

    A popular denial of service attack is to flood a public server with connection requests from incorrect or nonexistent source IP addresses. The intent is to use up the available slots for connection requests and thereby deny legitimate access from completing. z/OS CS provides protection from this attack regardless of IDS policy.

  – Interface floods

    If a large number of discards are occurring in proportion to the number of inbound packets, a malicious user might be attempting a denial of service attack. If this percentage of discards for an interface exceeds a specified percentage, this is considered an interface flood. The default percentage of discards used is 10%. You can override this default by specifying the interface flood percentage parameter.

    To prevent the false detection of an interface flood condition when there is a low volume of inbound traffic on an interface, to qualify as a flood, a minimum number of discards must occur in a one minute period. The default minimum is 1000 discards per minute. You can override this default by specifying the interface flood minimum discard parameter.

    When an interface flood condition is reported for an interface, the discard rate for the interface is evaluated for each subsequent 1-minute interval. An interface flood condition end is reported when the number of discards for the 1-minute interval falls below the interface flood minimum discard parameter value or the discard percentage falls below 50% of the interface flood percentage parameter value.

    If the interface flood continues for more than 5 minutes, an interface flood continues record is logged at 5 minute intervals while the interface flood

conditions exist, if logging was requested by policy. This log data contains additional information about the discarded packets for the interface.

Because it can be difficult to distinguish between a malicious user trying to flood a system, unusual spikes in traffic, and problems that can be caused by setup problems, it is possible for an interface flood condition to be reported when the source of the problem is not actually a flood. For example, if enough storage is not configured to handle the inbound traffic, a large percentage of the inbound packets might be discarded and cause the interface flood percentage to be exceeded.

You can use IDS policy to provide notification of an attack so that you may address the situation with your network administrators and service providers in a timely manner. Notification of a flood can include flood start and flood end event messages and tracing of the first 100 packets discarded due to the flood.

For each attack category (for example, restricted IP protocol) the single highest priority rule is mapped at policy change.

One or more notification options can be specified in the action to provide the desired documentation of detected attacks.

For IDS attack policy the notification options enable attack events to be logged to syslogd and the system console. Note that the console messages provide a subset of the information provided in the syslogd messages. For all attack categories except flood, a single packet triggers an event. To prevent message flooding to the system console, you can specify the maximum number of console messages to be logged per attack category within a 5-minute interval with the maximum event message parameter. If you specify logging to the console in your IDS policy, you should specify a maximum event message; there is no default if LDAP policy is used. To prevent message flooding to syslogd, a maximum of 100 event messages per attack category will be logged to syslogd within a 5-minute interval.

For IDS attack policy the statistics action provides a count of the number of attack events detected during the statistics interval. The count of attacks is kept separately for each category of attack (for example, malformed) and a separate statistics record is generated for each. If you want to turn on statistics for attacks, it is recommended that you specify exception statistics. With exception statistics, a statistics record will only be generated for the category of attack if the count of attacks is nonzero. If normal statistics is requested, a record will be generated every statistics interval regardless of whether an attack has been detected during that interval or not. An exception to this recommendation is when you want to provide overrides to the interface flood parameters (interface flood minimum percentage parameter and interface flood minimum discard parameter). In this case, run for a period with normal statistics to collect data to help determine the appropriate policy parameter values. When you determine the policy values, the previous recommendation to specify exception statistics applies.

For IDS attack policy, the trace data and trace record size parameters indicate whether packets associated with attack events are to be traced. For all attack categories except flood, a single packet triggers an event and the packet is traced. To prevent trace flooding, a maximum of 100 attack packets per attack category will be traced within a 5 minute interval. For the flood category, the first 100 packets discarded during a SYN flood will be traced. In the case of an interface flood, the flood is detected on an interface basis and the trace limit is applied on an interface basis.

For IDS attack policy, you can specify that packets associated with attack events should be discarded. It is applicable to all attack categories. However, malformed and flood packets are always discarded regardless of this setting.

An action can be unique to a specific category of attack (for example, malformed) or shared by one or more categories of attacks. If an action is shared, statistics data is still kept separately for each type of attack. Also, the maximum console message limit is enforced individually for each category of attack.

Traffic Regulation policies

IDS Traffic Regulation (TR) policies are used to limit memory resource consumption and queue delay time during peak loads.

TR TCP

IDS TR policies for TCP ports limit the total number of connections an application has active at one time. This can be used to limit the number of address spaces created by forking applications such as FTPD and otelnetd. A *fair share* algorithm is also provided based on the percentage of remaining available connections already held by a source IP address.

The percentage is applied against the number of available connections for the port. Therefore, as fewer connections become available, each host is allowed fewer new connections. The percentage is applied against the number of available connections, rather than the total number of connections allowed, in order to allow access to a larger number of different hosts when resources are low.

When a host requests a connection, the number of connections it currently holds for the port is compared to the percentage applied to the connections currently available for the port. If the number currently held is less than the percentage of currently available connections, the host is allowed to open an additional connection. If equal or greater, the host is not allowed to open further connections until more connections are freed up. All connection requesters for the port are regulated by this mechanism. If a host does not currently have any connections open on the port and unused connections are available, a host will always be allowed at least 1 connection. Multi-user source IP addresses may be allowed a larger number of connections by specifying a QoS policy with a higher number of connections (MaxConnections) than allowed by the TR policy. TR will honor the QoS differentiated services policy if the port is not in a *constrained state*. A QoS exception is made only when QoS differentiated service policy is applied for the specific source server port and specific outbound client destination IP address; if either of these attributes specify a range or are null, the QoS exception will not be made.

TR TCP generates a Constrained Event when a port reaches about 90% of its Connection Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator. TR TCP also generates events for each connection allowed because of a QoS override policy and for each connection denied for exceeding either the application's connection limit or the percent available limit.

To prevent possible flooding of syslog, TR TCP limits the number of connection refused, would have been refused, or QOS exception log records written in a five

minute interval. For a listening port, a maximum of 100 of these log records are written within a five minute interval. Globally, TR TCP writes a maximum of 1000 of these log records within a five minute interval. If a log record was not written due to these limits, the count of refused or would have been refused connection log records that were not logged is recorded in the `EZZ8660I TRMD TCP connection log records suppressed` log message after the five minute interval ends. Similarly, the count of QOS exception records that were not written is recorded in the `EZZ8661I TRMD TCP QOS exception log records suppressed` log message.

Guideline: TR TCP is intended for use with long-running servers, which typically use well-known ports or ports that are reserved for TCP applications. You should not use TR TCP to monitor transitory listeners; doing so can result in high storage usage. An example of a transitory listener is an FTP data connection that lasts only as long as it takes to move one file and typically uses ports above 1023.

TR UDP

Previously, control over UDP based applications consisted of application priority management and the TCP/IP profile parameter UDPQueueLimit ON | OFF. Inbound datagrams for bound UDP ports are accepted and queued until the queue limit is reached or buffer memory is exhausted. If UDPQueueLimit is set to OFF, any single bound port under a flood attack or with a stalled application could consume all available buffer storage. It is recommended that UDPQueueLimit always be set to ON. This limits the amount of storage that can be consumed by inbound datagrams for any single bound port. Sockets that use the Pascal API, have a limit of 160 KB in any number of datagrams. Sockets that use other APIs, have a limit of 2000 datagrams or 2880 KB.

IDS TR policies for UDP ports specify one of four abstract queue sizes for specified bound IP addresses and ports. The four abstract sizes are VERY_SHORT, SHORT, LONG and VERY_LONG. The actual queue sizes associated with these abstract values are internal values subject to change. Most UDP applications have timeout values based on human perceptions of responsiveness. These values tend to stay constant while system processing speeds and network delivery speeds continue to advance rapidly. This may require the physical sizes of these queues to change over time. The initial implementation uses the values of 16, 256, 2048 and 8192 (2**4, 2**8, 2**11, 2**13) for the number of datagrams and an average datagram size of 2 KB to calculate the byte sizes (32 KB, 512 KB, 4 MB, 16 MB). For performance reasons, sockets that use the Pascal API will only enforce the byte limit. Sockets that use other APIs will enforce both limits. Sockets without a policy specified for their port will use the existing UDPQueueLimit mechanism.

For applications that can process datagrams at a rate faster than the average arrival rate, the queue acts as a speed matching buffer that shifts temporary peak workloads into following valleys. The more that the application processing rate exceeds the average arrival rate and the larger the queue, the greater the variation in arrival rates that can be absorbed without losing work. Very fast applications with very bursty traffic patterns may benefit from LONG or VERY_LONG queue sizes.

For applications that consistently receive datagrams at a higher rate than they are able to process them, the queue acts to limit the effective arrival rate to the processing rate by discarding excess datagrams. In this case the queue size only influences the average wait time of datagrams in the queue and not the percentage of work lost. In fact, if the wait time gets too large, the peer application may have

given up or retransmitted the datagram before it is processed. Slow applications with consistently high traffic rates may benefit from SHORT queue sizes.

In general, client side applications will tend to have lower system priority giving them lower datagram processing rates. They also tend to have much lower datagram arrival rates. Giving them SHORT or VERY_SHORT queue sizes may reduce the risk to system buffer storage under random port flood attacks with little impact on percentage of datagrams lost.

TR UDP generates a Constrained Event when a port reaches about 90% of its Queue Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator.

Options for configuring IDS

You configure IDS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the IDS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF)

  z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.
- As a standalone application that you can run on your workstation

  You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

Through a series of wizards and online help panels, you can use the Configuration Assistant to create IDS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the Configuration Assistant, there are two types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP.
- Requirement maps that contain attack protection, scan protection, and traffic regulation. For scan protection and traffic regulation, traffic descriptors are used to identify the local applications that are provided the protection and regulation.

A single requirement map should contain a complete set of IDS requirements that will govern the level of IDS for a TCP/IP stack.

For each TCP/IP stack, you select a requirement map that provides IDS for the stack. The Configuration Assistant comes with a number of IBM-supplied traffic descriptors and a default requirement map that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The Configuration Assistant can dramatically reduce the amount of time that is required to create IDS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing IDS.

This information primarily describes option 2, manual configuration. However, if you are using the Configuration Assistant, reading this information will help you understand security concepts and the relationship between Policy Agent and IDS function.

Option 2: Manual configuration

You can manually create the IDS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by IDS policy statements that permit advanced users to carefully fine-tune IDS policy on a per-stack basis. This information describes the procedure for creating an IDS policy by manually creating and editing the configuration files. For details about the IDS policy statements, see *z/OS Communications Server: IP Configuration Reference*.

Specifying the IDS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see "Policy types and infrastructure overview" on page 829. Regardless of which option is used to configure IDS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IDS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IDS policies from the policy server, specify the configuration files using the IDSConfig statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the IDSConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

Defining IDS policies

IDS policies are stored in a Policy Agent IDS configuration file, a server that supports LDAP, or both. IDS policies are processed by Policy Agent and installed into a z/OS Communications Server TCP/IP stack. Before creating IDS policies, you should be familiar with the information about running Policy Agent, the IDS configuration file, and LDAP in Chapter 16, "Policy-based networking," on page 829.

A conservative approach to defining IDS policy will avoid unexpected application outages and excessive rule processing. The examples here describe policies provided in the sample files shipped with the system. (See "Policy sample files" on page 841.)

IDS policy definition considerations

IDS policies can be defined with different condition type values.

Tip: Condition type is configured in the IDS configuration file with the ConditionType statement, and in the LDAP configuration with the ibm-idsConditionType attribute.

Each IDS policy must define exactly one condition type. Specification of other additional conditions beyond those in the following list will cause the rule to not be found. The supported condition types are as follows:

SCAN GLOBAL
This policy is searched by only condition type. The single highest priority scan global rule is mapped at policy change and cached. The policy defines the FastScan and SlowScan parameters as well as reporting and tracing actions to take when a scan is detected. The Limit and Statistics actions are ignored.

SCAN EVENT
These policies are searched by condition type and a protocol condition of ICMP, TCP or UDP. For protocols TCP and UDP the policy search includes local destination port and bound IP address as well. For ICMP, the single highest priority scan event rule is mapped at policy change and cached. The TCP and UDP rules are mapped when a potentially countable event occurs. If the event is associated with a bound socket, the rule is cached. The policies associated with these rules define the sensitivity level to use for counting events towards the scan thresholds and source exclusion list to use for the mapped events. Packet tracing occurs if the action associated with the scan global rule activates tracing and the sensitivity indicates that the event is countable.

ATTACK
There are several attack types. The conditions supported on each are defined in the following list. For each attack type, the single highest priority rule is mapped at policy change and cached. The reporting, tracing and statistics actions are supported for all attack types.

Tip: Discard is configured in the IDS action in the IDS configuration file as ActionType ATTACK DISCARD, and in the LDAP configuration using the ibm-idsTypeActions:LIMIT attribute.

Other supported actions are defined for each attack type. The supported attack types are:

MALFORMED_PACKET
This policy is searched by only condition type and attack type. Malformed packets are always discarded by the stack, even if no discard was requested by the policy.

FLOOD
This policy is searched by only condition type and attack type. Flood packets are always discarded by the stack, even if no discard was requested by the policy.

ICMP_REDIRECT
This policy is searched by only condition type and attack type. ICMP redirect packets are discarded if this policy specifies discard or the TCPIP profile specifies IGNOREREDIRECT.

IP_FRAGMENT
This policy is searched by only condition type and attack type. If this policy specifies discard, datagrams that are fragmented within the first 88 bytes are discarded.

RESTRICTED_IP_OPTIONS
This policy is searched by only condition type and attack type. This attack type condition is expected to be ANDed with a list of conditions defining the IP options to disallow. IP option 0 (end of list) and 1 (NO-OP) cannot be disallowed and are ignored if specified. If this policy specifies discard, packets containing a disallowed option are discarded.

RESTRICTED_IP_PROTOCOL
This policy is searched by only condition type and attack type. This attack type condition is expected to be ANDed with a list of conditions defining the IP protocols to disallow. If no IP protocols are specified, the rule will not accomplish anything. IP protocols 1 (ICMP), 6 (TCP), and 17 (UDP) cannot be disallowed and are ignored if specified. If this policy specifies discard, packets containing a disallowed protocol are discarded.

OUTBOUND_RAW
This policy is searched by only condition type and attack type. This attack type condition can optionally be ANDed with a list of conditions defining the IP protocols to disallow. If this policy specifies discard, any packet written to a RAW socket that has a source IP address not in the stack's home list, that is fragmented by the application, that specifies one of the ICMP reply types or that specifies a disallowed protocol are discarded.

PERPETUAL_ECHO
This policy is searched by only condition type and attack type. A list of local UDP ports and a list of remote UDP ports is also necessary. Each of the port lists is limited by the stack to the first 20 ports specified. The inbound packet's destination port is always checked against the local port list. The source port is checked against the appropriate port list, based on whether the source IP address is in the stack's home list. If this policy specifies discard, UDP packets with both ports in checked port lists are discarded.

When defining the policy in LDAP, this attack type condition must be specified in a complex rule using CNF and multiple condition levels. The attack type condition is at one of the condition levels. There must be a list of conditions defining the local port list at a

second level. There must be a list of conditions defining the remote port list at a third level. The negated flag is ignored by the stack on port list conditions.

TR These policies can optionally be ANDed with any combination of conditions defining protocol (TCP or UDP), local destination port or local destination IP address. TCP rules are mapped when a local application does a listen on a socket or when an inbound connection handshake completes. UDP rules are mapped when an inbound packet arrives at a local bound socket. UDP TR policy supersedes the TCPIP PROFILE setting of UDPQUEUELIMIT for covered ports. Mapped rules are cached and associated with the bound socket.

For TCP, the policy defines the total number of allowed connections, the percentage of remaining available connections any single source IP can acquire and whether these limits are applied globally across all applications using this port number or applied individually to each application using an instance of this port number. For UDP, the policy defines which of the four available queue sizes is applied to each application using this port number. TR actions define the reporting, statistics and tracing actions for covered ports. If the policy specifies action LIMIT, connections or packets that exceed the limits are discarded.

Notes:

1. For TCP, a total connection limit or percentage available limit of zero, with an action of LIMIT effectively quiesces the application.
2. For TCP, a local host IP address cannot be specified in any condition if a TR TCP limit scope value of PORT is specified.
3. For UDP, a policy for a port without an action of LIMIT effectively makes the application unlimited.
4. Each LDAP IDS TR action must specify at least one ibm-idsTypeActions attribute.

IDS scan policy example

The goal of scan policy is to detect all scanners with potentially malicious intent while avoiding large numbers of false positives. You can make this process more efficient by reserving all unused low ports in the TCPIP profile. This will allow you to use the low sensitivity setting on scans for these ports. As you investigate the scans detected, you will initially find your own network management tools. These can be explicitly excluded. If you include UDP ephemeral ports in a high sensitivity policy, you will discover that your DNS servers show up as scanners. You can explicitly exclude these as well. To activate scan policy, a scan global rule and at least one scan event rule must be defined.

The following scan rules are defined:

- Scan Global

  Defines a global set of parameters for detecting scans, and also defines reporting parameters for scan events.
  - A Fast Scan is defined as 5 unique events in 2 minutes from a single source IP address.
  - A Slow Scan is defined as 10 unique events in 480 minutes (8 hours).
  - The first 200 bytes of the packet associated with each countable event will be traced.

- When a scan is detected an event will be written to syslog warning level, along with a detailed list of all the unique events included in the scan.
- No message will be written to the console.
- Statistics records will not be written to syslog.

- Scan Event Low

  Defines a set of traffic for which low sensitivity scan detection will be performed. Inbound traffic to all TCP and UDP ports between 1 and 1023 will be monitored. It is recommended that unused low ports be RESERVED in the TCPIP Profile.

- Scan Event Medium

  Defines a set of traffic for which medium sensitivity scan detection will be performed. ICMP inbound traffic will be monitored.

IDS configuration file example:

```

If you are using LDAP to define policy, see "IDS scan policy example" on page 1542.

IDS attack policy examples

The goal of attack policy is to help protect your system from both known and unknown attacks and to give you timely notification when attacks do occur. Malformed packet policy covers many known attacks designed to cause system *crashes*. These packets are always discarded and rarely have legitimate source address information. Many malformed packet attacks use fragmentation to overlay header fields. The IDS fragment restriction policy is intended to protect you from unknown attacks of this type by disallowing fragmentation in the first 88 bytes of any datagram. Unless you know you need ICMP redirect, you should disallow it with policy. There are several types of flood attacks. IDS can identify TCP SYN floods. IDS policy should be used to notify you when a flood occurs. You will need to work with your network administrators and service providers to track the flood backwards, one physical hop at a time, to locate the sources.

The IP protocol restrictions and IP option restrictions provide additional protection against future unknown attacks. The philosophy behind them is to disallow anything that you do not have a known reason to allow. The outbound raw policy is intended to help you detect someone using your system as the base for an attack. It looks for several behaviors associated with *spoofed* packets.

Attack rules define the set of conditions that define what constitutes an attack for a given attack type. The highest priority rule of each attack type is used. The action associated with an attack rule defines reporting and logging options for a detected attack.

The following types of attack rules are defined:

- Malformed Packet: Various types of known attacks based on malformed packets.
- Flood: TCP SYN flood and interface flood attacks.
- ICMP Redirect: Disallows ICMP redirect receipts.
- IP Fragment: Disallows fragmentation within first 88 bytes of datagrams.

- IP Protocol: Defines disallowable IP protocols.
  - Uses complex conditions to disallow everything except ICMP, TCP and UDP.
- Outbound Raw Restrictions: Validity checking for outbound packets using RAW sockets.
  - Uses complex conditions to disallow everything except ICMP, UDP, IGMP and OSPFIGP.
- Several reusable Protocol conditions are defined that can be shared between the IP Protocol Restriction rule and the Outbound Raw rule.
- A single reusable attack action is defined and shared among all the attack rules.
  - Events are written to syslog ALERT level.
  - Events are not written to the system console.
  - The first 200 bytes of packets associated with an attack are traced.
  - Statistics are evaluated every 60 minutes and only written if an attack occurred.
  - Limit was not specified, so packets associated with IP Protocol Restrictions, IP Fragment Restriction and Outbound Raw Restrictions will not be deleted.

IDS configuration file example:

```

If you are using LDAP to define policy, see "IDS attack policy example" on page 1545.

Traffic Regulation policy examples

The goal of Traffic Regulation (TR) policy is to protect your system from usage spikes. A phased approach to determine the correct policy for your system is recommended.

To gather baseline statistics, an installation will first need to run in normal statistics mode, with the traffic regulation daemon (TRMD) running. In normal statistics mode, the following information is provided for the port on a policy defined interval:

- Total number of connections requested during the interval
- Total number of connections closed during the interval
- The IP address of the host that requested a connection during the interval and held the highest number of concurrent connections during the interval, and the highest number of concurrent connections held by this IP address
- A suggested value for TotalConnections based on this interval
- A suggested value for Percentage based on this interval

While the baseline statistics records provide suggested policy values for the interval, the installation should evaluate data from multiple intervals. The values suggested are those that would avoid denying any of the connections in the interval. Choose lower values if the interval represents a workload larger than you want to allow.

After the installation determines the policy values to use, try running with the Log and Nolimit actions specified. Specifying the Nolimit action basically tests out the policy. The connections that would have been denied (if the Limit action was specified) are logged, but the connection is allowed to occur. After the installation is satisfied with the experimental policy, the policy action can be set to Limit.

The following traffic regulation TCP rules are defined:

- TRTcp-rule: Defines TCP baseline statistics gathering for the low port range.

  This temporary rule provides statistical reports to determine normal traffic patterns for several applications. After the baseline values are determined, this rule should be replaced by rules that include the specific conditions to be regulated.
- TRTcpWeb-rule: Defines application limits and host percentage limits for a single application.
  - This rule enforces set limits.
  - The rule has a higher priority than the TR TCP rule.

– The rule is limited to a single server application that is bound to a specific IP address.

IDS configuration file example:

```
#########################################################################
#########################################################################
# TR Policies
#########################################################################

#------------------------------------------------------------------------
# TR - IDSRule
#------------------------------------------------------------------------
IDSRule                     TRTcpWeb-rule
{
  ConditionType             TR
  Priority                   7
  IDSTRConditionRef         TRTcpWebCondition
  IDSActionRef              TRTcpLimit-action
}
IDSRule                     TRTcp-rule
{
  ConditionType             TR
  Priority                  2
  IDSTRConditionRef         TRTcpCondition
  IDSActionRef              TRTcpLog-action
  IpTimeConditionRef        Time1
}

#------------------------------------------------------------------------
# TR - IDSTRCondition
#------------------------------------------------------------------------
IDSTRCondition              TRTcpWebCondition
{
  Protocol                  Tcp
  LocalPortRange            80
  LocalHostAddr             10.14.243.87
  TRtcpTotalConnections     1000
  TRtcpPercentage           10
  TRtcpLimitScope           PORT_INSTANCE
}
IDSTRCondition              TRTcpCondition
{
  Protocol                  Tcp
  LocalPortRange            1:1023
}

#------------------------------------------------------------------------
# TR - IDSAction
#------------------------------------------------------------------------
IDSAction                   TRTcpLimit-action
{
   ActionType               TR LIMIT
   IDSReportSet             TRTcpLimitReportSet
   {
      TypeActions           Log
      TypeActions           Statistics
      StatType              Exception
   }
}
IDSAction                   TRTcpLog-action
{
   ActionType               TR NOLIMIT
   IDSReportSetRef          LogStatReportSet
}

#------------------------------------------------------------------------
```

```
# IDSReportSet
#---------------------------------------------------------------------
IDSReportSet               LogStatReportSet
{
   TypeActions             Log
   TypeActions             Statistics
}

#---------------------------------------------------------------------
# IPTimeCondition
#---------------------------------------------------------------------
IpTimeCondition            Time1
{
  TimeOfDayRange           1-22
  DayOfWeekMask            0111110
}
```

If you are using LDAP to define policy, see "IDS TCP traffic regulation policy example" on page 1550.

The following traffic regulation UDP rule is defined:

- TR UDP: Defines UDP queue size for the low port range.
  - This rule provides statistics reports to determine normal traffic patterns for several applications while monitoring queue sizes.

IDS configuration file example:

```
######################################################################
######################################################################
# TR Policies
######################################################################

#---------------------------------------------------------------------
# TR - IDSRule
#---------------------------------------------------------------------
IDSRule                    TRUdp-rule
{
  ConditionType            TR
  Priority                 2
  IDSTRConditionRef        TRUdpCondition
  IDSActionRef             TRUdpLogLimit-action
}

#---------------------------------------------------------------------
# TR - IDSTRCondition
#---------------------------------------------------------------------
IDSTRCondition             TRUdpCondition
{
  Protocol                 Udp
  LocalPortRange           1-1023
  TRUdpQueueSize           Long
}

#---------------------------------------------------------------------
# TR - IDSAction
#---------------------------------------------------------------------
IDSAction                  TRUdpLogLimit-action
{
   ActionType              TR LIMIT
   IDSReportSetRef         LogStatReportSet
}

#---------------------------------------------------------------------
# IDSReportSet
#---------------------------------------------------------------------
IDSReportSet               LogStatReportSet
```

```
{
   TypeActions             Log
   TypeActions             Statistics
}
```

If you are using LDAP to define policy, see "IDS UDP traffic regulation policy example" on page 1553.

Verification

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies active?
- Is the expected traffic mapping to the correct policies?
- Are the IDS Policy functions working correctly?

The following subtopics provide more details about these considerations.

Are the correct policies active?

Check your LDAP server log or command output for errors encountered when your policies were loaded into LDAP. Some LDAP servers treat consecutive blank lines in an LDIF file as end of file; ensure that all of the policy objects in your LDIF files are acknowledged by LDAP.

Check your Policy Agent log file for errors while processing your policy.

Use the pasearch command to verify that the intended policies are active and have the expected attributes for the target stack.

Is the expected traffic mapping to the correct policies?

Use the netstat -k SUMmary command to ensure that the intended policy has been mapped for each of the Attack types, Scan-Global type and the Scan-Event type for protocol ICMP. See *z/OS Communications Server: IP System Administrator's Commands* for more information on the netstat command.

These IDS functions each select the single highest priority policy for their respective types at each policy change.

Use the netstat -k PROTOcol TCP and netstat -k PROTOcol UDP commands to ensure that the intended Scan-Event and TR policies have been mapped to the intended local sockets.

These IDS functions select the highest priority policy for the Protocol, local Port and local IP address when there is relevant activity against the socket.

For TCP this usually entails either a listen or the completion of an inbound connection handshake. For UDP this usually entails either a bind or an inbound datagram. Scan policies are also selected on some inbound error paths.

Are the IDS policy functions working correctly?

IDS policies that include IDS actions with statistics, log, or syslog set cause the stack to make log record information available to TRMD. If TRMD is running you may run the IDS report generator TRMDSTAT against the appropriate log files to produce reports on the area of interest.

TRMD

TRMD runs as an APF-authorized program. The user ID associated with TRMD must be defined with a UID of 0, or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class. See the EZARACF member of SEZAINST for sample RACF commands for TRMD.

Use the **-p** start option or the resolver configuration file to determine the stack that TRMD uses. Ensure that you specify the **-p** start option or that the RESOLVER_CONFIG environment variable is correctly set before starting TRMD. A separate instance of TRMD must be run for each TCP/IP stack.

The Log records written by TRMD contain two timestamps:

- A timestamp generated when the event was detected by the stack. This timestamp is generated by the stack and is always Coordinated Universal Time (UTC).
- A timestamp that is generated when the syslogd record ID is created. This timestamp is dependent on the setting of the TZ environment variable at the time that TRMD is started. If you want this timestamp to be based on UTC, then ensure that the TZ environment variable is properly set (for example, export TZ=0) before starting TRMD.

You can set the TZ environment variable in the following ways:

- When starting TRMD from the z/OS shell:

  Export the TZ environment variable before starting TRMD; you should do this in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

  ```
  export TZ=EST5EDT
  ```

- When starting TRMD as a started task, use either of the following methods:
  - Specify TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

    ```
    // PARM='ENVAR("TZ=EST5EDT")/'
    ```

  - Export the TZ environment variable in a file specified with the STDENV DD statement. For example:

    ```
    // PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
    //STDENV DD PATH='/etc/trmd.env',PATHOPTS=(ORDONLY)
    ```

    Place the following statement in the /etc/trmd.env file:

    ```
    TZ=EST5EDT
    ```

    The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRM*xx* PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEECOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT') )
```

For more information on specifying run-time options, see *z/OS Language Environment Programming Guide*. For details on setting the TZ environment variable, see *z/OS UNIX System Services Command Reference*.

If running multiple instances of TRMD, consider using the syslogd **-u** option when starting syslogd. The **-u** option causes the jobname of the application writing the log record to be included in the log record.

The TCP/IP stack must be running before TRMD can be started.

TRMD can be started from the z/OS shell or as a started task.

Running TRMD as a started task

A sample procedure is shipped in member EZATRMDP in SEZAINST. Follow the instructions in the sample member to define your environment.

The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is required in UTC and has not been set by the TZ environment variable, specify the following in the TRMD procedure:

```
//  PARM=('POSIX(ON) ALL31(ON)',
//  'ENVAR("LIBPATH=/usr/lib"',
//  '"TZ=0")/-d 1')
```

To start TRMD as a started task, use the *S TRMD* command from the MVS console or SDSF. TRMD issues a fork, and in some cases the job name will be the original job name with a number appended. For example, *S TRMD* might result in the TRMD started task running under the job name TRMD1, whereas *S TRMDTASK* would result in the TRMD started task running under the job name TRMDTASK. Use the *D A,TRMD** command to verify the job name that TRMD is running under.

If running as a started task, issue *P jobname* to stop TRMD.

To automatically start TRMD when the TCP/IP stack is started, add TRMD to the AUTOLOG statement in the TCP/IP profile as follows:

```
AUTOLOG
    TRMD  JOBNAME TRMD
ENDAUTOLOG
```

Running TRMD from the z/OS UNIX shell

Ensure that you specify the **-p** start option or that the RESOLVER_CONFIG environment variable is correctly set before starting trmd.

The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is to appear in Coordinated Universal Time (UTC), change the TZ specification in /etc/profile or export TZ="0" before starting TRMD.

After the proper environment is set up, issue the following to start TRMD:

```
trmd
```

Stopping TRMD

To stop TRMD, issue the following kill command :

```
kill -s TERM pid
```

where pid is the TRMD process ID

To obtain the TRMD process ID, issue the following z/OS UNIX command:

```
ps -A
```

Debug options can also be specified when starting TRMD. See *z/OS Communications Server: IP Configuration Reference* for more information.

TRMDSTAT

Trmdstat is a utility program that runs from the z/OS UNIX shell. Trmdstat reads a log file, analyzes the log records generated by TRMD, and provides summary or detailed reports based on the options specified.

The following reports can be requested:

- Overall summary of logged connection events
- IDS summary of logged events
- Reports of logged connection events
- Reports of logged intrusions defined in the ATTACK policy
- Reports of logged intrusions defined in the TCP policy
- Reports of logged intrusions defined in the UDP policy
- Reports of statistics events

See *z/OS Communications Server: IP System Administrator's Commands* for the TRMDSTAT command and samples of the reports generated by TRMDSTAT.

Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is a rule to discard packets, and is separate from IP security filters. Filter processing matches a defensive filter rule to data traffic based on any combination of IP source or destination address, protocol, source or destination port, or direction of flow. Filter processing checks defensive filters before IP security filters.

The z/OS UNIX **ipsec** command is used to add and manage defensive filters. Defensive filters are typically added as an automated action that results from the analysis of the external security information and event manager. However, you can also add a defensive filter by manually issuing the **ipsec** command. The Defense Manager Daemon (DMD) is an integral part of managing the defensive filters.

Figure 30 on page 145 shows an overview of defensive filtering and the DMD.

For more information about defensive filters and the DMD, see Chapter 21, "Defensive filtering," on page 1177.

Chapter 19. IP security

This topic contains a description of IP filtering, IPSec-protected traffic, and preparing and configuring a z/OS system for IP security. Various business configurations are explained, including host-to-host, host-to-gateway, gateway-to-gateway, and gateway-to-host.

Terms and concepts for IP security

The following terms and concepts are used in this information:

3DES Also known as triple DES, this encryption method uses three DES operations on a single data block with three different keys. Provides greater security than single DES.

Active Used in three ways:

- Describes the filter policy that is in effect (default or Policy Agent).
- Describes the state of the rules or actions that are defined in Policy Agent. These rules or actions can be active or inactive due to a time condition.
- Describes the state of a manual tunnel installed in the TCP/IP stack. A manual tunnel can be active (available for use) or inactive (not available for use).

Active IPSec policy
The policy that is in effect, either the default filter policy or the IP security filter policy.

Advanced Encryption Standard (AES)
A symmetric block cipher that can encrypt (encipher) and decrypt (decipher) information. IP security for z/OS Communications Server supports AES with a 128-bit key length.

AES Cipher Block Chaining (CBC) (AES_CBC) mode
The AES algorithm using the CBC mode. IP security for z/OS Communications Server supports AES_CBC with a 128-bit or 256-bit key length.

AES Galois Counter Mode (GCM)
The AES algorithm using Galois Counter Mode and with a 16-byte integrity check value (ICV). Galois Counter Mode is a combined-mode algorithm that performs both encryption and authentication simultaneously. IP security for z/OS Communications Server supports AES_GCM with a 128-bit or 256-bit key length.

AES Galois Message Authentication Code (GMAC)
The AES algorithm using Galois Counter Mode to encode authentication data in either AH or ESP headers. AES_GMAC functions as a combined-mode algorithm; however, it provides authentication without encryption. IP security for z/OS Communications Server supports AES_GMAC with a 128-bit or 256-bit key length.

AES Extended Cipher Block Chaining (XCBC)
The AES algorithm using the XCBC mode to encode authentication data in either AH or ESP headers, with 128-bit keys and hash truncation to 96 bits.

Asymmetric encryption
Also known as public/private key encryption, this type of encryption is performed between two parties using pairs of encryption and decryption keys.

Authentication Header (AH)
An IP protocol (51) used with an IPSec Security Association to provide authentication of IP packets.

Autoactivation
The process by which a dynamic tunnel is activated when IP security policy is installed into the TCP/IP stack, either as the result of a user action, or the result of TCP/IP or the IKED initialization.

Certificate authority
A trusted third party that verifies information that is contained in an X.509 digital certificate.

Certificate revocation list (CRL)
A time-stamped list of revoked certificates that is signed by a certificate authority.

Child Security Association
The IKEv2 name for a phase 2 Security Association.

Command-line activation
The process of activating a tunnel through the use of the **ipsec** command. Both manual and dynamic tunnels can be activated from the z/OS UNIX command line.

CRLDistributionPoints
An optional x.509 certificate extension that identifies one or more locations where the CRL for a certificate resides.

Data encryption standard (DES)
A block cipher with 64-bit blocks and a 56-bit key.

Default IP filter policy
Used until the IP security filter policy is installed by Policy Agent. The default IP filter policy includes both the filter rules you define in the TCP/IP profile and the implicit default filter rules that the stack generates. The implicit default filter rules deny all traffic that does not match any configured filter rule.

Dynamic tunnel
An IPSec tunnel whose security parameters are negotiated and whose encryption keys are generated dynamically using IKE.

Elliptic curve digital signature algorithm (ECDSA)
The algorithm that is used to authenticate a remote security endpoint using ECDSA with either SHA2-256 on the P-256 curve, SHA2-384 on the P-384 curve, or SHA2-521 on the P-521 curve.

Encapsulating Security Payload (ESP)
An IP protocol (50) used with an IPSec Security Association to provide authentication and encryption of IP packets.

Hashed message authentication code (HMAC)
A one-way hash function that combines the contents of a message and a secret key to produce a hash value; used for authentication.

HMAC_MD5
HMAC using the MD5 algorithm.

HMAC_SHA1
HMAC using a SHA1 algorithm that encodes authentication data in AH or ESP headers, using a 160-bit hash value and 96-bit integrity check value (ICV).

HMAC_SHA2
HMAC using a SHA2 algorithm that encodes authentication data in AH or ESP headers and that is qualified by the length of key and hash truncation. The algorithm can have 256-bit keys and hash truncation to 128 bits, 384-bit keys and hash truncation to 192 bits, or 512-bit keys and hash truncation to 256 bits.

IKE negotiation
A process by which two communicating IKE-enabled peers agree on a set of parameters that are used to protect traffic between them. This set of parameters is collectively known as a Security Association. One peer acts as the initiator of the negotiation, the other as the responder.

IKE Security Association
The IKEv2 name for a phase 1 Security Association.

IKE tunnel
A tunnel that protects IKE phase 2 messages.

Internet Key Exchange (IKE)
A protocol for the secure generation and management of encryption keys over an existing IP network. There are two versions, commonly referred to as IKE version 1.0 (IKEv1) and IKE version 2.0 (IKEv2).

Internet Security Association and Key Management Protocol (ISAKMP)
Defines IKEv1 procedures and packet formats to establish, negotiate, modify, and delete Security Associations.

IP filter rule
A configured rule that defines the action applied to an IP traffic pattern that is encompassed by the rule. The possible actions include permit, deny, and permit with IPSec protection.

IP filter table
An ordered list of IP filter rules. When IP filtering is active on a host, the table is consulted for each IP packet that is sent or received. The action of the matching IP filter rule is enforced by the TCP/IP stack.

IPSec A suite of protocols and standards defined by the Internet Engineering Task Force (IETF) for secure communication over an existing IP network.

IPSec tunnel
A tunnel that protects IP traffic between two endpoints using one or both of the IPSec protocols. Manual and dynamic tunnels are both instances of an IPSec tunnel.

IP security filter policy
The policy that is installed by the Policy Agent. It includes the filter rules you define in the Policy Agent configuration files and an implicit deny all rule that is generated by Policy Agent.

IP traffic pattern
The set of IP traffic attributes that can be used as input to an IP filter table query. Typically, this includes IP source address, IP destination address, source port, destination port, protocol, and direction (inbound or outbound).

Manual tunnel
An IPSec tunnel whose security parameters and encryption keys are statically configured and must be manually managed by a security administrator.

Message authentication code (MAC)
A tag derived from the contents of a message and a secret key. The tag can be used to authenticate the integrity of a message as well as the source of the message.

Message digest algorithm 5 (MD5)
A MAC algorithm that produces a 128-bit hash value.

NAT traversal (NATT)
Traversal of IPSec traffic through a NAT device.

Network address port translation (NAPT)
A technique where multiple internal IP addresses are translated into a single public IP address. As part of this translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade.

Network address translation (NAT)
Network address translation is a broad term that encompasses both a one-to-one address translation function, translating a single internal IP address to a single public IP address, and the NAPT function.

Network security services (NSS)
Services performed in support of security enforcement or management.

NSS client
Requests network security services from an NSS server. The z/OS IKE daemon can act as an NSS client for a TCP/IP stack.

NSS server
Provides network security services for one or more NSS clients.

On-demand
The process by which a dynamic tunnel is activated by outbound traffic flow without user intervention.

Phase 1
The first stage of an IKE negotiation, in which an ISAKMP Security Association is established between two IKEv1-enabled peers, or in which an IKE Security Association is negotiated between two IKEv2-enabled peers. A phase 1 Security Association refers to IKEv1 ISAKMP SAs, as well as to IKEv2 IKE SAs.

Phase 2
The second stage of an IKE negotiation, in which an IPSec Security Association is established between two IKEv1-enabled peers, or in which a child Security Association is negotiated between two IKEv2-enabled peers. A phase 2 Security Association refers to IKEv1 IPSec SAs, as well as to IKEv2 child SAs.

Rivest Shamir Adleman (RSA)
An asymmetric key encryption method, in which the key that is used to encrypt data is different than the key that is used to decrypt the data. RSA can be used for encryption, or to authenticate a digital signature.

Secure hash algorithm 1 (SHA1)
A MAC algorithm similar to MD5, but more secure. This algorithm produces a 160-bit hash value.

Secure hash algorithm 2 (SHA2)
A MAC algorithm similar to SHA1, but more secure. This algorithm produces a 256-bit, 384-bit or 512-bit hash value.

Security Association (SA)
An agreement between two IPSec-enabled hosts that describes the type of data to protect and the methods that are used to protect the data. IKE creates a phase 1 Security Association to protect IKE messages (also known as the ISAKMP Security Association or the IKE Security Association), and a phase 2 Security Association to protect data traffic (also known as the IPSec Security Association or the child Security Association).

Symmetric encryption
Encryption that is performed between two parties sharing the same encryption key. Also known as secret key encryption.

Transport mode encapsulation
A process used to construct IPSec packets by inserting one or more additional IPSec headers between the IP header to be protected and the IP payload of the packet to be protected.

Tunnel
A secure logical connection or channel that is defined by a collection of Security Associations that define the security parameters protecting traffic between two endpoints.

Tunnel activation
The process by which a tunnel becomes active or usable. For dynamic tunnels, this process involves initiating an IKE negotiation.

Tunnel mode encapsulation
A process used to construct IPSec packets by creating a new IP header with an IP payload consisting of the entire IP packet being protected, and then inserting one or more additional IPSec headers between the new IP header and its IP payload (that is, the original IP packet).

UDP encapsulation
A process used to construct IPSec packets by first applying tunnel mode encapsulation or transport mode encapsulation to an IP packet to be protected by the ESP protocol, and then inserting a UDP header between the IP header and the ESP header.

Virtual private network (VPN)
A logical network of connected network nodes that communicate through secure channels (tunnels), typically by using the IPSec protocols (AH and ESP).

X.500 distinguished name
A collection of X.509 values, such as common name, host name, organization, organizational unit, and so on, that is stored in an X.509 digital certificate. An X.500 distinguished name is used as a globally unique identifier for the owner.

X.509 digital certificate
A set of information in the X.509 standard containing various attributes about an entity, including identity information and a public key that is used for encrypted communications with that entity.

Terminology conventions for IP security

The following terminology conventions are used throughout this information when referring to z/OS IP security:

IP security
The z/OS Communications Server function.

IPSec The protocol suite.

ipsec The action associated with an IP filter action, or the z/OS UNIX System Services command.

IPSEC The statement in the TCP/IP profile.

IPSECURITY
The parameter on the IPCONFIG statement in the TCP/IP profile.

NAT The general network address translation function. NAT encompasses both one-to-one address translation and network address port translation.

NAPT Network address port translation. This term is used when information is specific only to this form of NAT.

Commands used to administer IP security

The following commands are used to administer IP security. For more information on these commands, see *z/OS Communications Server: IP System Administrator's Commands*.

certbundle
Use the z/OS UNIX System Services **certbundle** command to create a certificate bundle file that contains certificate and CRL information.

ipsec Use the z/OS UNIX System Services **ipsec** command to display information about active filters and Security Associations, and to control aspects of Security Association negotiation. The **ipsec** command is used to:

- Display filters that are active in the stack
- Revert to default IP filter policy, as defined in the TCP/IP profile
- Reload IP security policy, as defined in the Policy Agent configuration files
- Activate Security Association negotiations
- Display existing phase 1 Security Associations
- Display existing phase 2 Security Associations
- Display remote port mappings used with NAT traversal configurations
- Display network security configuration information for the active stacks on the local system
- Display information for each NSS IPSec client that is currently connected to the NSS server
- Refresh existing phase 1 Security Associations
- Refresh existing phase 2 Security Associations
- Deactivate existing phase 1 Security Associations
- Deactivate existing phase 2 Security Associations
- Test for a filter rule match for a given set of IP traffic characteristics

Authority to use the **ipsec** command is controlled through RACF. There are two distinct types of SERVAUTH profiles that define access to the **ipsec** command, one for display capabilities and one for control capabilities.

Tip: Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

For the steps to configure access control to the **ipsec** command, see Appendix E, "Steps for preparing to run IP security," on page 1505.

For detailed syntax and usage, and how to control access of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

pasearch

Use the **pasearch** command to display Policy Agent information that is defined in the Policy Agent configuration files, including IP security and other types of policies. The options that are related to IP security include the ability to view IP security policy rules and actions, both active and inactive, for any TCP/IP stack for which policies have been defined and that is IPSECURITY-enabled.

If the user of the **pasearch** command is not a superuser, authority is controlled through RACF.

For detailed syntax and usage of the **pasearch** command, see *z/OS Communications Server: IP System Administrator's Commands*.

MODIFY

Use the MODIFY console command to have:

- The IKE daemon reread the IKED configuration file
- Policy Agent reread the Policy Agent configuration files

For detailed syntax and usage of the MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

Netstat

Use the Netstat command to display the following:

- IPSECURITY enablement for a particular stack (Netstat CONFIG/-f)
- SecurityClass (SECCLASS) for a specific interface (Netstat DEVLINKS/-d)

For detailed syntax and usage of the Netstat command, see *z/OS Communications Server: IP System Administrator's Commands*.

Overview of using IP security

z/OS Communications Server provides the ability to control and monitor network traffic on one or more TCP/IP stacks on a z/OS system. IP security for z/OS Communications Server supports IP filtering, IPSec, and Internet Key Exchange (IKE). IP security for z/OS Communications Server supports two versions of the IKE protocol: IKEv1 and IKEv2. See "Dynamic key management - IKE and IPSec negotiations" on page 974 for more information.

IP security policy can be used for the following:

- Protect a secure host on an internal network from unwanted network traffic

- Provide protection for traffic between partner companies over connected networks
- Allow secure sending of data over the Internet by providing IPSec virtual private network (VPN) support

These features are implemented in the IP layer on a per packet basis, and thus are available to any network application without requiring any special modifications. Applications can also implement their own additional security features as necessary, on top of the underlying IP security.

IP security policy is enabled, enforced, managed, and monitored through a coordinated effort of several z/OS Communications Server components:

- Policy Agent

  The Policy Agent is used to configure IP security on a z/OS system. It reads the configuration files that contain the IP security policy configuration statements, checks them for errors, and installs them into the IKE daemon and the TCP/IP stack.
- Internet Key Exchange daemon (IKED)

  The Internet Key Exchange daemon is responsible for retrieving IP security policy from Policy Agent, and dynamically managing keys that are associated with dynamic IPSec VPNs. This daemon also provides network management capabilities for IP security aspects of local TCP/IP stacks.
- Network Security Services daemon (NSSD)

  The Network Security Services daemon provides the NSS server functionality. It provides the NSS IPSec certificate service to perform digital signature creation and verification operations on behalf of NSS IPSec clients. The NSS IPSec certificate service is used by the IKED during phase 1 negotiations when digital signature authentication is required.
- TCP/IP stack

  The stack maintains a list of currently active IP filters and IPSec Security Associations, actively filters network traffic, controls encryption and decryption of network data, and maintains counters that are associated with an IPSec Security Association lifetime.
- Traffic Regulation Manager daemon (TRMD)

  The Traffic Regulation Manager daemon is responsible for logging IP security events that are detected by the stack, including IP filter events, updates to IP security policy, and the creation, deletion, and refresh of IPSec Security Associations.
- System logging daemon (syslogd)

  The system logging daemon manages the logging of messages and events for all of the other components, including where the log messages are written.

These components provide a combination of technologies that form the basis of IP security:

- IP filtering
- IP filter logging
- Data encryption and authentication

FIPS 140 and IP security

The Internet Key Exchange daemon (IKED), the network security services daemon (NSSD), and the TCP/IP stack components perform a wide variety of

cryptographic operations for IP Security. The IKED and the NSSD manage cryptographic keys and digital signatures and perform hashes for authentication. The IKED and the TCP/IP stacks perform encryption and decryption of messages that flow over the IPSec tunnels. Architectural enhancements to the IKE protocols periodically introduce new cryptographic algorithms for performing hashes and encryption.

Federal Information Processing Standards (FIPS) document 140 (FIPS 140) provides a higher degree of assurance of the integrity of cryptographic operations by placing restrictions on the cryptographic components and the operations performed by these components. Weaker algorithms are forbidden and all the operations must be performed by cryptographic modules that are contained within a well defined cryptographic boundary.

You can configure the IKED, the NSSD, and the TCP/IP stack components to operate in FIPS 140 mode. When you do, you restrict the cryptographic algorithms they support, and you modify their interactions with each other and with the other hardware and software components of the z/OS system related to cryptography, such as Integrated Cryptographic Services Facility (ICSF) and System SSL.

In FIPS 140 mode, the IKED, the NSSD and the TCP/IP stacks enforce the following restrictions on the cryptographic algorithms that can be used for IP security:

- You cannot use the DES encryption algorithm.
- You cannot use the HMAC-MD5, HMAC-MD5-96, AES128-XCBC, and AES128-XCBC-96 algorithms for authentication or pseudo-random function.
- You cannot use Diffie-Hellman groups 1, 2, and 5.
- You cannot use certificates for RSA signature authentication that have key lengths less than 1024 bits.
- You cannot use pre-shared keys whose length is less than half the key size of the chosen HowToAuthMsgs (IKEv1) or PseudoRandomFunction (IKEv2) algorithm.

When the FIPS 140 mode is configured for a TCP/IP stack, the Policy Agent enforces some of the FIPS 140-related restrictions when it parses the IP security policy files. Other restrictions are enforced when dynamic tunnels are being activated, after the FIPS 140 mode of all of the relevant software components (the IKED and the NSSD) is known.

You configure FIPS 140 mode independently for each of the IKED, the NSSD and the TCP/IP stack components. FIPS 140 mode must also be configured in ICSF and System SSL. If you use FIPS 140 mode in some components and not others, the resulting system might not operate in FIPS 140 mode. The components that are configured to use FIPS 140 mode can only use cryptographic services from components that are also operating in FIPS 140 mode, so the FIPS 140 mode mismatch can cause functional problems.

- If a TCP/IP stack is configured to use FIPS 140 mode, but the IKED is not, the IKED does not perform any dynamic VPN tunnel activations for the stack. The IKED performs many cryptographic operations on behalf of the stack during tunnel activation.

  Rule: Whenever the stack is configured for FIPS 140 mode, also configure FIPS 140 mode for the IKED.
- If the IKED and the TCP/IP stacks it supports are configured to use FIPS 140 mode, but the NSSD is not, the IKED cannot use the NSS IPSec certificate service for its stacks. Because the IKED must use the NSS IPSec certificate

service to create and verify digital signatures for IKEv2 tunnels, this FIPS 140 mode mismatch prevents activation of any IKEv2 tunnels that use digital signature authentication.

Rule: Whenever the IKED is configured for FIPS 140 mode, also configure FIPS 140 mode for the NSSD.

- If you have a sysplex that is configured for Sysplex Wide Security Associations (SWSA), and the distributor stack is not configured to use FIPS 140 mode, then it will not be able to successfully distribute tunnels to target stacks that are configured in FIPS 140 mode.

  Rule: Whenever you have target stacks that are configured in FIPS 140 mode, first configure FIPS 140 mode for the distributing stack.

When possible, you should enable FIPS 140 mode for the IKED, the NSSD, and the TCP/IP stacks all at once. If you must implement FIPS 140 support in stages, enable FIPS 140 mode in the components in the following order:

1. Configure FIPS 140 mode in the NSSD. If the NSSD is configured in FIPS 140 mode and the IKED and the TCP/IP stacks are not, the IKED still uses the NSS IPSec certificate service provided by the NSSD. Note that the NSSD creates and verifies signatures only for certificates that conform to FIPS 140 restrictions, even if the IPSec client is not operating in FIPS 140 mode.
2. Configure FIPS 140 mode in the IKED. When the NSSD and the IKED are both in FIPS 140 mode, but the stacks are not, dynamic VPN tunnels can be activated and data can flow, as long as those tunnels follow the FIPS 140 cryptographic algorithm restrictions.
3. If you are using SWSA in a sysplex, configure FIPS 140 mode in the distributor stack of the sysplex.
4. Configure FIPS 140 mode in all other TCP/IP stacks.

Enabling FIPS 140 mode on a system can affect performance. For example, you might have to change from using a weak encryption algorithm to using one that requires more processing to perform. Even if no algorithm changes are necessary, the IKED, the NSSD, and the TCP/IP stacks perform their cryptography operations in a different way when FIPS 140 mode is enabled than when it is not enabled, because FIPS 140 imposes additional self-verification requirements and access restrictions, and because hardware accelerated implementations of some cryptographic operations might not be available in FIPS 140 mode.

Steps for configuring IP security to support FIPS 140 mode

To configure IP security to support FIPS 140 mode, perform the following steps for each system and stack that needs to use FIPS 140 mode. If you are using Sysplex Wide Security Associations (SWSA), perform these steps first on your distributor and backup stacks, and then on each of your target stacks.

1. Ensure that Integrated Cryptographic Services Facility (ICSF) is started and that FIPS 140 mode is enabled for ICSF.

   Tip: You do not need to create TKDS data sets in order for IP security to use ICSF.

   For more information about enabling FIPS 140 mode for ICSF, see *z/OS Cryptographic Services ICSF Administrator's Guide*.
2. Ensure that one of the following conditions are true:
   - The SAF class CRYPTOZ is not active.
   - No SAF profile exists for the FIPSEXEMPT.SYSTOK-SESSION-ONLY resource in the CRYPTOZ class.

- The IKED, the NSSD, and the TCP/IP stacks that are configured in FIPS 140 mode have no access (NONE) to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.

  Tip: A single z/OS system can support multiple TCP/IP stacks, and you can configure some TCP/IP stacks with FIPS 140 support and others without FIPS 140 support. The stacks that are configured in FIPS 140 mode must have no access to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.

3. Ensure that System SSL FIPS 140 support is available and configured. For more information, see the information about System SSL and FIPS 140-2 in *z/OS Cryptographic Services System SSL Programming*.
4. If you are using network security services (NSS), configure NSS to support FIPS 140.

   You can configure FIPS 140 by specifying **Yes** as the FIPS140 value in the NSS configuration file (for example, nssd.conf). In the Configuration Assistant, configure the FIPS 140 option in the Advanced Server Settings for NSS in the NSS perspective.

   After you have configured FIPS 140, restart the NSS daemon if it was active.

   Tip: If TCP/IP is enabled for FIPS 140 but the NSSD is not, then the NSSD cannot provide NSS certificate services to the TCP/IP stack.
5. Configure IKE to support FIPS 140.

   You can configure FIPS 140 by specifying **Yes** as the FIPS140 value in the IKED configuration file (for example, iked.conf). In the Configuration Assistant, configure the FIPS 140 option in the Advanced IKE Daemon Settings in the IPSec perspective.

   After you have configured FIPS 140, restart the IKE daemon if it was active.

   Tip: If TCP/IP is enabled for FIPS 140 but the IKED is not, then the IKED will not negotiate dynamic VPN tunnels for that TCP/IP stack.
6. Configure the TCP/IP stack to support FIPS 140.

   You can configure FIPS 140 by specifying **FIPS140 Yes** on the IpFilterPolicy statement in the IPSec policy file for the stack. In the Configuration Assistant, configure the FIPS 140 option in the Advanced Stack Settings in the IPSec perspective.

   After you have configured FIPS 140, restart the stack if it was active.

Configuring IP security

You configure z/OS IP security using an extensive set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the set of IP security requirements for each TCP/IP stack. IBM provides two alternatives for creating the Policy Agent configuration files:

- "Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server"
- "Configuring IP security using manual configuration" on page 934

Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent and IKE daemon configuration files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF). z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When invoked in z/OSMF, the Configuration Assistant runs natively in the z/OS system and is accessed by your system administrators through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be running z/OS V1R11 or later.
- As a stand-alone application that you can run on your workstation. You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

It is possible to use the Configuration Assistant on your workstation, and then later migrate your work to the z/OSMF environment. Information on transferring Configuation Assistant data to z/OSMF is provided in *IBM z/OS Management Facility Configuration Guide*.

Through a series of wizards and online help panels, you can use the Configuration Assistant to create IP security configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the Configuration Assistant, there are four types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP
- Security levels that define the different ways to protect data, such as the encryption level
- Requirement maps that map traffic descriptors to security levels

  A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.
- Address groups that define a set of addresses to be used in an IP filter rule

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The Configuration Assistant comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied to an existing network topology, or the IBM-supplied definitions can be used as the basis for your own set of reusable objects.

The Configuration Assistant can dramatically reduce the amount of time that is required to create IP security policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, use of the GUI is encouraged to ensure that you have a consistent and easily manageable interface for implementing IP security.

This information primarily describes option 2, manual configuration. However, if you are using the Configuration Assistant, reading this information will help you understand security concepts and the relationship between Policy Agent and IP security function.

Configuring IP security using manual configuration

You can manually create the IP security policy configuration files by coding all of the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by IP security policy statements that permit advanced users to carefully fine-tune IP security policy on a per-stack basis. This information describes the procedure for creating an IP security policy by manually creating and editing the configuration files. There are examples that step through the process of creating a configuration file that includes zones

corresponding to various security models. For details about the configuration statements and parameters, see the Policy Agent and policy applications topic in *z/OS Communications Server: IP Configuration Reference*.

Specifying the IP security configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see "Policy types and infrastructure overview" on page 829. Regardless of which option is used to configure IP security policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IP security policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IP security policies from the policy server, specify the configuration files using the IPSecConfig statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the IPSecConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

IP filtering

IP filtering controls the flow of network traffic. An administrator can deny or allow any given network packet into or out of a z/OS system with an IP security policy.

Filter rules and actions

The IP security policy enables a z/OS system to classify any IP packet that comes across a network interface and take specific action according to a predefined set of rules. The set of properties that identify a packet, together with the action to be performed on it, is known as an IP filter rule. The rule can be used to filter out unwanted packets from the network stream, while allowing others. The collection of all filter rules comprise the IP filter table. The IP filter table contains all of the IP filter rules in the order in which they were configured. IP filter rules are configured using the IpFilterRule statement in an IP security policy configuration file. For more details about the IpFilterRule statement, see *z/OS Communications Server: IP Configuration Reference*.

For example, a simple filter table might have the following set of rules:

1. Allow Telnet traffic from IP address A.
2. Allow FTP traffic from IP address B and IP address C.
3. Allow any traffic from subnet D, but ensure that it is encrypted.
4. Allow encrypted traffic from any location if the remote IKE identity is a corporate email address.
5. Allow outbound connections to anywhere.
6. Deny anything that does not match the previous rules.

This set of rules would be considered to be a filter table consisting of six rules.

The filter table that is configured for a particular installation reflects the security needs for that site. The rules can be restrictive or permissive, as the security policy

allows. Normally the rules would deny anything not explicitly permitted, a configuration known as a default-deny policy, in which rules are added as necessary to allow only crucial network traffic. In a default-deny environment, the absence of any IP filter rules essentially isolates the system from the network. The alternative, a default-allow policy, allows all network traffic in the absence of any configured rules. Specific rules can be added as needed to deny unwanted or potentially malicious traffic. A default-deny policy is considered to be much more secure.

Rule: A z/OS Communications Server TCP/IP stack that is configured for IP security follows a default-deny policy by default, in the absence of any configured filter rules.

IP filter tables can grow very complex, and in many implementations are difficult to maintain. However, the configuration mechanism that is provided by IP security enables you to attach meaningful descriptors to rules, hosts, and other configured items, which makes keeping track of complex filter tables an easier task.

To protect data between hosts, hosts must agree on what type of traffic to protect, and how to protect that traffic. These IP traffic pattern definitions are stored in the locally configured security policy and installed in the IP filter table, which is consulted for each IP packet that enters or leaves the system. When a packet matches one of the rules in the IP filter table, the policy determines what action is taken for that packet. IP filter actions are configured using the IpGenericFilterAction statement in an IP security policy configuration file. For more details about the IpGenericFilterAction statement, see *z/OS Communications Server: IP Configuration Reference*.

On a z/OS stack that has IPCONFIG IPSECURITY configured (and perhaps also has IPCONFIG6 IPSECURITY configured) and an active IP security policy, there are three possible actions:

- Deny the packet.
- Permit the packet.
- Permit the packet with IPSec protection.

If the action that is associated with the filter rule is an ipsec action, the packet is subject to the application of IPSec authentication and encryption before it is received or sent. Any packet that matches a filter rule with an ipsec action is processed using the IPSec protocols, either Authentication Header (AH), Encapsulating Security Payload (ESP), or both, depending on the locally configured policy. z/OS IP security requires that data authentication be done if the filter rule specifies an ipsec action.

Filtering criteria in an IP packet

IP packets match IP filters based on a number of selection criteria. There are five primary pieces of information that are gathered from the IP packet, commonly referred to as a 5-tuple:

- Source address

  An IP packet can be filtered based on the source address located in the IP header of the packet.
- Destination address

  An IP packet can be filtered based on the destination address located in the IP header of the packet. For IPv6 packets that contain a type 0 or type 2 routing

header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, not on the destination address in the IP header.

- Protocol

  An IP packet can be filtered based on the protocol in the IP header of the packet.

- Source port

  If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the source port in the TCP/UDP header of the data portion of the packet.

- Destination port

  If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the destination port in the TCP/UDP header of the data portion of the packet.

Additional filtering criteria based on protocol

Following are some additional filtering criteria that are based on protocol:

- ICMP type and code

  If the protocol in an IP packet is ICMP or ICMPv6, the packet can be filtered based on the ICMP type and code located in the ICMP header of the data portion of the packet.

  Guideline: Typically, if an ICMP error is generated for a packet that arrived over a Security Association, and there is no matching rule for the ICMP error, z/OS Communications Server attempts to send the ICMP packet over the same Security Association that carried the original packet. If you want to disable this processing, you must code a rule that covers ICMP errors.

- OSPF type

  If the protocol in an IP packet is OSPF, the packet can be filtered based on the OSPF type located in the OSPF header of the data portion of the packet.

- Mobility header type

  If the protocol in an IP packet is IPv6 mobility header, the packet can be filtered based on the mobility header type located in the mobility header of the data portion of the packet.

Additional filtering criteria based on network attributes

Some filtering criteria are inferred from the external characteristics of the IP traffic, rather than being found in the actual IP packet. The following additional attributes are used to distinguish IP packets:

- Direction

  The direction of an IP packet is either inbound or outbound.

- Routing

  The routing attribute of an IP packet is either local or routed. IP packets are considered local if either of the following is true:

  – The packet is inbound and the destination address in the IP packet exists on the IPSECURITY stack.

  – The packet is outbound and the source address in the IP packet exists on the IPSECURITY stack.

  Otherwise the IP packet is considered routed.

- Security class

  Each non-virtual interface on a z/OS system is assigned a security class. The security class of an IPv4 interface is determined by the SECCLASS parameter

that is coded on the LINK statement or the DYNAMICXCF parameter of the IPCONFIG statement in the TCP/IP profile. The security class of an IPv6 interface is determined by the SECCLASS parameter that is coded on the INTERFACE statement or the DYNAMICXCF parameter of the IPCONFIG6 statement in the TCP/IP profile. The value of SECCLASS is a number in the range 1-255. If SECCLASS is not specified for an interface, the interface has a default security class of 255.

Each IP packet entering or leaving the system inherits the security class of the interface that it traverses:

– For inbound traffic, this is the interface on which the packet arrived.
– For outbound traffic, this is the interface over which the packet is sent.

The value for SECCLASS has no inherent meaning. A SECCLASS of 255 is no more or less secure than a SECCLASS of 1. You can optionally assign a SECCLASS value either to uniquely identify an interface, or to group interfaces with similar security requirements, based on site policy. Consequently, this attribute can be used as an additional criterion for IP filtering. Security class can be used to define broad filter rules that encompass all of the IP traffic that uses a group of interfaces without explicit knowledge of network addressing, or to ensure that an IP packet arrived on a valid interface.

For example, as shown in Figure 87, consider a z/OS system with three physical interfaces that are assigned the following security classes:

```
I1: SECCLASS 10
I2: SECCLASS 20
I3: SECCLASS 20
```

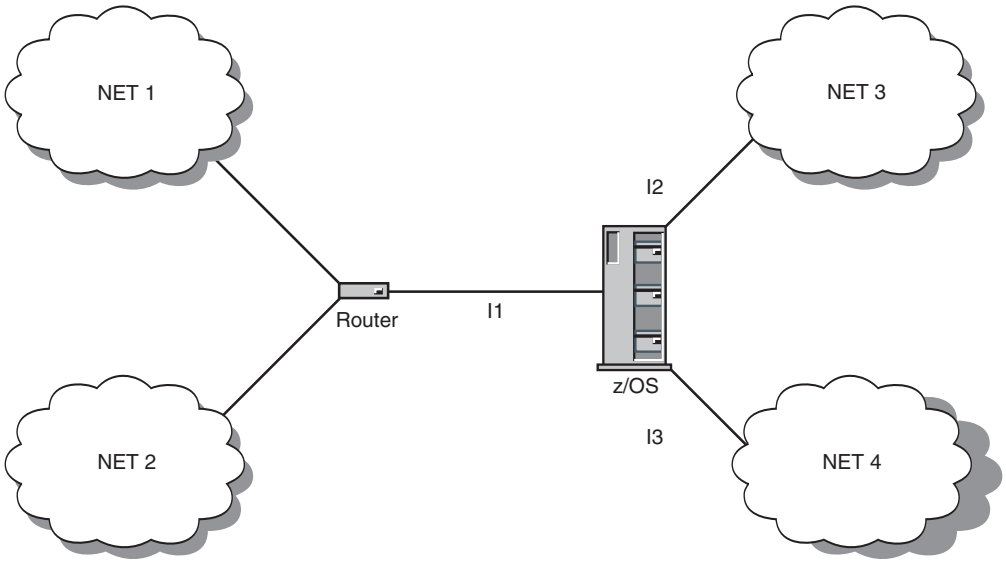

Figure 87. Using SECCLASS to identify interfaces

All IP packets from NET1 and NET2 have the same security class (10), and all IP packets from NET3 and NET4 have the same security class (20). Even though each interface on the z/OS system can reach multiple networks, you can configure a single IP filter rule that matches all of the IP traffic from NET3 and NET4 without explicitly identifying any attributes of the IP packets, other than security class. For instance, if NET3 and NET4 are trusted internal networks in which you want to allow all network traffic, you can configure one IP filter rule permitting all traffic with a security class of 20, without regard to IP address.

An IP filter using security class as a criterion is not limited to scenarios in which the IP addresses are ignored. To counter IP address spoofing, IP filter rules can take into account both security class and IP address. IP address spoofing involves the creation of an IP packet whose source address has been modified to reflect an address other than that of the originator. Because routers ignore the source address when making routing decisions, the modified IP packet can still reach its destination. An IP packet whose source IP address has been spoofed is usually not legitimate and is often used in a malicious manner. IP filtering can counter an attempt to spoof a source IP address by ensuring that an IP packet arrived on a valid network interface. For instance, any inbound packet that has a source address of an internal network node, but entered the system though an external interface, is probably spoofed and should be denied.

Rule: The SecurityClass parameter cannot be used on an IpFilterRule statement with a dynamic ipsec action. The IKE protocols do not provide for the negotiation of SecurityClass, and therefore it cannot be used as a selection criterion for a Security Association. The SecurityClass parameter can be configured only for an IpFilterRule statement that has an action of permit, deny, or manual ipsec. Coding a SecurityClass parameter with a value other than 0 on a dynamic ipsec rule is considered a configuration error.

Guidelines:

- If there are multiple interfaces by which a packet can reach its destination, the SECCLASS values for the interfaces and the filter rules should be consistent. If a packet could reach its intended destination by traversing one of a number of interfaces, the SECCLASS values and the related filter rules should account for the possibility of alternate routing.
- If the same IPv6 link-local address exists in multiple LANs in your network and you want to define filter rules to distinguish these IP addresses, configure different SECCLASS values for the interfaces onto these LANs to make the filter rules unique. However, if you are using dynamic IPSec for link-local addresses, you cannot use SECCLASS values to make the filter rules unique, so you must ensure that there are no overlapping or duplicate link-local addresses.

For more details about the SecurityClass parameter on the IpService statement, the SECCLASS parameter on the LINK and INTERFACE statements, and the SECCLASS keyword on the DYNAMICXCF parameter of the IPCONFIG and IPCONFIG6 statements, see *z/OS Communications Server: IP Configuration Reference*.

- Remote IKE identity

  For traffic that is protected by IPSec, the remote IKE identity can be used as a filtering criterion. This is particularly useful in cases where a client is roaming or mobile and does not have a fixed IP address, but has a known authenticated IKE identity.

  Filter rules with a remote IKE identity often have wildcard IP addresses that are not very specific, because mobile users can connect from a variety of locations.

  Guidelines:

  - Consider placing filter rules with a remote IKE identity near the bottom of your IP filter policy, so that other traffic has optimal filter searching. Because the wildcard IP addresses are not very specific for these rules, much IP traffic needs to be compared against these rules to test whether the traffic matches the rule.
  - Consider whether the mobile client's traffic might intersect with other filter rules; for example, when a mobile user occasionally brings their laptop into the office. If you choose to permit the user to continue to establish their IPSec

connection while in the office, then you should order the remote identity filter rules in your IP filter policy so that they precede the office network filter rules.

IP traffic patterns

The information that is gathered from an IP packet can be used to identify a specific type of network traffic, based on common Internet protocols. For example:

- Web traffic to a server consists of TCP packets inbound to and outbound from port 80.
- TN3270E Telnet server traffic consists of TCP packets inbound to and outbound from port 23.
- IKE traffic consists of UDP packets inbound from and outbound to port 500. In addition, if NAT traversal is enabled, IKE traffic can use UDP port 4500.
- Ping (IPv4) consists of ICMP packets outbound with type 8, code 0 (echo request), and inbound with type 0, code 0, (echo reply).
- Ping (IPv6) consists of ICMPv6 packets outbound with type 128, code 0 (echo request), and inbound with type 129, code 0, (echo reply).

The IpService statement groups these attributes into definitions of common traffic patterns that can subsequently be incorporated in an IP filter rule. The sample configuration file /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf provides definitions for many of the common traffic patterns that are seen on a typical z/OS server.

For more details about the IpService statement, see *z/OS Communications Server: IP Configuration Reference*.

Routed traffic and fragmented packets

Fragmented packets are problematic for IP security implementations because transport layer headers (UDP, TCP, and so on) are not present in every fragment. For some packet fragments, the transport layer selector values (for example, UDP ports, ICMP type and code) are indeterminate, which complicates IP packet filtering. In the case of IPv6, a fragment's IP protocol value might also be indeterminate.

Tip: z/OS Communications Server filters fragmented packets only for routed traffic. For all local traffic, z/OS Communications Server performs filtering on the fully assembled packet.

Because some packet fragments do not contain the transport layer header and cannot be filtered based on transport layer selector values, z/OS Communications Server enforces the following restriction for routed traffic.

Restriction: All routed traffic between two endpoints must be filtered in the same manner without regard to TCP or UDP port, ICMP or ICMPv6 type and code, or OSPF and MIPv6 type.

Guideline: To perform more granular filtering for this traffic, enforce a port-specific filtering policy, or a type-specific and code-specific filtering policy, at the final destination for this IP traffic.

z/OS Communications Server supports the specification of Opaque for matching indeterminate IPv6 protocol values in packet fragments. Packets that have an indeterminate value match filter rules only when Opaque or Any is specified.

z/OS Communications Server also supports explicit matching on fragmented packets. The IpService policy object's fragment specification can be used to match any fragmented packet, even if the packet's selector values are known. Explicit matching can be used to deny all fragmented packets in situations in which they are not part of normal traffic patterns and are considered to be a security risk.

Conditionally controlling IP filters

When IP filters from IP security policy files are installed into the stack, they are always active by default. Depending on the business need, this might not always be desirable. For instance, you might want to restrict certain types of IP traffic to a specific time, day, or week. IP security provides this flexibility by allowing you to specify a time condition for an IP filter rule. The IpTimeCondition statement specifies when an IP filter or a manual IPSec tunnel is active. You can prescribe not only what traffic is allowed, but when that traffic is allowed, in a way that is not disruptive and without having to edit the IP security policy files.

For more details about the IpTimeCondition statement, see *z/OS Communications Server: IP Configuration Reference*.

Special considerations when using IP security for IPv6

This topic describes considerations for using IP security for IPv6.

Neighbor discovery and multicast listener discovery

For IPv6, TCP/IP uses the neighbor discovery protocol, which provides the following functions:

- Address resolution (neighbor solicitations and neighbor advertisements to perform ARP functions for IPv6)
- Duplicate address detection (neighbor solicitations and neighbor advertisements to ensure unique IP addresses)
- Router discovery (router solicitations and router advertisements to keep track of neighboring routers)
- Neighbor unreachability detection (to keep track of the reachability of neighbors)

TCP/IP also uses multicast listener discovery (MLD), which notifies routers that nodes are ready to receive multicast packets.

Neighbor discovery and MLD are implemented using ICMPv6 packets.

When the stack is enabled for IP security for IPv6, TCP/IP performs IP filtering for these packets and denies these packets by default. You must consider these packets when configuring filter rules for IPv6. For example, if you configure permit rules for IPv6 TCP or UDP traffic over an OSA-Express QDIO interface, but do not configure permit rules for the neighbor discovery address resolution flows over the interface, the traffic will not succeed because the stack denies the ICMPv6 neighbor solicitation and neighbor advertisement packets during address resolution. Also, you must configure permit filter rules for neighbor solicitation and neighbor advertisement packets, so that the stack can perform duplicate address detection (and learn about valid duplicate addresses).

In addition, for the stack to be able to learn about neighbors, you must configure permit filter rules for outbound router solicitations and inbound router advertisements. Similarly, for the stack to be able to perform the MLD listener

function, you must configure permit filter rules for outbound MLD listener reports and inbound MLD listener query packets.

For example filter rules to permit neighbor discovery and MLD packets, see the TCP/IP sample profile and policy sample.

Guideline: Configure permit rules for neighbor discovery and MLD packets.

Result: z/OS Communications Server does not apply IPSec protection for outbound neighbor discovery or MLD packets, but does apply permit and deny actions for these packets. If such an outbound packet matches an IP filter rule that specifies an IPsec action, the stack permits the packet but does not encapsulate it.

Stateless address autoconfiguration

If you use autoconfiguration, your IPv6 addresses might not be predictable. To configure IP filter rules for dynamic Security Associations with autoconfigured IPv6 addresses, you need to specify the IP addresses using wildcards.

Manual Security Associations typically use specific IP addresses for the endpoints. You can use wildcards for the security endpoint addresses so that the data endpoints and security endpoints are considered identical. Alternatively, you can use predictable IPv6 addresses for the security endpoints. You can obtain predictable IPv6 addresses by configuring full 128-bit IPv6 addresses on your INTERFACE statements, by specifying the INTFID keyword on your INTERFACE statements, or by using VIPAs.

IPv6-specific protocols

The protocol number for ICMPv6 (58) is different from the protocol number for IPv4 ICMP (1); remember this when configuring IPv6 filter rules. Also, you can configure filter rules for IPv6 fragments using protocol IPv6Frag (44). For more considerations regarding fragmented IPv6 packets, see “Routed traffic and fragmented packets” on page 940.

IPv6 address types

You can configure IP filter rules for any valid IPv6 address, including multicast addresses, link-local addresses, IPv4-mapped addresses, IPv4-compatible addresses, and so on.

You can configure IPSec tunnels for link-local and global addresses. For multicast addresses, you can configure manual tunnels but not dynamic tunnels. You cannot configure IPSec tunnels for IPv4-mapped addresses or IPv4-compatible addresses.

IPv6 extension headers

If an IPv6 packet contains an extension header that is a type 0 or type 2 routing header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, rather than using the destination address in the IP header.

Considerations for IPv6 OSPF security

IPv4 OSPF authentication is implemented within the IPv4 OSPF protocol. However, IPv6 OSPF security (both authentication and encryption) is implemented using IPsec. Because OSPF uses both multicast messages and unicast messages, it is not possible to use dynamic tunnels for OSPF traffic. Instead, manual tunnels must be

used. The IBM Configuration Assistant for z/OS Communications Server automates the process of creating IPv6 OSPF tunnels. Following is a description of the process of manually creating the IPv6 OSPF tunnel definitions.

It is expected that the same manual tunnel is to be used for all link-local unicast and multicast traffic. Additional tunnels might be used for IPv6 OSPF virtual links.

Because multicast traffic is one-to-many, the manual tunnel must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. Whatever SPI values and keys are used must be coordinated with all IPv6 OSPF peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify **any6** for the local and remote security endpoint locations. The following example uses AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```
IpManVpnAction tunnel-ipv6ospf-internal
{
  LocalSecurityEndpointAddr  any6
  RemoteSecurityEndpointAddr any6
  HowToAuth                  AH HMAC_SHA1
    AuthOutboundSa      2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
    AuthInboundSa       2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  HowToEncrypt               DES
    EncryptOutboundSa   2701 0x3e6dcf72459ef551
    EncryptInboundSa    2701 0x3e6dcf72459ef551
  HowToEncap                 transport
}
```

For the filter rules, you first need to create an IP service to describe the OSPF traffic. To distinguish the traffic, you specify the OSPF protocol, and the SECCLASS of the interfaces on which the traffic will flow. For the purpose of this example, assume that the interfaces for the LAN segment that is being protected are defined with SECCLASS 10.

```
IpService service-ipv6ospf-internal
{
  Protocol      ospf
  Direction     bidirectional
  Routing       local
  SecurityClass 10
}
```

You now need to define three filter rules to match the OSPF traffic. The first filter rule matches all link-local unicast traffic on the LAN segment:

```
IpFilterRule ipv6ospf-unicast-internal
{
  IpSourceAddr             fe80::/10
  IpDestAddr               fe80::/10
  IpServiceRef             service-ipv6ospf-internal
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-ipv6ospf-internal
}
```

The remaining two filter rules are for the OSPF link-local multicast traffic. The first rule matches outbound multicast traffic, which has a link-local unicast source address and a link-local multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is link-local unicast, and a local (source) address that is link-local multicast. These rules are as follows:

```
IpFilterRule ipv6ospf-outbound-multicast-internal
{
  IpSourceAddr             fe80::/10
  IpDestAddr               ff02::/16
  IpServiceRef             service-ipv6ospf-internal
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-ipv6ospf-internal
}
IpFilterRule ipv6ospf-inbound-multicast-internal
{
  IpSourceAddr             ff02::/16
  IpDestAddr               fe80::/10
  IpServiceRef             service-ipv6ospf-internal
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-ipv6ospf-internal
}
```

Virtual links

You can also configure IPsec protection for IPv6 OSPF virtual links. You can use the following method to configure manual tunnels for IPv6 OSPF virtual links.

Guideline: Because virtual links use global unicast addresses, you should use dynamic tunnels for IPv6 OSPF virtual links whenever possible. Dynamic tunnels provide numerous benefits over manual tunnels.

Because the virtual link addresses are not known beforehand, you must specify the security endpoint addresses for the manual tunnel with a wildcard value. The Security Association does not protect multicast traffic, so the inbound and outbound SPI values and keys do not need to be identical. Whatever SPI values and keys you use must be coordinated with the virtual link peer.

```
IpManVpnAction tunnel-ipv6ospfvirt-internal
{
  LocalSecurityEndpointAddr  any6
  RemoteSecurityEndpointAddr any6
  HowToAuth                  AH HMAC_SHA1
    AuthOutboundSa      2702 0xf5c58a6e6f0761b68f424f39257f0ea89a4be3b4
    AuthInboundSa       2703 0x39a341ed1b7127b7905df2411ed0770854b54d10
  HowToEncrypt               DES
    EncryptOutboundSa   2704 0xb9571d20fe98ecca
    EncryptInboundSa    2705 0xfeba84c113fb40ed
  HowToEncap                 transport
}
```

Only one filter rule is needed for the virtual link. For this example, the same IP service used for the link-local traffic is used, which restricts this filter rule to OSPF traffic flowing over interfaces with SECCLASS 10. Because the virtual link addresses are not known beforehand, the filter rule addresses are specified with a wildcard value to include all global unicast addresses. If you have more specific information about the address prefixes for the virtual link endpoints, you can use this to further restrict the addresses on the filter rule.

```
IpFilterRule ipv6ospf-virtual-internal
{
  IpSourceAddr              4000::/3
  IpDestAddr                4000::/3
  IpServiceRef             service-ipv6ospf-internal
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-ipv6ospfvirt-internal
}
```

Default IP filter policy and IP security policy

Policy Agent provides IP filter policy to the stack, as defined by the IP security policy configuration files. For the stack to be enabled for IP security for IPv4, the TCP/IP profile must have IPCONFIG IPSECURITY coded. For the stack to be enabled for IP security for IPv6, the TCP/IP profile must also have IPCONFIG6 IPSECURITY coded. For the stack to receive configured policy, the Policy Agent must be active. IP filter policy is installed when Policy Agent and the stack are active. If Policy Agent is not active when an IPSECURITY-enabled stack initializes, the stack cannot be provided with IP filter rules from that policy. Therefore, in the interest of network security, the stack provides a default IP filter policy when an IP filter policy is unavailable from Policy Agent. The default IP filter policy effectively denies all network traffic, with the exception of some select ICMP and ICMPv6 messages that are necessary for internal stack function. These deny rules are not explicitly coded, but rather are always implicitly added at any time that the default IP filter policy is in effect. The default IP filter policy can be in effect at times other than stack initialization. Default IP filter policy is in effect in all of the following cases:

- An IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not been started, or an IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not completely initialized.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IP security configuration file exists.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but the IP security configuration file contains errors.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IpFilterPolicy statement exists in either IP security configuration file.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, and IP filter policy has been provided to the stack, but the stack is using the default IP filter policy because the **ipsec -f default** command was issued.

This default behavior ensures that network security is not compromised in the event that IP filter policy is not installed, and is consistent with a secure default-deny policy. However, you can modify the default IP filter policy by coding an IPSECRULE statement (for IPv4) or IPSEC6RULE statement (for IPv6) in the TCP/IP profile. The IPSECRULE and IPSEC6RULE statements describe the attributes of the IP traffic that is allowed when the default policy is active. Because the default behavior is to deny all network traffic, IPSECRULE and IPSEC6RULE statements are always permit rules that denote exceptions to the default-deny policy.

It is also important to note that neither the default IP filter policy nor a modified default IP filter policy provides authentication and encryption capabilities such as those provided by a complete IP security policy; it only offers the stack the ability to perform simple IP filtering in the absence of an IP security policy.

Modifying the default IP filter policy

The default IP filter policy is in effect when the IP security policy, as configured in the Policy Agent, is not available. The default IP filter policy denies all network traffic, unless you modify the TCP/IP profile.

Two IP filters are created by the default IP filter policy, one denying IPv4 inbound traffic and the other denying IPv4 outbound traffic. If IP security for IPv6 is also enabled, the stack also creates two similar filters, one denying IPv6 inbound traffic

and the other denying IPv6 outbound traffic. For example, assuming that the default IP filter policy is active, the following sample of the **ipsec -f display** command shows that SYSDEFAULTDENYRULE was added to the filter table:

```
ipsec -f display

Use IPSECRULE and IPSEC6RULE for permit rules that denote exceptions to the default-deny policy. When the default IP filter policy is active, these permit rules appear in the default IP filter table before the SYSDEFAULTDENYRULE entries. Typically, these exceptions are few in number and are used for administrative access to the system in the event that IP security policy is unavailable. For instance, a sample default set of permit rules might include entries to provide the following:

- Administrative access
- Basic network services, such as DNS and OSPF routing advertisements
- Use of ping to test for server availability

IPSECRULE and IPSEC6RULE entries are coded in the IPSEC block of the TCP/IP profile. They describe the attributes of the IP traffic that is allowed when the default IP filter policy is active. These rules can specify source address, destination address, protocol, source port, destination port, routing, and security class.

Unlike IP filter rules that are defined in Policy Agent, which allow direction to be specified, an IPSECRULE or IPSEC6RULE is always bidirectional. This means that for any IPSECRULE or IPSEC6RULE entry that specifies a source and destination address or port, an outbound rule is created with that source and destination address and port, along with an inbound rule with the source and destination addresses and ports reversed. (This equates to the use of the bidirectional keyword in an IpFilterRule statement.)

IPSECRULE and IPSEC6RULE entries always have an action of permit; there is no action specification for deny or permit with IPSec protection.

Assuming the administrative machine has an IP address of 9.1.1.2 and connects through an interface whose security class is 100, the following sample IPSECRULE entries enable the z/OS system to communicate IPv4 DNS queries and OSPF routing advertisements to anyone, while giving blanket access to the administrator. The example IPSEC6RULE entry permits any ICMPv6 packets. An asterisk (*) is the default and represents all, indicating that any packet matches this attribute.

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr   Logging Protocol   SrcPort    DestPort     Routing  Secclass

; OSPF protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO OSPF

; IGMP protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO 2

; DNS queries to UDP port 53
  IPSECRule *       *         NOLOG   PROTO UDP  SRCPort *  DESTport 53

; Administrative access
  IPSECRule *       9.1.1.2   LOG                                          SECCLASS 100

; ICMPv6 protocol
  IPSEC6Rule *      *         NOLOG   PROTO ICMPv6
ENDIPSEC
```

Any IPSECRULE and IPSEC6RULE entries that are coded are given a system-generated name for purposes of display. These rules are prefixed with the string SYSDEFAULTRULE. The IPSECRULE entries that are configured in the previous example are reflected in the **ipsec -f display** command as shown in the following example. Notice that there are two rules created for each IPSECRULE or IPSEC6RULE entry configured, one for each direction. The five rules that are configured in the example IPSEC block have been expanded into ten IP filters. Four additional filters have been created for the default-deny behavior. Each rule is given a unique filter name comprised of SYSDEFAULTRULE.*number*, where *number* is a numerical extension that indicates the relative order of the rule in the IP filter table. Since each IPSECRULE and IPSEC6RULE statement results in multiple filter rules with the same name (inbound and outbound), a FilterNameExtension value is assigned by the system to uniquely identify each filter.

```
ipsec -f display

```

For an IP security-enabled stack, one of the two security policies is always in effect, either the default policy or the IP security policy as defined in Policy Agent. The policy that is in effect at any given time is considered to be the active policy. The source field of the report header for the **ipsec -f display** command can be used to determine which policy is currently active as follows:

```
ipsec -f display

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 09:55:31 2010
Primary:  Filter          Function: Display           Format:   Detail
Source:   Stack Profile   Scope:    Current           TotAvail: 14
Logging:  On              Predecap: Off               DVIPSec:  No
NatKeepAlive:  0          FIPS140:  No
Defensive Mode: Inactive

FilterName:                   SYSDEFAULTRULE.1
FilterNameExtension:          1
```

`Stack Profile` indicates that the default IP filter policy is active; `Stack Policy` would indicate that the IP security policy as defined in Policy Agent is active.

You can also choose which policy is the active policy. The **ipsec** command provides the ability to switch the active policy between the default IP filter policy in the TCP/IP profile and the IP security policy in Policy Agent. Issuing the **ipsec -f default** command causes the default policy to become the active policy, while issuing the **ipsec -f reload** command reloads the IP security policy from Policy Agent, provided that Policy Agent is active and that IP security has been correctly configured.

There are cases in which you might want to switch to the default policy. For instance, in the event of a security breach, the **ipsec -f default** command allows only the network traffic that has been explicitly coded in the TCP/IP profile IPSEC block, which typically permits only administrative access.

It is important to use the **ipsec -f default** command with discretion. Issuing **ipsec -f default** on an operational system can have a dramatic impact and cause packets to be dropped, depending on how the IPSECRULE and IPSEC6RULE entries are coded. Consider the use of **ipsec -f default** as equivalent to a shutdown, and do not use it in normal conditions unless the following are true:

- The system is in maintenance mode.
- There is no productive work being done on the system.

- The site policy for IP traffic is default-allow and the appropriate IPSECRULE and IPSEC6RULE entries were coded.

Malicious use of network resources can be identified by unusual IP traffic conditions, console messages, or log inspection. Should a security concern arise in a production environment, the following steps should be performed quickly to minimize the impact of potentially restricted flow of IP traffic.

1. To secure the system, switch to the default IP filter policy by issuing the **ipsec -f default** command.
2. Analyze system logs to determine the nature and the source of the security concern. If packet logging was active for the time period in question, then inspect the TRMD packet filtering log entries.
3. Update the IP security policy configuration to alleviate the security concern. For example, add an IpFilterRule that denies any suspicious IP address or port use, and activate IP filter logging.
4. Activate the updated IP security policy from the Policy Agent by issuing the **ipsec -f reload** command.
5. Verify that the security concern is eliminated. Monitor the network traffic and inspect the system logs, including any related IP filter log messages.

IP filter logging

Monitoring network events is an important aspect of network security. Logs can be used to verify that policies have been correctly configured and enforced, or to gather statistics on any traffic of interest. For instance, traffic that is persistently denied might be suspect. With IP filter logging, you can inspect any traffic on the system and even fine tune the configuration to show only those entries of interest. Logging can be controlled at the global level or at the individual rule level, including the ability to specify whether to log permitted traffic, denied traffic, or both. The IP filter log entries provide detailed information about each packet, including the rule that the packet matched and any pertinent IPSec information.

TRMD and syslogd provide the logging service for IP security. If running in the common INET environment, you must configure one instance of TRMD for each stack on a z/OS system.

Guideline: Exhaustive logging of IP traffic can have a negative effect on performance. If logging is excessive, it can be turned off temporarily at the global level while the appropriate logging modifications are made to the individual IP filter rules. IP filter logging is controlled by the IpFilterLogging parameter on the IpGenericFilterAction statement. For more details, see *z/OS Communications Server: IP Configuration Reference*.

IP filter discard action

When packets are denied by IP filter policy, IP security supports sending an ICMP or ICMPv6 destination unreachable message, which indicates that a packet is administratively prohibited. You can enable this action for the implicit Policy Agent deny filter rules using the ImplicitDiscardAction parameter on the IpFilterPolicy statement, and for individual filter rules using the DiscardAction parameter on the IpGenericFilterAction statement.

Rule: To make a system effectively invisible to attackers, choose the discard action Silent. Choose the discard action ICMP only in cases in which doing so is a useful diagnostic aid, such as for users of internal networks.

Data encryption and authentication — IPSec

To participate in a virtual private network (VPN), a host must encrypt and authenticate individual IP packets between itself and another communicating host. IPSec is one of several mechanisms for achieving this, and one of the more versatile.

IPSec is defined by the IPSec working group of the IETF. It provides authentication, integrity, and data privacy between any two IP entities. Management of cryptographic keys and Security Associations can be either manual or dynamic using an IETF-defined key management protocol called Internet Key Exchange (IKE).

IPSec provides flexible building blocks that can support a variety of configurations. Because an IPSec Security Association can exist between any two IP entities, it can protect a segment of the path or the entire path. The main advantage of using IPSec for data encryption and authentication is that IPSec is implemented at the IP layer. Consequently, any network traffic that is carried by an IP network is eligible to use IPSec services without any special changes to higher level protocols that are used by applications. However, if the system is using any of these alternate security protocols to secure specific applications, IP filtering can be used to avoid the overhead of multiple security protocols. For example, you might want to exclude Web traffic (based on the well-known secure port of the Web server, port 443) from IPSec coverage because you would like to use SSL.

IPSec enables the creation of VPNs. A VPN enables an enterprise to extend its network across a public network, such as the Internet, through a secure tunnel using Security Associations. IPSec VPNs enable the secure transfer of data over the public Internet for same-business and business-to-business communications, and protect sensitive data within an enterprise's internal network.

IPSec uses IP filtering to determine which traffic should be protected by IPSec. A special type of filter action specifies to permit the traffic, but only with IPSec protection. The IP filters represent IP security policy to the stack by specifying the traffic that requires IPSec protection. The filters are also used in locating the outbound IPSec Security Association, and for verifying that inbound traffic is received using the correct Security Association.

The IETF has standardized the IPSec protocol suite and key management schemes in a series of IPSec RFCs. For more information on these RFCs, see Appendix G, “Related protocol specifications,” on page 1555.

IPSec has three major components:

- IP Authentication Header (AH)
- IP Encapsulating Security Payload (ESP)
- Internet Key Exchange (IKE)

AH and ESP protocols

IPSec uses two distinct protocols, Authentication Header (AH) and Encapsulating Security Payload (ESP), which are defined by the IETF.

The AH protocol provides a mechanism for authentication only. AH provides data integrity, data origin authentication, and an optional replay protection service. Data integrity is ensured by using a message digest that is generated by an algorithm such as HMAC-MD5 or HMAC-SHA. Data origin authentication is ensured by

using a shared secret key to create the message digest. Replay protection is provided by using a sequence number field with the AH header. AH authenticates IP headers and their payloads, with the exception of certain header fields that can be legitimately changed in transit, such as the Time To Live (TTL) field.

The ESP protocol provides data confidentiality (encryption) and authentication (data integrity, data origin authentication, and replay protection). ESP can be used with confidentiality only, authentication only, or both confidentiality and authentication. When ESP provides authentication functions, it uses the same algorithms as AH, but the coverage is different. AH-style authentication authenticates the entire IP packet, including the outer IP header, while the ESP authentication mechanism authenticates only the IP datagram portion of the IP packet.

Either protocol can be used alone to protect an IP packet, or both protocols can be applied together to the same IP packet. The choice of IPSec protocol is determined by the security needs of your installation, and is configured by the administrator. It does not have to be applied system-wide, and can be configured differently for each set of connection endpoints. For a dynamic tunnel, the choice of IPSec protocol is configured using the IpDataOffer statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the IpDataOffer statement and the IpManVpnAction statement, see *z/OS Communications Server: IP Configuration Reference*.

z/OS IP security requires authentication due to potential security exposures when encryption is used alone. Authentication can be provided by the ESP or AH protocol. The complete list of combinations for authentication and encryption that are provided by z/OS IP security and that can be used for a specific connection are shown in Table 45.

Table 45. Possible authentication and encryption combinations for a connection

Encryption		Authentication	
Protocol	**Algorithm**	**Protocol**	**Algorithm**
None	None.	ESP or AH	Any of the following algorithms: • HMAC_MD5 • HMAC_SHA1 • AES128_XCBC_96 • HMAC_SHA2_256_128 • HMAC_SHA2_384_192 • HMAC_SHA2_512_256 • AES_GMAC_128 • AES_GMAC_256
ESP	Any of the following algorithms: • DES • 3DES • AES_CBC KeyLength 128 • AES_CBC KeyLength 256	ESP or AH	Any of the following algorithms: • HMAC_MD5 • HMAC_SHA1 • AES128_XCBC_96 • HMAC_SHA2_256_128 • HMAC_SHA2_384_192 • HMAC_SHA2_512_256

Table 45. Possible authentication and encryption combinations for a connection (continued)

Encryption		Authentication	
Protocol	**Algorithm**	**Protocol**	**Algorithm**
ESP	Any of the following algorithms: • AES_GCM_16 KeyLength 128 • AES_GCM_16 KeyLength 256	ESP	NULL (AES_GCM provides built-in authentication)

Guideline: RFC 4835 discourages the use of DES. Use the 3DES or AES encryption algorithms wherever possible for better security and interoperability.

Restriction: The combination of ESP protocol for encryption and AH protocol for authentication is not supported by IKEv2. If you are using IKEv2 and require both encryption and authentication, you should use ESP for both.

Encapsulation

In the process of applying either AH or ESP to an IP packet, the original IP packet is modified. Outbound packets are rebuilt with additional IPSec headers in a process known as encapsulation, while inbound packets are stripped of their IPSec headers in a process known as decapsulation. Before leaving a host, outbound packets are encapsulated using a cryptographic key that is known to both communicating hosts. Inbound packets are decapsulated on the receiving side using the same cryptographic key, thereby recovering the original datagram. If encryption is used, any packet that is intercepted on the IP network is unreadable to anyone without the encryption key. Any modifications to the IP packet while in transit are detected by authentication processing at the receiving host and discarded.

Transport mode and tunnel mode: The manner in which the original IP packet is modified depends on the encapsulation mode used. There are two encapsulation modes used by AH and ESP, transport and tunnel.

Transport mode encapsulation retains the original IP header. Therefore, when transport mode is used, the IP header reflects the original source and destination of the packet. Transport is most often used in a host-to-host scenario, where the data endpoints and the security endpoints are the same. A transport mode encapsulated datagram is routed, or transported, in the same manner as the original packet.

Figure 88 shows an IPv4 packet that is encapsulated using AH in transport mode:

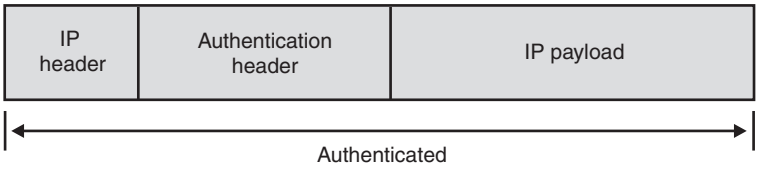

Figure 88. IPv4 packet encapsulated using AH in transport mode

Figure 89 on page 970 shows an IPv4 packet that is encapsulated using ESP in transport mode:

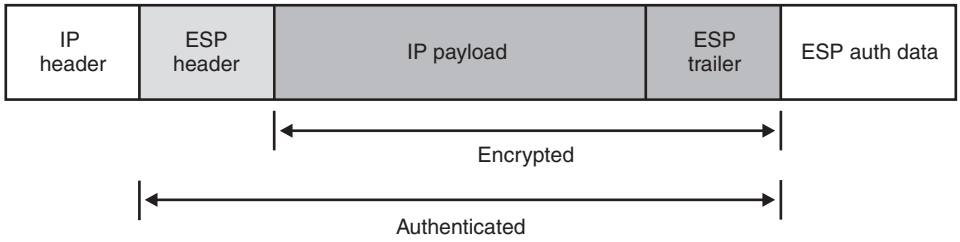

Figure 89. IPv4 packet encapsulated using ESP in transport mode

Figure 90 shows an IPv6 packet that is encapsulated using AH in transport mode:

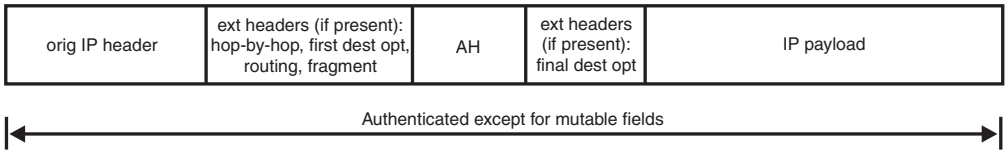

Figure 90. IPv6 packet encapsulated using AH in transport mode

For a description of the IPv6 mutable fields, see RFC 2402. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Figure 91 shows an IPv6 packet that is encapsulated using ESP in transport mode:

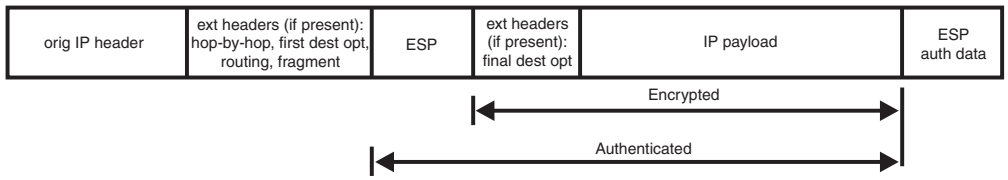

Figure 91. IPv6 packet encapsulated using ESP in transport mode

Tunnel mode encapsulation builds a new IP header containing the source and destination address of the security endpoints. When tunnel mode is used, the outer IP header reflects the source and destination of the security endpoints, which might or might not be the same as the original source and destination IP address of the data connection. The choice of transport or tunnel mode depends on the structure of the network and relies heavily on logical connections between the endpoints. Tunnel mode is required if one of the IKE peers is a security gateway that is applying IPSec on behalf of another host or hosts. A datagram that is encapsulated in tunnel mode is routed, or tunneled, through the security gateways, with the possibility that the secure IPSec packet will not flow through the same network path as the original datagram. To successfully encapsulate and send an outbound packet, the route table must contain a route that can be used to reach the security gateway, as well as a route that can be used to reach the data endpoint. If policy-based routing is being used on a TCP/IP stack where IP security is active, it is important to understand how the two functions interact. For more information, see "Considerations for using policy-based routing with IP security" on page 344.

Figure 92 on page 971 shows an IPv4 packet that is encapsulated using AH in tunnel mode:

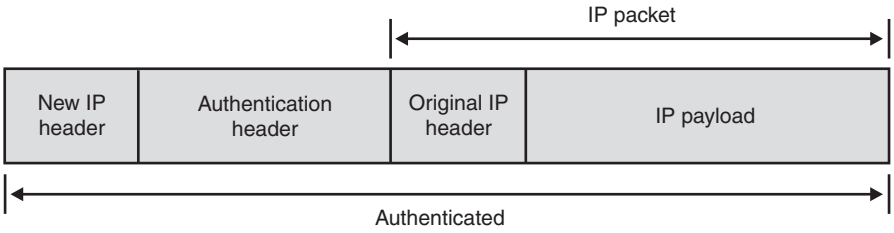

Figure 92. IPv4 packet encapsulated using AH in tunnel mode

Figure 93 shows an IPv4 packet that is encapsulated using ESP in tunnel mode:

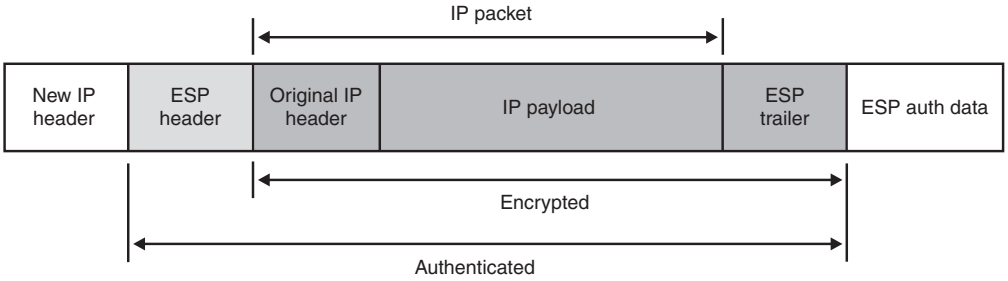

Figure 93. IPv4 packet encapsulated using ESP in tunnel mode

Figure 94 shows an IPv6 packet that is encapsulated using AH in tunnel mode:

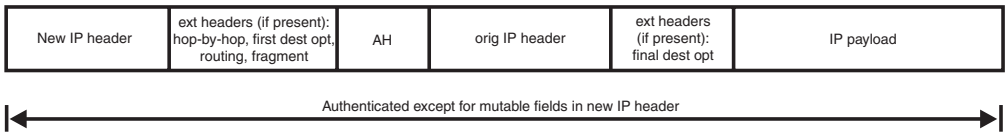

Figure 94. IPv6 packet encapsulated using AH in tunnel mode

For a description of the IPv6 mutable fields, see RFC 2402.

Figure 95 shows an IPv6 packet that is encapsulated using ESP in tunnel mode:

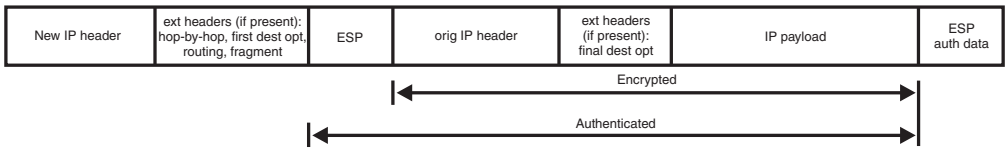

Figure 95. IPv6 packet encapsulated using ESP in tunnel mode

Do not confuse tunnel mode encapsulation with IKE tunnel or IPSec tunnel. In this context, tunnel refers only to the method by which IPSec packets are constructed, while IKE and IPSec tunnels are conceptually defined as secure logical connections between hosts. IPSec tunnels can use transport mode or tunnel mode encapsulation.

For a dynamic tunnel, the choice of encapsulation mode is configured using the IpDataOffer statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the

IpDataOffer statement and the IpManVpnAction statement, see *z/OS Communications Server: IP Configuration Reference*.

Guideline: In host-to-host scenarios, transport mode is commonly used because it does not incur the overhead of having to build an additional IP header. However, tunnel mode is equally valid.

Tip: Any configurations that include a secure gateway as an IKE endpoint require tunnel mode; however, if IKEv2 is used, then the selection of encapsulation mode is performed automatically. The IKED will use transport mode if it determines that the connection is host-to-host; otherwise the IKED will use tunnel mode encapsulation. This behavior can be overridden by using the HowToEncapIKEv2 parameter on the associated KeyExchangeAction statement; see the KeyExchangeAction statement in *z/OS Communications Server: IP Configuration Reference* for details.

Rule: If you are using sysplex-wide Security Associations, a dynamic Security Association cannot use a subnet or range that encompasses a DVIPA address. For takeover to work consistently, Security Associations must be negotiated for single IP addresses only. If two DVIPAs that are covered by the same Security Association are subsequently taken over by two different backup stacks, the coverage of the Security Association is ambiguous because it is then linked to two DVIPAs on two different stacks.

UDP encapsulation of IPSec ESP packets

When building an ESP packet, it can be further encapsulated by placing a UDP header in front of the ESP header. This is known as UDP encapsulation. UDP encapsulation is used to allow IPSec traffic to successfully traverse a NAT device. For more information on NAT traversal (NATT), see "IPSec and network address translation devices" on page 982. z/OS Communications Server supports NAT traversal for only IKEv1 Security Associations and for only IPv4 traffic.

There are two modes of UDP encapsulation:

- UDP-Encapsulated-Transport mode
- UDP-Encapsulated-Tunnel mode

As shown in Figure 96, UDP-Encapsulated-Transport mode inserts a UDP header in between the IP header and the ESP header of a normal transport mode ESP packet.

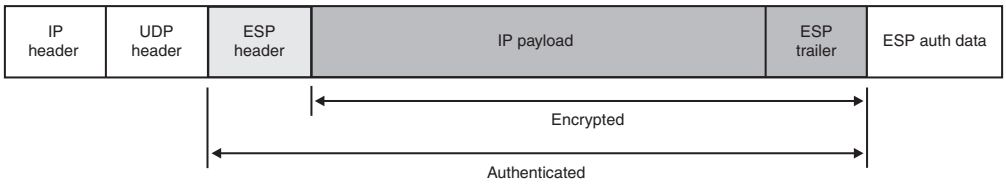

Figure 96. UDP-Encapsulated-Transport mode

As shown in Figure 97 on page 973, UDP-Encapsulated-Tunnel mode inserts a UDP header in between the new IP header and the ESP header of a normal tunnel mode ESP packet.

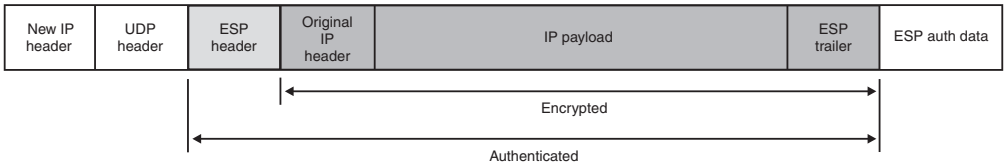

Figure 97. UDP-Encapsulated-Tunnel mode

When an IPSec UDP-encapsulated packet is built, the source and destination port values in the UDP header are set to the IKE port value of 4500.

Configure the choice of transport or tunnel mode using the IpDataOffer statement in the IP security policy configuration file. For more details about the IpDataOffer statement, see *z/OS Communications Server: IP Configuration Reference*.

The decision to use a UDP-encapsulated mode is not configured, but instead inferred, when a NAT is detected between two IKE daemons.

IPSec and symmetric key management

At the center of encryption and authentication is the notion of a cryptographic key. Security endpoints use keys to encrypt and decrypt data. The IPSec protocols create Security Association keys that are directional. As shown in Figure 98, the key that is used to encrypt outbound data on one host is used to decrypt the same data on the remote host, while the key that is used to encrypt data on the remote host is used to decrypt data on the local host.

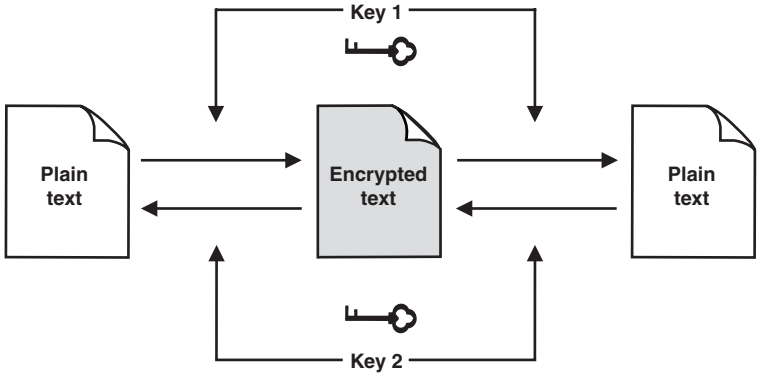

Figure 98. Symmetric encryption

This type of encryption is known as symmetric, because it requires that both hosts use the same keys on the same data.

Manual key management

IPSec keys and values can be configured manually. Manual management of keys was the only non-proprietary option for implementing IPSec before the standardization of the IKE protocols. In a manual IPSec configuration, the keys that are used to encrypt data, and the Security Parameter Index (SPI) values that are used to uniquely identify a Security Association, are determined by the administrator and configured beforehand on both hosts. However, the steps that you must take to manually generate encryption keys can become quite cumbersome, as shown in the following examples:

- A single IPSec connection requires two keys, because encryption keys are unidirectional (one for inbound traffic, one for outbound traffic).

- A single IPSec connection can require up to four SPI values, depending on the type of IPSec protection required.
- The keys and SPI values must be individually installed on both the local and remote system.
- To help ensure that the keys are not compromised, they need to be changed periodically and updated on both hosts. Manual IPSec has no key refresh capabilities unless the Security Associations are deactivated, reconfigured with the new key, and then reactivated.
- During the refresh maintenance period, IPSec functionality is unavailable, disrupting any IP traffic requiring IPSec protection.
- Because of the disruptive nature of key refresh with manual IPSec, key lifetimes are frequently defined with much larger values, thus increasing the security exposure.
- These steps must be carried out for each remote host that communicates with IPSec, with different keys for each of them.

In a small installation with minimal security concerns, this manual process can work quite well, and might actually be preferable. However, given the large number of communicating hosts in a typical network, this manual process quickly becomes unwieldy, error prone, maintenance intensive, and not scalable. Nevertheless, z/OS IP security does support manual IPSec configuration for compatibility with systems that use it. If an IP filter rule specifies a manual ipsec action, the corresponding action is consulted to determine all aspects of the encryption and authentication policy for that data, including the identities of the communicating hosts, the keys that are used for encryption and authentication of outbound and inbound packets, and the SPI values. Manual IPSec protection is configured using the IpManVpnAction statement in an IP security policy configuration file. For more details about the IpManVpnAction statement, see *z/OS Communications Server: IP Configuration Reference*.

Dynamic key management - IKE and IPSec negotiations

The primary role of the IKE daemon in an IP security environment is the automatic management of cryptographic keys. Dynamic key management, as provided by the IKE daemon, removes much of the administrative burden that is associated with the creation, distribution, and maintenance of cryptographic keys. IKE provides the following services:

- Host authentication (ensuring that both hosts are certain of the other's identity)
- The negotiation of a Security Association as follows:
  - Agreeing on the type of traffic to be protected
  - Agreeing on the authentication and encryption algorithms to be used
  - Generating cryptographic keys
- Nondisruptive periodic refresh of keys
- The deletion of Security Associations whose lifetimes have expired

There are two versions of the IKE protocol: IKEv1 and IKEv2. The architectural differences between IKEv1 and IKEv2 are as follows:

- IKEv2 requires fewer network flows for Security Association establishment.
- IKEv2 provides a mechanism for re-keying an IKE Security Association without reauthentication, which reduces the CPU cost.
- IKEv2 allows each peer to manage its own values for lifetime and lifesize, whereas in IKEv1 Security Association lifetimes and lifesizes are negotiable

attributes. This reduces coordination of configuration parameters between the peer nodes and avoids potential race conditions when the SAs expire.
- IKEv2 supports the hash and URL certificate encoding types, but IKEv1 does not.

The following are differences between IKEv1 and IKEv2 that are specific to the z/OS implementation:
- NAT traversal is supported for IKEv1 but not for IKEv2.
- Sysplex-wide Security Associations are supported for IKEv1 but not for IKEv2.
- To use any authentication method for IKEv2 based on a digital signature, the certificate service must be provided by an NSS server. You cannot use the IKED native certificate service.

IKE operates at the application layer. IKE negotiations are communicated between two IKE peers by a series of UDP messages. Ports 500 and 4500 are used by the IKE daemon. For both IKEv1 and IKEv2, Security Association negotiation proceeds in phases. In each phase, IKE negotiates a Security Association with a remote host. During the initial phase, IKE negotiates a phase 1 Security Association, which establishes a secure channel over which the IKE peers communicate. The phase 2 Security Association is negotiated to provide data authentication and encryption for subsequent IP traffic. The distinction between a phase 1 Security Association and a phase 2 Security Association is what the Security Associations protect:
- Phase 1 Security Associations are used to protect IKE messages that are exchanged between two IKE peers, or security endpoints.
- Phase 2 Security Associations are used to protect IP traffic, as specified by the security policy for a specific type of traffic, between two data endpoints.

Every Security Association that the IKE daemon negotiates contains information about the type of traffic it is to protect, the IP addresses of the two endpoints, the type of encryption or authentication that is provided, the keys that are used to protect data, how often the keys are refreshed, and an identifier called a Security Parameter Index (SPI) that is used to uniquely identify the Security Association.

An IPSec configuration contains separate policies governing each phase. Although many of the same attributes apply for phase 1 and phase 2 negotiations and keys, there are two major differences:
- The phase 1 Security Association can specify only a single IP address for the security endpoints, while the phase 2 Security Association can specify a contiguous range or subnet as the data endpoint.
- The phase 1 Security Association must specify an encryption method, while encryption is optional for the phase 2 Security Association. An authentication method must be specified for both the phase 1 and phase 2 Security Association.

The exact specifications for each phase 1 Security Association and each phase 2 Security Association are configured in the IP security configuration file. The specific IP security policy statements that apply to the phase 1 and phase 2 specifications are the KeyExchangeOffer statement (phase 1) and the IpDataOffer statement (phase 2). For more details about the KeyExchangeOffer statement and the IpDataOffer statement, see *z/OS Communications Server: IP Configuration Reference*.

Because the IKE protocols deal with initializing keys, they must be capable of running over links where no security is assumed to exist. IKE addresses the problem of secure key distribution by automatically deriving the keying material

using a Diffie-Hellman exchange during the IKE phase 1 negotiation. This automatic creation and distribution of the key during phase 1 eliminates the need to manually distribute the session key between remote sites. Besides the obvious administrative advantage of IKE, the manual method of key distribution is prone to key compromise.

In addition, IKE non-disruptively refreshes the session keys based on the security policy of the installation. IKE specifies that this can be based on time (lifetime) and bytes transmitted (life size). IKE provides a property called perfect forward secrecy (PFS), and if PFS is used, each phase 2 key is derived independently through a separate Diffie-Hellman exchange. With PFS, if a single key is compromised, the integrity of subsequently generated keys is not affected.

Phase 1

Before IKE can negotiate the security parameters and generate the keys that are used to protect data between the two hosts, it must have a way of protecting the negotiation itself. The IKE phase 1 negotiation provides this protection by performing two tasks:

- Authenticating the IKE peer

  Peer authentication is performed either by the pre-shared key method or a digital signature method. For details of peer authentication, see "Peer authentication."
- Generating cryptographic keys

  A Diffie-Hellman exchange is performed to create a shared secret between the two IKE peers. This shared secret is then utilized in the generation of keying material. Keys to encrypt and authenticate messages sent during phase 2 are produced from this keying material. Cryptographic keys utilized by phase 2 Security Associations are generated from this keying material. The creation of the Diffie-Hellman shared secret is secure, but computationally expensive.

The phase 1 Security Association contains the following:

- The key that is used to encrypt IKE messages
- The key that is used to authenticate IKE messages
- Keying material used to generate keys produced during phase 2
- The security endpoints (single IP addresses)
- The type of protection that is required (authentication and encryption)
- How often the keys should be renewed
- A Security Parameter Index (SPI) value, which is used together with the remote security endpoint IP address to uniquely identify the Security Association
- The Diffie-Hellman group, which is an attribute of the public key cryptography algorithm

Because the tasks of authentication and master key generation are so resource intensive, a phase 1 Security Association is usually refreshed less often than a phase 2 Security Association.

Peer authentication: Peer authentication is a critical part of a phase 1 negotiation. Before two hosts can participate in the negotiation of a Security Association, each must be authorized to negotiate with the other. IKE does not allow negotiation with a host that cannot be properly identified. IP addresses are not a guarantee of identity (an IP packet can be spoofed), and the IP address from an inbound packet alone is insufficient to prove the identity of a remote host. Therefore, the IKE

daemon needs a more reliable method for determining the remote host's identity. This proof of identity is first presented during the phase 1 negotiation.

z/OS IP security implements two methods of host authentication as follows:

- Digital signature (RSA or ECDSA)
- Pre-shared key

Each of these authentication methods provides a way for hosts to verify the identity of the other, and while the pre-shared key mechanism is easier to configure, the digital signature methods are more versatile, secure, and scalable. The choice of authentication method is configured in an IP security policy configuration file for each IPSec connection, using the KeyExchangeOffer statement for IKEv1 and the KeyExchangeAction statement for IKEv2. For more details about the KeyExchangeOffer and KeyExchangeAction statements, see *z/OS Communications Server: IP Configuration Reference*.

Peer authentication is not the same as data authentication. Data authentication uses IPSec to authenticate an IP packet after an IPSec Security Association has been negotiated by two IKE daemons. Peer authentication is used during an IKE phase 1 negotiation to identify two IKE peers to each other before the establishment of any phase 2 Security Associations.

Guideline: As a matter of security, pre-shared keys should not be shared among multiple remote IKE peers. If the pre-shared key method of authentication is used, each remote host should have its own unique key and KeyExchangeRule specific to that host. If multiple remote hosts are identified by the same KeyExchangeRule, digital signature methods of peer authentication should be used.

Rule: For IKEv2, if digital signatures are used as the authentication method, then the IKED must be configured to use the certificate services of the NSSD. For more details about the configuring the IKED and the NSS IPSec client, see Chapter 20, "Network security services," on page 1149.

Identity information: Multiple identities can be assigned down to the level of individual IP addresses for each IKE negotiation, or for ease of configuration, a single identity can be assigned to represent the IKE daemon for the entire system. With either method, the identity that is assigned must be an identity that is known to the remote IKE peer. Similarly, the local server must know the identity of any remote IKE peer with which it is to negotiate. The identity can be one of the following types:

- X500dn (the host's X.500 distinguished name)
- IpAddr (an IP address)
- Fqdn (a fully qualified domain name)
- UserAtFqdn (an e-mail address)
- KeyID (EBCDIC, ASCII or hexadecimal string)

  Restriction: An identity of KeyID is valid only when using preshared key authentication.

If a digital signature method of peer authentication is used, the local identity must be in an X.509 digital certificate on the IKE daemon's key ring for an IKEv1 negotiation, or on the NSS server's key ring for an IKEv1 or IKEv2 negotiation that uses the NSS certificate service. If the pre-shared key method of peer authentication is used, any of the identity types can be used to identify this IKE

peer. Because digital certificates are not used in the pre-shared key method, the only requirement for the use of an identity type is that it be known to both hosts.

Identity information is configured using the LocalSecurityEndpoint and RemoteSecurityEndpoint statements in an IP security policy configuration file. For more details about the LocalSecurityEndpoint and RemoteSecurityEndpoint statements, see *z/OS Communications Server: IP Configuration Reference*.

Digital signatures: Digital signature authentication methods include RSA and ECDSA. They use X.509 digital certificates. An X.509 digital certificate contains information that was verified by a certificate authority to uniquely identify a host. IKE peers exchange certificates during the phase 1 negotiation to identify each other. Of the information that is typically included in an X.509 digital certificate, there are four fields that are relevant to an IKE exchange:

Subject Name
A certificate's subject name is the unique name by which the host is known. The subject name is used to extract the host's X.500 distinguished name (X.500dn). IKE can use the X.500dn as an identifier for the remote host, or use one of the certificate's Subject Alternative Names.

Subject Alternative Name
An optional field, X.509 extensions, can contain a Subject Alternative Name field. Although the X.500dn is the most specific way to identify a certificate, the Subject Alternative Name can be used as well, often acting as a simple alias to identify the certificate. If the certificate includes optional X.509v3 extensions, the certificate can contain any or all of the following:

- IpAddr - an IP address
- Fqdn - a fully qualified domain name
- UserAtFqdn - an e-mail address

Subject Public Key Info
The public key is used for encrypting information that can be decrypted only with the certificate's private key. Likewise, information that is encrypted using the certificate's private key can be decrypted only with the public key. Using this scheme, information from the owner can be encrypted, digitally signed, and authenticated. IKE uses the public key to assist in verifying a host's identity.

Issuer Name
Certificate signing is a method by which a certificate is verified by a trusted third party. A signed certificate contains the subject name and key identifier of the certificate authority that signed it, known as the issuer.

Because there are many commercial and private certificate authorities, it is possible for a host to own multiple certificates that are signed by different certificate authorities. Depending on a site's policy, only certain certificate authorities might be trusted. Therefore, a z/OS IP security host might request that a peer use only certificates that are signed by a specific trusted certificate authority. Two configuration parameters refer to certificate authorities, the SupportedCertAuth parameter of the IkeConfig statement in the iked.conf file, and the CaLabel parameter of the RemoteSecurityEndpoint statement. The SupportedCertAuth parameter names a specific certificate authority that is recognized by the IKE daemon. The CaLabel parameter identifies a portion of a certificate authority hierarchy that is preferred by the local security endpoint.

For more information about the IkeConfig and RemoteSecurityEndpoint statements, see *z/OS Communications Server: IP Configuration Reference*.

Pre-shared key: The pre-shared key method of authentication enables a remote host to authenticate itself by providing a secret key, which is known to both hosts. This key is pre-configured by the administrator, and is used along with the Diffie-Hellman shared secret to derive cryptographic keys used to protect and authenticate data that flows during the phase 1 negotiation. The pre-shared key is a shared secret between the two IKE peers, and any host that does not know the shared key cannot enter into negotiation. IKE maintains a list of all the remote hosts that are authorized to negotiate. This list contains the identity of the remote host and the pre-shared key known to that host.

Negotiation modes for phase 1: For IKEv1, the phase 1 negotiation that takes place between two IKE peers happens in one of two modes, Main mode or Aggressive mode.

Main mode is more secure because it encrypts the identities of the two hosts that are contained in the IKE messages, but somewhat slower because more message exchanges are required. Main mode requires a total of six messages, three from the initiator and three from the responder.

Aggressive mode is faster, in that fewer messages are exchanged. Aggressive mode requires only three messages, two from the initiator and one from the responder. However, the identity of the two hosts is not protected in Aggressive mode. An IKE implementation is not required to support Aggressive mode.

The choice of mode depends in part on the security needs of the installation. If it is important that the identities of either host are not to be in clear text on the network, use Main mode. Otherwise, if both hosts support it, you can use Aggressive mode for faster, more efficient key exchange. One limitation of Aggressive mode is that the initiator can specify only a single Diffie-Hellman group because the key exchange data is sent in the first message. If you need to allow the initiator to send multiple offers with different Diffie-Hellman groups, use Main mode.

For IKEv2, there is only one set of network flows defined for phase 1 negotiation. The set requires four messages, two from the initiator and two from the responder. The first two of these four messages flow in the clear on the network; the other two messages are encrypted. The negotiation of the first phase 2 Security Association is accomplished within these four flows; when the fourth message flows, both phase 1 and phase 2 Security Associations are activated. Either the initiator or the responder can subsequently activate additional phase 2 Security Associations using this phase 1 Security Association.

You configure the choice of negotiation mode using the KeyExchangeAction statement and the Diffie-Hellman group using the KeyExchangeOffer statement in an IP security policy configuration file. For more details about the KeyExchangeAction and KeyExchangeOffer statements, see *z/OS Communications Server: IP Configuration Reference*.

Phase 2

The purpose of phase 2 negotiation is to establish a set of parameters known as a Security Association, which is used to protect specific types of IP traffic. The phase 2 Security Association contains the keys that are used to encrypt and decrypt IPSec packets on the host, authenticate IPSec packets on the host, or both. The phase 2

Security Association is negotiated for a specific set of data endpoints for a specific type of traffic, and contains the following:

- The keys that are used to encrypt, if encryption is being used
- The keys that are used to authenticate
- The data endpoints, either a single IP address or range of IP addresses
- The protocol of the traffic to be protected, either a single protocol or all protocols
- The ports of the traffic to be protected, either a single port, a range of ports if the IKEv2 protocol is used to negotiate the phase 2 Security Association, or all ports
- The IPSec protocol that is used to protect the data: AH or ESP, or both if the IKEv1 protocol is used for the negotiation
- The type of authentication algorithm to be used
- The type of encryption algorithm to be used, if encryption is being used
- How to build the IPSec packets (tunnel, transport, UDP-Encapsulated-Tunnel, or UDP-Encapsulated-Transport)
- How often the keys should be refreshed, if the IKEv1 protocol is used for the negotiation
- A security parameter index (SPI) value, used together with the remote security endpoint IP address to uniquely identify the Security Association
- The Diffie-Hellman group for perfect forward secrecy (PFS)

A phase 2 negotiation can begin only after the completion of a corresponding phase 1 Security Association. The encryption methods that are agreed upon during the phase 1 negotiation are used to protect the data that is exchanged during the phase 2 negotiation. For instance, if the KeyExchangeRule between two security endpoints specified SHA1 and 3DES, the IKE data that is exchanged during the phase 2 negotiation is authenticated using HMAC-SHA and encrypted using 3DES encryption. Although both phase 1 and phase 2 Security Associations might use the same authentication and encryption methods, this is not required. For instance, a phase 1 Security Association can specify SHA1 authentication and 3DES encryption, while a phase 2 Security Association might use ESP with HMAC-MD5 authentication and DES encryption.

The keys that are generated during the phase 2 negotiation can be derived from the phase 1 master key to amortize the cost of the phase 1 key generation. As an alternative, you can configure the phase 2 negotiation to use perfect forward secrecy (PFS) for stronger security. Each has its advantage as follows:

- If PFS is used, phase 2 negotiation does not derive its keys from the master key, but instead generates new keying material using the Diffie-Hellman algorithm. Because it is independently derived, the resultant phase 2 key is more secure.
- If PFS is not used, phase 2 negotiation is completed much more quickly, but the resultant phase 2 key is less secure.

In either case, phase 2 does not incur the same degree of processing overhead that is involved in phase 1 negotiation with the remote IKE peer.

For IKEv2, the negotiation of the first phase 2 Security Association on a given phase 1 is a special case because it is performed during activation of the phase 1. In this case, the phase 1 Diffie-Hellman group is used for the phase 2 negotiation, regardless of what was defined on the IpDataOffer statement that corresponds to the phase 2.

When phase 2 negotiation has completed, the Security Association is available for use by the stack. Now, any traffic that is mapped to this Security Association by an IP filter rule is IPSec-protected. Since each phase 2 Security Association corresponds to a single unique phase 1 Security Association, the identity of the remote peer is implicitly authenticated when the phase 2 Security Association is used.

Policy for phase 2 Security Associations is defined by referencing an IpDynVpnAction statement on an IpFilterRule statement. For more details on referencing an IpDynVpnAction statement on an IpFilterRule statement, see *z/OS Communications Server: IP Configuration Reference*.

Only tunnel or transport mode encapsulation can be specified on the IpDataOffer statement. For IKEv1, the decision to use UDP-Encapsulated-Transport mode or UDP-Encapsulated-Tunnel mode is made heuristically by the z/OS IKE daemon. If a NAT is detected in the process of creating a phase 1 Security Association, all phase 2 Security Associations negotiated under the protection of that phase 1 Security Association are negotiated utilizing UDP encapsulation. In this case, the z/OS IKE daemon internally converts all IpDataOffer statements containing ESP with tunnel mode encapsulation to UDP-Encapsulated-Tunnel mode, and IpDataOffer statements containing ESP with transport mode encapsulation to UDP-Encapsulated-Transport mode. Any IpDataOffer statements that are configured to use AH authentication are ignored, since the IPSec protocols do not allow for AH authentication when NAT is being used.

The phase 2 parameter values supported can differ between IPSec implementations. For example, z/OS provides configuration to negotiate a phase 2 Security Association for specific port and specific protocol values. Many implementations of IPSec support negotiating only a wide Security Association, covering all ports and protocols.

Refreshing phase 1 Security Associations

Refreshing a Security Association is the process of creating a new Security Association to replace an existing Security Association. The IKED automatically refreshes Security Associations when they are about to expire.

When an IKEv1 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association using a main mode or aggressive mode exchange.
- It negotiates new keys and it reauthenticates the identity of the IKE peer.

When an IKEv2 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association by using a create child exchange process.
- It negotiates new keys but does not reauthenticate the identity of the IKE peer.

You can use the ReauthInterval parameter on the KeyExchangeAction statement to cause the IKED to periodically reauthenticate an existing IKEv2 phase 1 Security Association. For more information about the KeyExchangeAction statement, see the KeyExchangeAction statement in *z/OS Communications Server: IP Configuration Reference*.

You can use the refresh option on the **ipsec** command to refresh an existing phase 1 Security Association. When you use the **ipsec** command to refresh an existing

IKEv1 or IKEv2 phase 1 Security Association, new keys are negotiated and the identity of the IKE peer is reauthenticated. For more information about the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

IPSec and network address translation devices

There are inherent incompatibilities between IPSec and network address translation (NAT) functions. RFC 3715, *IPsec-Network Address Translation (NAT) Compatibility Requirements*, provides a description of the problems that arise when IPSec is used to protect traffic that traverses a NAT. One basic problem is that when IPSec Security Associations traverse a NAT, the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). RFCs 3947 and 3948 define mechanisms that enable specific uses of IPSec to traverse one or more NAT devices.

- RFC 3947, *Negotiation of NAT-Traversal in the IKE*, allows an IKE daemon to detect when one or more NATs are being traversed.
- RFC 3948, *UDP Encapsulation of IPsec ESP Packets*, defines two IPSec encapsulation modes, UDP-Encapsulated-Tunnel mode and UDP-Encapsulated-Transport mode. These modes facilitate the traversal of IPSec traffic through a NAT by encapsulating ESP packets within a UDP packet.

When IPSec traverses one or more NAT devices, it is known as NAT traversal (NATT). z/OS Communications Server supports NAT traversal for only IKEv1 Security Associations and for only IPv4 traffic.

UDP-Encapsulated-Tunnel mode and UDP-Encapsulated-Transport mode Security Associations are negotiated by IKE when NAT traversal is enabled and a NAT is detected. Manually configured Security Associations do not support UDP-Encapsulated-Tunnel mode or UDP-Encapsulated-Transport mode.

There are several reasons why network address translation might be used. One reason is to economize on the use of public addresses within the internal network, using a public address only when data must be globally routed. A second reason is to hide internal IP addresses from network segments outside the internal IP address domain.

It should be noted that the NAT traversal support, as defined by the IETF, transmits internal IP addresses to its IPSec peer. These internal addresses are not exposed on the external network. However, the internal addresses are available for display at the remote security endpoint. If you are considering using this support, evaluate whether transmitting internal IP addresses to an IPSec peer is acceptable from a security policy perspective.

NAT encompasses the following IP address mapping techniques:

- One technique performs a one-to-one address translation. An internal-external IP address mapping is maintained by the NAT device. IP addresses are translated, but ports are unchanged. The mapping can be static or dynamic. For a static mapping, there is a definition in the NAT that always translates IP address *x.x.x.x* to IP address *y.y.y.y*. An outbound packet is not needed to establish the mapping. For a dynamic mapping, the NAT has a pool of IP addresses that are assigned as needed, so IP address *x.x.x.x* might be mapped to IP address *y.y.y.y* one time, and to IP address *z.z.z.z* at another time. The mapping is established when an outbound packet is processed.
- The network address port translation (NAPT) technique uses multiple internal IP addresses that are translated into a single public IP address. As part of this

translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade. The mapping is typically dynamic and established in the NAPT when an outbound packet is processed. For example, the NAPT might create a mapping for internal address *x.x.x.x* port *y* to external address *a.a.a.a* port *b* and a mapping for internal address *z.z.z.z* port *v* to external address *a.a.a.a* port *c*.

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the remote peer to detect whether the public address is being used for one-to-one address translation or for NAPT. When multiple clients have active Security Associations, the remote peer can detect when port translation is being performed.

The terms *in front of* and *behind* are used to convey which IP address a NAT is translating. When a NAT is said to be in front of a client, it means the client's address will be translated by the NAT. When a server is said to be behind a NAT, it means that server's address will be translated by the NAT.

NATT support level

z/OS supports NAT traversal as defined in RFCs 3947 and 3948. Platforms that have implemented their NAT traversal support using pre-RFC drafts might not inter-operate with implementations that are compliant with RFC 3947 and 3948. z/OS does provide limited support for the following pre-RFC implementations:

- draft-ietf-ipsec-nat-t-ike-02 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-02 (pre-RFC draft of RFC 3948)
- draft-ietf-ipsec-nat-t-ike-03 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-03 (pre-RFC draft of RFC 3948)

Dynamic structures used to map Security Associations

The negotiation of a phase 2 Security Association results in the dynamic creation of new filters used to map the Security Association to a specific type of traffic. These dynamic filters are then added to the filter table and remain as long as the Security Association is available for use. Additional structures are added to the filter table when the remote security endpoint is behind a NAT.

Anchor filters and dynamic filters

Filters with ipsec actions are flagged as anchor filters. Anchor filters are neither permit or deny rules, but rather serve as place holders for dynamic filters in the ordered list of filter rules. A dynamic filter is an extension of an anchor filter and is created when a phase 2 Security Association is created. Each phase 2 Security Association that is negotiated is associated with two dynamic filters, an inbound filter and an outbound filter. When an IP packet matches an anchor filter rule, there is a secondary search for a matching dynamic filter rule. If one is not found, the packet is denied, unless the packet is an outbound packet and on-demand negotiations are allowed. In that case, an IKE negotiation ensues to create a Security Association and the matching dynamic filter. If a dynamic filter already exists, the action taken is to permit with IPSec processing applied. The dynamic filter rule indicates which Security Association should be used when applying IPSec processing, because there is a one-to-one correspondence between dynamic filter pairs (inbound and outbound) and phase 2 Security Associations. For a sample display of anchor and dynamic filters, see “Displaying active filters with the ipsec command” on page 1111.

NATT anchor and NATT dynamic filters

When the remote peer is behind a NAT, the dynamic anchor still serves as a place holder in the ordered list of filter rules. However, the dynamic filters that are

created when a phase 2 Security Association is created are handled differently. When the phase 2 negotiation is successful, the dynamic filter pair that is created contains the 5-tuple information for which the Security Association was negotiated:

- The data endpoints, either a single IP address or range of IP addresses
- The protocol of the traffic to be protected, either a single protocol or all protocols
- The ports of the traffic to be protected, either a single port or all ports

In cases when the remote peer is behind a NAT, this 5-tuple might not be unique for a Security Association. An additional structure, a NATT anchor, is generated to anchor dynamic filters that share the same 5-tuple information. The dynamic filter is then an extension to the NATT anchor and is flagged as a NATT dynamic. For a sample display of NATT anchor and NATT dynamic filters, see "Displaying active filters with the ipsec command" on page 1111.

NAT resolution filters

When the remote peer is behind a NAT, a connection level filter structure is also created for TCP and UDP connections, the NAT resolution filter (NRF). Unlike the NATT anchor and NATT dynamic filters, which are created when the phase 2 Security Association is created, the NRF is created when the first inbound packet is received for the connection over the phase 2 Security Association. The NRF contains a single source and destination IP address, a single source and destination port value, and a single protocol. This connection-level filter is needed to determine the phase 2 Security Association that will be used for outbound data. For a sample display of NAT resolution filters, see "Displaying active filters with the ipsec command" on page 1111.

Remote port translation

When the remote peer is a security gateway behind a NAT, the remote data endpoint of the client is represented by the security gateway's public IP address. From the z/OS server's perspective, multiple clients residing behind the security gateway are all identified by the IP address of their corresponding security gateway, not the client's private IP address. Consequently, if two clients behind the security gateway were to open a connection to the same service (FTP, for example) from the same ephemeral port (1024, for example), the two connections could not be uniquely identified.

Similarly, when the remote peer is a host behind a NAPT, the remote data endpoint of the host is represented by the public address assigned by the NAPT. Typically, multiple hosts residing behind the NAPT are all assigned the same public IP address, with port translation distinguishing the hosts. The port that is being translated by the NAPT is the port found in the UDP header of the IKE packet and the UDP-encapsulated ESP packet, not the connection port. Consequently, if two hosts behind the NAPT open a connection to the same service (FTP, for example) from the same ephemeral connection port (1024, for example), the two connections cannot be uniquely identified.

Traditionally, the combination of local and remote IP addresses and ports is enough to distinguish the connections; in these instances, since the connection requests appear to be coming from the same IP address, they look identical. To avoid such conflicts, Communications Server provides remote port translation for TCP and UDP connections when needed. Without remote port translation, the first inbound TCP connection request for a unique 5-tuple would succeed. However, a subsequent inbound connection request using the same 5-tuple would fail.

Communications Server's remote port translation allows subsequent inbound connections using the same 5-tuple to succeed by translating the remote port value to a different ephemeral port.

Remote port translation does not need to be configured or enabled. It is built into Communications Server's NAT traversal support and is always in effect when the remote peer is behind a NAT. When a remote port is translated, message EZ0827I, remote port translated, is logged. Remote port translation determines whether the source port in an inbound packet represents a duplicate port. If it does, an attempt is made to assign an unused ephemeral port value. If the inbound packet matches a configured filter rule that covers all ports, any unused ephemeral port value can be assigned. If the configured filter rule applies only to a range of ports, the remote port is translated only to an unused ephemeral port in that range. If an unused port cannot be found, the connection request fails. When a remote port value is translated, there is both an original remote port and translated remote port for a connection. Various commands, such as Netstat, enable you to view connection information including the port, or even to select display data based on port. For connection data, if only one remote port is being provided, the translated port is displayed or used for a selection, if remote port translation has been done.

The **ipsec -o display** command provides a display of port mappings in effect. For a sample display of remote port translation, see "Displaying remote port translation with the ipsec command" on page 1128.

Steps for preparing the z/OS system for IP security

Before you begin: You need to be familiar with the concepts of IP filter logging and IPSec protection. See "Overview of using IP security" on page 929. You also need to be familiar with the commands used to administer IP security. See "Commands used to administer IP security" on page 928.

Perform the following steps to prepare the z/OS system for IP security.

1. Develop a site policy to address the security needs of your installation.

   The following are some questions that you must consider before beginning to build a robust IP security policy:

   - Do you want a default-allow or default-deny policy?
   - If a default-deny policy is desired, what traffic is allowable as critical to the proper functioning of the system?
   - What hosts are allowed to send data to the secure host?
   - Do you understand the network topology, and where the communicating hosts are located within the network?
   - Are there network address translation (NAT) devices in the network topology?
   - What type of traffic is allowable from those hosts?
   - What general network services that rely on well-known ports do you want to allow?
   - Will you forward any packets you receive that are not destined for you?
   - Who is allowed to configure the IP security policy?
   - Are you running with one TCP/IP stack, or more than one TCP/IP stack?
   - Are you running IPv6 traffic?
   - Will all TCP/IP stacks share the same policy definitions, or will they have unique differences?

- Will traffic that is sent or received by the secure host traverse the Internet?
- Do you want to participate in a VPN? (If so, IPSec is required.)
- If IPSec is required:
  - What are the IPSec capabilities of the remote endpoints?
  - How do you want to authenticate participating hosts:
    - Pre-shared key?
    - Digital signature? (requires digital certificates)
  - What type of authentication is needed for the data that is involved?
  - Is encryption needed for the data that is involved, and how strong should the encryption algorithms be?
  - Will all participating hosts use the same level of data encryption and authentication, or do you need to define unique policies for individual hosts?

2. Identify the resources to be secured.

   Create a worksheet for each TCP/IP stack you will enable for IP security. This information aids in determining which interfaces and connected networks are secured. You can later use the information from the worksheets to provide values for IP security policy configuration statements. Figure 99 includes a sample worksheet:

```
Host name of z/OS system _____________________________________

Complete for each TCP/IP stack on this host:
TCP/IP stack name _____________IPSECURITY-enabled (Y/N)______
Network interface(s)
IPv4 address/Mask_____________________Security Class_________
IPv4 address/Mask_____________________Security Class_________
IPv4 address/Mask_____________________Security Class_________
IPv4 address/Mask_____________________Security Class_________
IPv6 address/Prefix___________________Security Class_________
IPv6 address/Prefix___________________Security Class_________
Virtual IPv4 address/Mask_____________________
Virtual IPv4 address/Mask_____________________
Virtual IPv4 address/Mask_____________________
Virtual IPv4 address/Mask_____________________
Virtual IPv6 address/Prefix___________________
Virtual IPv6 address/Prefix___________________

Identities, other than IP address, by which the IKE daemon will be known
(e.g., X500dn, Fqdn, UserAtFqdn, KeyID)
____________________
____________________
____________________
____________________
____________________
```

Figure 99. Sample worksheet for stack security

Security class is an optional designation for a network interface. You can assign network interfaces a security class (1-255) that is used to group interfaces with similar security requirements. This concept is an extension of the traditional notion of secure and nonsecure interfaces, to allow for more than two classes. The secure and nonsecure model can still apply if only two security classes are defined.

Complete a table of remote hosts and subnetworks with which this host needs to transfer data, as shown in Table 46 on page 987. The remote hosts can optionally be grouped in a user-defined zone to simplify the number of IP

filter rules that are required. For instance, you might want to define an internal, external, trusted, Internet, partner company, or other zone that has meaning to your site.

Rule: If the remote IKE peer resides on a security gateway to the remote host, the IP address of the remote host might not match the IP address of the remote IKE peer. If this is the case, tunnel-mode encapsulation of IPSec traffic is required.

Table 46. Table of remote hosts and subnetworks

Remote IP address or subnet	User-defined zone of remote hosts	Identity of remote IKE peer (IpAddr, X500dn, KeyID, Fqdn, or UserAtFqdn)	IP address of remote IKE peer	Allowed list of services (Telnet, FTP, Web, EE, ALL, or other)	Security action (permit, deny, ipsec)	IPSec security level, if applicable

3. Modify the default IP filter policy (optional).

   After the site policy is established, you can modify the default IP filter policy if necessary. For a description and examples of how to modify the default IP filter policy, see "Default IP filter policy and IP security policy" on page 945.

   Guideline: You should define IPSECRULE and IPSEC6RULE statements that permit access from at least one administrative machine. In the event that Policy Agent is unavailable, or the IP security configuration files contain errors, the active default policy would deny access to the IP security-enabled stack. Should this situation occur, if you have added the appropriate IPSECRULE and IPSEC6RULE statements to the default policy, you can still access the secure z/OS host and make the necessary administrative changes to correct the problem.

4. Set up the key required applications:

   - TCP/IP

     To enable IP security on a z/OS stack, make the following changes in the TCP/IP profile:

     – Add IPCONFIG IPSECURITY.
     – To also enable IP security for IPv6, add IPCONFIG6 IPSECURITY.
     – Reserve ports 500 and 4500 for IP security. If the IKE daemon is running on this system, reserve the ports for the user ID under which the IKE daemon is running. In this example, the IKE daemon is running under the IKED user ID:

       ```
       500   UDP        IKED
       4500  UDP        IKED
       ```

       If the IKE daemon is not running on this system, reserve the ports by specifying RESERVED:

       ```
       500   UDP        RESERVED
       4500  UDP        RESERVED
       ```

     – To direct IPSec's AH and ESP protocol processing to zIIPs, add GLOBALCONFIG ZIIP IPSECURITY.

For information on the IPCONFIG, IPCONFIG6, GLOBALCONFIG, and PORT statements, see *z/OS Communications Server: IP Configuration Reference*.

- Policy Agent

  For information on configuring the Policy Agent, see Chapter 16, "Policy-based networking," on page 829.

- TRMD

  For information on configuring TRMD, see "TRMD" on page 919.

- Syslogd

  For information on configuring the syslog daemon, see "Configuring the syslog daemon" on page 185.

- IKED

  The IKED can be started from a z/OS UNIX command line or as an MVS procedure. The iked.conf file controls the overall function of the IKE daemon, such as the following settings:

  – The logging level of the IKE daemon
  – The logging level of the Policy Agent when performing IP security-related tasks on behalf of the IKE daemon
  – The name of the RACF key ring that is owned by the IKE daemon
  – Whether IKE messages are echoed to STDOUT when the daemon is started for the UNIX System services shell
  – How long to wait when attempting to connect to the Policy Agent
  – The list of certificate authorities that are acceptable for RSA signature negotiation when the IKED is using the native certificate service (when the Network Security Services (NSS) server is providing the certificate service, this list is not used)

  Most of the configuration parameters have a default value and do not require modification.

  Rule: If the RSA signature method is to be used in any IKE phase 1 negotiation and the IKED is using the native certificate service, the name of the IKE key ring must be included in the iked.conf file. If the NSS server is providing the certificate service, the IKE key ring name is not needed.

  Tip: If the RSA signature method is used and the IKED is using the native certificate service, including a list of supported certificate authorities enhances the performance of certificate searches.

  Guideline: The logging levels of the IKE daemon (IkeSyslogLevel) and Policy Agent (PagentSyslogLevel) should not be changed from their default values for normal day-to-day operation. Higher logging levels can affect performance and should be used for temporary diagnostic purposes only. The default PagentSyslogLevel of 0 prevents the IKE daemon from logging diagnostic information about its interactions with Policy Agent. The default IkeSyslogLevel of 1 provides basic informational and error messages. The IkeSyslogLevel can be set to 0 to disable IKE syslog messages entirely (for both IkeSyslogLevel and PagentSyslogLevel; to collect PagentSyslogLevel tracing, IkeSyslogLevel must also be set to a nonzero value). The IkeSyslogLevel can be set higher to identify the source of an error; for example, if you experience problems with Security Association negotiations due to a configuration error, you might enable IkeSyslogLevel 4 (debugging information for Security Association negotiations).

  For detailed syntax and a description of the iked.conf file, and details on starting the IKE daemon as an MVS procedure, see *z/OS Communications Server: IP Configuration Reference*.

5. Define access controls for key required applications:
   - TRMD

     TRMD runs as an authorized program and requires RACF setup. TRMD must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST.
   - Policy Agent

     Policy Agent runs as an authorized program and requires RACF setup. Policy Agent must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST and "Step 1: Configure general information" on page 849.
   - IKED

     For the steps to prepare for running the IKE daemon, see Appendix E, "Steps for preparing to run IP security," on page 1505.
6. Configure the IKE daemon.

   See Appendix E, "Steps for preparing to run IP security," on page 1505.
7. (Optional) Configure the NSS daemon.

   If the IKED is using the NSS certificate service for any IKEv1 or IKEv2 Security Association negotiation, then configure the NSS daemon. The IKED must use the NSS certificate service for any IKEv2 negotiation that uses certificates for authentication. The IKED can use either the native certificate service or the NSS certificate service for an IKEv1 negotiation that uses certificates for authentication.

   For more information about the NSS daemon, see Chapter 20, "Network security services," on page 1149.
8. (Optional) Configure additional encryption products.
   - 3DES support

     For 3DES (triple DES), the IP security level 3 feature, FMID JIP614K, is required.
   - AES support (including AES-CBC, AES-GCM and AES-GMAC)

     For AES, the Communications Server Security Level 3 feature and the z/OS Security Level 3 feature are required and ICSF must be started.
   - FIPS 140

     In order for the IKED, the NSSD, and TCP/IP to run in FIPS 140 mode, you must start ICSF and configure the FIPSMODE(COMPAT) setting.
   - ICSF

     There are several options available on z/OS to perform encryption in hardware. The ICSF product is required to support these various options. For a description and information about how to configure these options, see *z/OS Cryptographic Services ICSF Administrator's Guide*.

     For the RACF commands that authorize ICSF, see Appendix E, "Steps for preparing to run IP security," on page 1505.
   - SHA2 support (including SHA2-256, SHA2-384, and SHA2-512, as well as all corresponding HMAC-SHA2 algorithms) and AES authentication (AES-XCBC)

     For SHA2 and AES-XCBC authentication, ICSF must be started.
9. Create IP security policy configuration files.

After the security needs of your installation are established, the next step is to create one or more IP security policy configuration files. There are two main configuration files in which IP security policy configuration is stored:

Stack-specific IP security configuration file
Configured on a per-stack basis and contains only IP security policy configuration that applies to the stacks for which it is configured.

Common IP security configuration file
Contains IP security policy configuration that applies to every stack on the system and can be used to hold shared definitions.

The stack-specific file can refer to various definitions in the common file, and can override policy definitions in the common file.

Although Policy Agent uses LDAP to store policy for some other policy types, IP security policy configuration is stored exclusively in human-readable text files, either in the z/OS UNIX file system or in an MVS data set. These configuration files are then read by Policy Agent when it initializes and before being installed into the stack.

IP security policy configuration

This topic describes the general steps for creating IP security policy configuration files for the most common configurations. Configuring a complete and specific IP security policy that meets the needs of any installation is beyond the scope of this text, but guidance for more advanced configurations is provided.

"Overview of configuring IP security policy" describes the common IP security configuration file, the stack-specific IP security configuration file, and the general content, structure, and use of these files.

"Component policies of IP security policy configuration files" on page 997 describes the types of policies contained in IP security policy configuration files.

"Steps for configuring IP security policy" on page 1026 describes the steps for manually creating IP security policy configuration files.

"Quick start using IP filtering and IPSec host-to-host" on page 1008 describes a complete IP security policy allowing connections from a secure server to an administrative machine on an internal network, and represents the minimum configuration needed to provide IPSec protection with dynamic key management between two hosts. This topic also describes the use of the **ipsec** command to display filters and Security Associations.

"Configuring specific security models" on page 1028 provides more examples and describes the configuration needed for common security models.

Overview of configuring IP security policy

There are three options for IP security policy configuration for a system:

- Use a common IP security configuration file that applies to all stacks on the system, enforcing a consistent policy. In this instance, a stack-specific IP security configuration file is not necessary.
- Use a unique and separate stack-specific IP security configuration file for each stack on the system. In this instance, a common IP security configuration file is not necessary.
- Use both a common and a stack-specific IP security configuration file.

– The common IP security configuration file can be used as a common repository for frequently used definitions, which can be referenced by any stack-specific IP security configuration file.
– The stack-specific IP security configuration file can contain unique statements that apply only to the stack for which it is configured, and can reference statements that are defined in the common IP security configuration file.

Although not an error, note that when using the last approach, it is possible for duplicate statements to exist in the common and the stack-specific IP security configuration files (for example, two IpFilterRule statements with the same name). In this case, the statement in the stack-specific IP security configuration file is honored. Statements in the stack-specific IP security configuration file always take precedence over the common IP security configuration file.

Structure of an IP security configuration file

The common IP security configuration file and the stack-specific IP security configuration file have exactly the same structure. They are comprised of a number of statements that define items that are used to define policy, such as policies, rules, actions, groups, and objects. Statement names and attribute names are not case sensitive, though they appear in mixed case in this information for readability. Only user-defined names are case sensitive. For the complete syntax of all IP security policy statements, see *z/OS Communications Server: IP Configuration Reference*.

An IP security policy configuration statement has the following generic form:

```
StatementType     user-defined name
{
   Attribute1     value1
   Attribute2     value2
   .
   .
   .
}
```

Statements often contain other inline statements in a recursive form:

```
StatementType1     user-defined name
{
   Attribute1      value1
   StatementType2  optional user-defined name
   {
      Attribute1   value1
      Attribute2   value2
   }
   Attribute2      value2
}
```

There are three main sections in an IP security configuration file, identified by the following three statements:

- IpFilterPolicy
- KeyExchangePolicy
- LocalDynVpnPolicy

Additional statements that define rules, actions, groups, and objects are found both in the main body of the configuration file and within any of these other three policy blocks. A high-level view of an IP security configuration file follows. Although the statement blocks are shown in a specific order, the ordering is arbitrary.

```
IpFilterPolicy #(required)
{
  <local statements>
}

KeyExchangePolicy #(optional)
{
  <local statements>
}

LocalDynVpnPolicy #(optional)
{
  <local statements>
}

  <global statements>
```

Groups: Groups provide a method to combine related objects in a meaningful way into sets. The following IP security policy configuration statements can be used as groups:

- IpAddrGroup
- IpFilterGroup
- IpServiceGroup
- KeyExchangeGroup
- LocalDynVpnGroup

Reference statements: A reference statement can be recognized by the suffix Ref. References provide a convenient way to reuse definitions, eliminating the need to repeatedly specify things such as host addresses and common services. Nearly all statements in the IP security configuration file can be referenced, and all action statements must be referenced. To be referenced, an IP security policy configuration statement must be given a user-defined name. Names of statements can be up to 32 characters. The following IP security policy configuration statements can be referenced, and therefore reused:

- IpAddr
- IpAddrSet
- IpDataOffer
- IpDynVpnAction
- IpFilterGroup
- IpFilterRule
- IpGenericFilterAction
- IpLocalStartAction
- IpManVpnAction
- IpService
- IpServiceGroup
- IpTimeCondition
- KeyExchangeAction
- KeyExchangeGroup
- KeyExchangeOffer
- KeyExchangeRule
- LocalDynVpnGroup
- LocalDynVpnRule
- LocalSecurityEndpoint

- RemoteIdentity
- RemoteSecurityEndpoint

Steps for configuring local IP security policy using only a common IP security configuration file

Perform the following steps to configure local IP security policy using only a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

   ```
   CommonIpSecConfig      /etc/common.ipsecpol
   ```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each IP security stack to be configured:

   ```
   TcpImage TCPCS  /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ⋮
   ```

3. In each configuration file that was identified on the TcpImage statement shown in step 2, include a line that contains IpSecConfig with no file name, as follows:

   ```
   In /etc/TCPCS.image:
   IpSecConfig

   In /etc/TCPCS2.image:
   IpSecConfig
   ```

All stacks on the z/OS system will adhere to the policy that is specified in the /etc/common.ipsecpol file.

Steps for configuring remote IP security policy using only a common IP security configuration file

Perform the following steps to configure remote IP security policy using only a common IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

   ```
   ServerConnection
   {
       ...
   }
   TcpImage TCPCS  /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ⋮
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

   For example, in /etc/TCPCS.image:

   ```
   PolicyServer
   {
      ClientName  IPSecClientTCPCS
      PolicyType IPSec
      {
         ...
      }
      ...
   }
   ```

In /etc/TCPCS2.image:

```
PolicyServer
{
   ClientName  IPSecClientTCPCS2
   PolicyType IPSec
   {
      ...
   }
   ...
}
```

3. In the main configuration file on the policy server, include a DynamicConfigPolicyLoad statement, as follows:

```
DynamicConfigPolicyLoad  IPSecClient.*
{
   PolicyType IPSec
   {
      CommonPolicyLoad /etc/common.ipsecpol
   }
   ...
}
```

All stacks on the z/OS policy client system will adhere to the policy that is specified in the /etc/common.ipsecpol file on the policy server.

Steps for configuring local IP security policy using only a stack-specific IP security configuration file

Perform the following steps to configure local IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

```
TcpImage TCPCS  /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
⋮
```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include an IPSecConfig line that identifies the stack-specific IP security configuration file, as follows:

```
In /etc/TCPCS.image:
IpSecConfig     /etc/TCPCS.ipsecpol

In /etc/TCPCS2.image:
IpSecConfig     /etc/TCPCS2.ipsecpol
```

Each stack on the z/OS system will adhere to the policy that is specified by its unique policy file. Stack TCPCS uses the policy that is configured in /etc/TCPCS.ipsecpol, and stack TCPCS2 uses the policy that is configured in /etc/TCPCS2.ipsecpol.

Steps for configuring remote IP security policy using only a stack-specific IP security configuration file

Perform the following steps to configure remote IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

```
ServerConnection
{
   ...
}
TcpImage TCPCS  /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
⋮
```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

   For example, in /etc/TCPCS.image:

```
PolicyServer
{
   ClientName  IPSecClientTCPCS
   PolicyType IPSec
   {
      ...
   }
   ...
}
```

   In /etc/TCPCS2.image:

```
PolicyServer
{
   ClientName  IPSecClientTCPCS2
   PolicyType IPSec
   {
      ...
   }
   ...
}
```

3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```
DynamicConfigPolicyLoad  IPSecClientTCPCS
{
   PolicyType IPSec
   {
      PolicyLoad /etc/TCPCS.ipsecpol
   }
   ...
}
DynamicConfigPolicyLoad  IPSecClientTCPCS2
{
   PolicyType IPSec
   {
      PolicyLoad /etc/TCPCS2.ipsecpol
   }
   ...
}
```

Each stack on the z/OS policy client system will adhere to the policy that is specified by its unique policy file. Stack TCPCS uses the policy that is configured in /etc/TCPCS.ipsecpol on the policy server, and stack TCPCS2 uses the policy that is configured in /etc/TCPCS2.ipsecpol on the policy server.

Steps for configuring local IP security policy using both a stack-specific file and a common file

Perform the following steps to configure local IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

   ```
   CommonIpSecConfig    /etc/common.ipsecpol
   ```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

   ```
   TcpImage TCPCS  /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ⋮
   ```

3. In each configuration file that was identified on the TcpImage statement in step 2, include an IPSecConfig line that identifies the stack-specific IP security configuration file, as follows:

   ```
   In /etc/TCPCS.image:
   IpSecConfig     /etc/TCPCS.ipsecpol

   In /etc/TCPCS2.image:
   IpSecConfig     /etc/TCPCS2.ipsecpol
   ```

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPCS.ipsecpol or /etc/TCPCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

Steps for configuring remote IP security policy using both a stack-specific file and a common file

Perform the following steps to configure remote IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

   ```
   ServerConnection
   {
      ...
   }
   TcpImage TCPCS  /etc/TCPCS.image
   TcpImage TCPCS2 /etc/TCPCS2.image
   ⋮
   ```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

   For example, in /etc/TCPCS.image:

   ```
   PolicyServer
   {
      ClientName  IPSecClientTCPCS
      PolicyType IPSec
      {
         ...
      }
      ...
   }
   ```

   In /etc/TCPCS2.image:

```
PolicyServer
{
   ClientName  IPSecClientTCPCS2
   PolicyType IPSec
   {
      ...
   }
   ...
}
```

3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```
DynamicConfigPolicyLoad  IPSecClientTCPCS
{
   PolicyType IPSec
   {
      CommonPolicyLoad /etc/common.ipsecpol
      PolicyLoad /etc/TCPCS.ipsecpol
   }
   ...
}
DynamicConfigPolicyLoad  IPSecClientTCPCS2
{
   PolicyType IPSec
   {
      CommonPolicyLoad /etc/common.ipsecpol
      PolicyLoad /etc/TCPCS2.ipsecpol
   }
   ...
}
```

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPCS.ipsecpol or /etc/TCPCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

Component policies of IP security policy configuration files

There are three types of policies in IP security policy configuration files:

- IP filter policy (IpFilterPolicy statement)
- Key exchange policy (KeyExchangePolicy statement)
- Local dynamic VPN policy (LocalDynVpnPolicy statement)

IP filter policy

An IP filter policy can stand alone to provide IP filtering and IPSec protection with manual key management. Used in conjunction with the two other policies, it is also required to provide IPSec protection with dynamic key management (IKE). Because filtering is crucial to secure traffic on a host, an IP security policy that contains no IpFilterPolicy statement block or an empty IpFilterPolicy statement block is considered an error, leaving the default policy that is provided by the stack in effect.

The IpFilterPolicy statement block consists of:

- A set of global configuration options
- An ordered list of IP filter rules (IpFilterRule statements)

The purpose of the global configuration options is to control global policy items, such as whether logging is active or whether on-demand Security Association

negotiations are allowed, and so forth. These global options apply to all of the IP filter rules that are contained in the policy. Each IP filter rule, in turn, contains data endpoints, traffic descriptions, and actions. When a packet entering or leaving the system matches the data endpoints and traffic description in an IP filter rule, the associated action is taken. If the action is an ipsec action, additional action statements are coded that define the parameters of the IPSec Security Association.

Following is a sample IpFilterRule statement that allows Web traffic on an internal server, and a description of each line in the sample:

```
1  IpFilterRule             InternalNetWeb
2       {
3          IpSourceAddr          9.1.1.1
4          IpDestAddrSet         9.1.1.0/24
5          IpService
6          {
7             SourcePortRange        80
8             DestinationPortRange   1024 65535
9             Protocol               tcp
10            Direction              bidirectional InboundConnect
11            Routing                local
12            SecurityClass          0
13         }
14         IpGenericFilterActionRef  permit-nolog
15      }
```

Line **Description**

1 The IpFilterRule keyword, followed by a required user-defined name for this rule.

2 An open brace ({) marks the start of an IpFilterRule statement block.

3 The source address of the rule. Outbound IP packets that match this rule must have 9.1.1.1 as the source address in the IP header.

4 The destination address of the rule. Outbound IP packets that match this rule must have an address in the range of 9.1.1.0 - 9.1.1.255 as the destination address in the IP header.

5 The IpService statement block describes the type of traffic that is allowed between the two data endpoints. The IpService block in this rule is inline to the rule, meaning that the entire definition of the IP service is included within the rule. Many policy statements, including the IpService statement, can be referenced rather than included inline.

6 An open brace ({) marks the start of the IpService statement block.

7 The range of source ports that is allowed for outbound packets. The value can be a single number, or a range of ports.

8 The range of destination ports that is allowed for outbound packets. The value can be a single number, or a range of ports.

9 The specific protocol that is allowed by this rule.

10 The direction specification for the IP packet.

Bidirectional indicates that this rule allows outbound traffic from local address 9.1.1.1 on local port 80 to any address in subnet 9.1.1.0/24 using any ephemeral port (that is, 1024-65535), and inbound traffic from any address in subnet 9.1.1.0/24 using any ephemeral port to local address 9.1.1.1 on local port 80. Without the use of the bidirectional keyword, it would be necessary to create two filter rules, one for outbound traffic and one for inbound traffic.

InboundConnect indicates that the rule will match inbound TCP connection attempts as well as bidirectional data on an established connection, but it will not match outbound TCP connection attempts.

11 The routing information for a packet matching this rule. For a packet to match this rule, the traffic must be local. In other words, this rule does not allow any packets that must be forwarded to another network node. Possible values are local, routed, or either.

12 The security class of the interface on which the packet must arrive or leave. The security class of an interface is defined using the SECCLASS parameter on the statement that is used to define the interface in the TCP/IP profile (that is, the LINK, INTERFACE, IPCONFIG DYNAMICXCF, or IPCONFIG6 DYNAMICXCF statement). Each interface on the system can be assigned a SECCLASS in the range 1 – 255. If the SECCLASS parameter is not coded in the TCP/IP profile for an interface, by default the interface is SECCLASS 255. In the SecurityClass parameter in this example, the value 0 indicates that a packet that matches this rule is not restricted and can traverse any interface (1 – 255).

13 A close brace (}) marks the end of the IpService block.

14 The action that is taken on a packet that matches this rule. In this case, permit the packet and log all occurrences of a match. All IP filter rules must include an IpGenericFilterActionRef statement. The IpGenericFilterAction statement itself should be defined elsewhere, outside of the IpFilterRule block, either in the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction     permit-nolog
{
  IpFilterAction          permit
  IpFilterLogging         no
}
```

15 A close brace (}) marks the end of the IpFilterRule statement block.

Rule: Do not include policy action statements inline. They must be referenced.

Example 1: Permit rule allowing outbound FTP client connections from the local host (9.1.1.1) to a remote FTP server (9.1.1.2):

```
IpFilterRule              FTP-client
{
      IpSourceAddr           9.1.1.1
      IpDestAddr             9.1.1.2
      IpService
      {
        SourcePortRange      1024 65535
        DestinationPortRange 21
        Protocol             tcp
        Direction            bidirectional OutboundConnect
        Routing              local
        SecurityClass        0
      }
      IpService
      {
        SourcePortRange      1024 65535
        DestinationPortRange 20
        Protocol             tcp
        Direction            bidirectional InboundConnect
        Routing              local
```

```
        SecurityClass        0
      }
      IpGenericFilterActionRef  permit
}
```

Normal (non-passive mode) FTP requires that the FTP client be allowed to initiate outbound connections to port 21, and be able to receive inbound connections from port 20. The `IpGenericFilterAction permit` block must be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction     permit
{
  IpFilterAction          permit
}
```

Example 2: Deny rule that blocks all traffic from all private address spaces that is inbound to a public interface:

```
IpFilterRule              deny-private
{
      IpSourceAddrGroupRef   PrivateAddrs
      IpDestAddr             all
      IpService
      {
        SourcePortRange      0
        DestinationPortRange 0
        Protocol             all
        Direction            inbound
        Routing              either
        SecurityClass        0
      }
      IpGenericFilterActionRef  deny-log
}
```

The IpSourceAddrGroupRef parameter references an IP address group that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpAddrGroup PrivateAddrs
{
   IpAddrSet
   {
     Prefix 10.0.0.0/8
   }
   IpAddrSet
   {
     Prefix 172.16.0.0/12
   }
   IpAddrSet
   {
     Range 192.168.0.0-192.168.255.255
   }
}
```

The IpGenericFilterActionRef parameter references an IpGenericFilterAction statement that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction     deny-log
{
  IpFilterAction          deny
  IpFilterLogging         yes
}
```

Example 3: An ipsec rule that requires IPSec protection for all traffic between the secure server and an administrative machine on the internal network:

```
IpFilterRule                Rule2Admin
{
     IpSourceAddrRef            InternalServerAddressA1
     IpDestAddrRef              AdminClient
     IpServiceRef               All-traffic-local
     IpGenericFilterActionRef   ipsec
     IpDynVpnActionRef          Silver-TransportMode
}
```

The use of multiple references in this example makes the IP filter rule easier to read. For each referenced object or action, there should be a corresponding definition elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpAddr                 InternalServerAddressA1
{
  Addr                 9.1.1.1
}

IpAddr                 AdminClient
{
  Addr                 9.1.1.2
}

IpService              All-traffic-local
{
  Protocol             all
  Direction            bidirectional
  Routing              local
  SecurityClass        0
}

IpGenericFilterAction  ipsec
{
  IpFilterAction       ipsec
  IpFilterLogging      yes LogDeny
}

IpDynVpnAction         Silver-TransportMode
{
  Initiation           either
  InitiateWithPfs      None
  AcceptablePfs        None
  IpDataOfferRef       SHA-DES-Transport
}

IpDataOffer            SHA-DES-Transport
{
  HowToEncap           transport
  HowToEncrypt         DES
  HowToAuth            ESP HMAC_SHA1
}
```

IP filter rule order: "Example 1" on page 999, "Example 2" on page 1000, and "Example 3" on page 1000 show individual IP filter rules. A complete IP filter policy contains any number of IP filter rules, configured in much the same manner. It is important to remember that IP filter rules in an IP filter policy are searched in the order listed. Because it is possible for a packet to match more than one rule, a search for a matching filter rule stops after the first match is found, even if there are additional matches further down in the list. Use the **ipsec** command traffic test option (**ipsec -t**) as an aid in determining which IP filter rule an IP packet matches.

The command-line arguments to the **ipsec -t** command are a set of characteristics that describe a particular IP packet. The existing set of filter rules are searched for

potential matches. Unlike normal filter processing, which stops the search after a match is found, the **ipsec -t** command displays all matching filter rules. Input to the **ipsec -t** command does not have to specify all possible filtering criteria from an IP packet. The output of the **ipsec -t** command must be inspected to determine which of the returned rules match for a given case.

For instance, an IP filter rule for ICMP can be configured for a specific type and code value, while the traffic test does not provide ICMP type and code as inputs. If more than one IP filter rule matches on the ICMP protocol, they are all displayed. You must determine, from among those listed, which rule applies for a specific IP packet.

For a complete description of the **ipsec** command, including the **ipsec -t** option, see *z/OS Communications Server: IP System Administrator's Commands*.

Key exchange policy

A key exchange policy is required by IKE to provide dynamic key management. The policy contains the definitions about how the negotiation of keys is to be performed (using IKEv1 or IKEv2), how the negotiations are to be protected, and which hosts are allowed to negotiate keys. The absence of a key exchange policy is not considered an error, but without it, the IKE daemon is unable to provide dynamic key management.

A key exchange policy consists of an ordered list of key exchange rules. A key exchange rule consists of a set of security endpoints, and an action to be taken when the two security endpoints engage in an IKE phase 1 negotiation.

Optionally, a key exchange rule can contain a shared key known only to the two negotiating entities that are described in the rule. When an IKE negotiation is initiated, the current list of key exchange rules is searched for a match, based on four criteria:

- The identity of the local IKE peer, if known
- The identity of the remote IKE peer, if known
- The location (IP address) of the local IKE peer, if needed to distinguish it or if local identity is not known
- The location (IP address) of the remote IKE peer, if needed to distinguish it or if remote identity is not known

Following is a sample KeyExchangeRule block that allows an IKE negotiation between IKE daemons at 9.2.2.2 and 9.4.4.4. A description of each line in the sample follows the sample.

```
1   KeyExchangeRule             ZoneB_KeyExRule1
2   {
3      LocalSecurityEndpoint
4      {
5         Identity              IpAddr 9.2.2.2
6         Location              9.2.2.2
7      }
8      RemoteSecurityEndpoint
9      {
10        Identity              X500dn CN=ZoneB Cert,T=IKE ServerB,OU=endicott,O=ibm,C=US
11        Location              9.4.0.0/16
12        CaLabel               CA4endicott
13     }
14     KeyExchangeActionRef     Gold-RSA
15     SharedKey                Ascii TheEagleHasLanded
16 }
```

Line Description

1 The KeyExchangeRule keyword, followed by a required user-defined name.

2 An open brace ({) marks the beginning of the KeyExchangeRule statement block.

3 The LocalSecurityEndpoint statement identifies a local security endpoint, or local IKE peer.

4 An open brace ({) marks the beginning of the LocalSecurityEndpoint statement block.

5 The identity of the local security endpoint that must match this rule. This can be one of five types:

- Fqdn
- IpAddr
- KeyID
- UserAtFqdn
- X500dn

In the example, an IP address is used as the identity value.

6 The IP address of the local IKE peer.

7 A close brace (}) marks the end of the LocalSecurityEndpoint statement block.

8 The RemoteSecurityEndpoint statement identifies a remote security endpoint, or remote IKE peer. The RemoteSecurityEndpoint statement can also be used to define a related group of remote IKE peers by using wildcard values for identity and location.

9 An open brace ({) marks the beginning of the RemoteSecurityEndpoint statement block.

10 The identity of the remote security endpoint that must match this rule. This can be one of five types:

- Fqdn
- IpAddr
- KeyID
- UserAtFqdn
- X500dn

In the example, an X.500 distinguished name is used as the identity value.

11 The IP subnetwork that defines a group of remote IKE peers.

12 Used only for digital signature peer authentication. Specifies the certificate authority that is advertised to the remote security endpoint as an acceptable authority. The value for this parameter must be the label of a certificate authority that is defined in RACF. The CaLabel parameter can be specified multiple times.

13 A close brace (}) marks the end of the RemoteSecurityEndpoint statement.

14 A reference to a key exchange action that has been defined elsewhere, in either the common or the stack-specific IP security configuration file, as follows:

```
KeyExchangeAction            Gold-RSA
{
   HowToInitiate              main
```

```
   HowToRespondIKEv1          main
   KeyExchangeOffer
   {
      HowToEncrypt               3DES
      HowToAuthMsgs              SHA1
      HowToAuthPeers             RsaSignature
   }
}
```

The KeyExchangeAction statement specifies the detailed parameters that govern a phase 1 negotiation between these two security endpoints, such as who can begin the negotiation and what type of encryption is used.

15 An optional shared key used only for pre-shared key host authentication.

16 A close brace (}) marks the end of the KeyExchangeRule statement block.

Example 1: Following is a key exchange rule for an IKEv1 Aggressive-mode phase 1 negotiation using pre-shared key authentication:

```
KeyExchangeRule              Admin_KeyExRule1
{
  LocalSecurityEndpointRef   Internal_IKED
  RemoteSecurityEndpointRef  Admin_IKED
  KeyExchangeActionRef       Bronze-PSK
  SharedKey                  Ascii TheEagleHasLanded
}
```

This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and Admin_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the Bronze-PSK action as follows:

```
KeyExchangeAction        Bronze-PSK
{
   HowToInitiate         Aggressive
   HowToRespondIKEv1     Aggressive
   KeyExchangeOffer
   {
      HowToEncrypt       DES
      HowToAuthMsgs      SHA1
      HowToAuthPeers     PreSharedKey
   }
}
```

The optional SharedKey parameter is required only when the pre-shared key authentication method is used for the phase 1 negotiation.

Example 2: Following is a KeyExchangeRule statement for an IKEv1 Main-mode phase 1 negotiation using digital signature authentication:

```
KeyExchangeRule              ZoneA_KeyExRule1
{
  LocalSecurityEndpointRef   Internal_IKED
  RemoteSecurityEndpointRef  ZoneA_IKED
  KeyExchangeActionRef       Silver-RSA
}
```

The referenced objects are presumed to be defined elsewhere in the policy file. This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED. The specifics of the negotiation are covered by the Silver-RSA action as follows:

```
KeyExchangeAction      Silver-RSA
{
   HowToInitiate       main
```

```
   HowToRespondIKEv1   main
   KeyExchangeOffer
   {
      HowToEncrypt     DES
      HowToAuthMsgs    SHA1
      HowToAuthPeers   RsaSignature
   }
}
```

Example 3: Following is a key exchange rule for an IKEv2 phase 1 negotiation using digital signature authentication:

```
KeyExchangeRule             IKEv2_Example
{
  LocalSecurityEndpointRef  Internal_IKED
  RemoteSecurityEndpointRef ZoneA_IKED
  KeyExchangeActionRef      IKEv2-DigitalSignature
}
```

This rule defines the parameters for the IKEv2 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the IKEv2-DigitalSignature action as follows:

```
KeyExchangeAction            IKEv2-DigitalSignature
{
   HowToInitiate             IKEv2
   HowToAuthMe               DigitalSignature
   ReauthInterval            0
   BypassIpValidation        Yes
   KeyExchangeOffer
   {
      HowToEncrypt           AES_CBC KeyLength 128
      HowToVerifyMsgs        HMAC_SHA1_96
      PseudoRandomFunction   HMAC_SHA1
      HowToAuthPeers         RsaSignature
   }
}
```

Key exchange rule order: "Example 1" on page 1004 and "Example 2" on page 1004 show individual key exchange rules. A complete key exchange policy contains any number of key exchange rules. Key exchange rules in a key exchange policy are searched in the order listed. In the process of an IKE negotiation, Policy Agent searches the list of active key exchange rules to locate a best match. It is possible for more than one key exchange rule to match a pending IKE negotiation. For this reason, the list of key exchange rules in the key exchange policy should be ordered from most specific to least specific in much the same way as the IP filter rules. If the key exchange policy contains key exchange rules with both unique and wildcard security endpoints, the most specific definitions should be placed higher in the list than the wildcard definitions.

For instance, there might be one key exchange rule governing a connection from an internal administrative machine, and another key exchange rule governing all other hosts on the internal network, as follows:

```
KeyExchangeRule             Admin_KeyExRule1
{
  LocalSecurityEndpointRef  Internal_IKED
  RemoteSecurityEndpointRef Admin_IKED
  KeyExchangeActionRef      Bronze-PSK
  SharedKey                 Ascii TheEagleHasLanded
}

KeyExchangeRule             ZoneA_KeyExRule1
```

```
{
  LocalSecurityEndpointRef   Internal_IKED
  RemoteSecurityEndpointRef  ZoneA_IKED
  KeyExchangeActionRef       Silver-RSA
}
```

In this case, because the remote IKE peer that is defined by the remote security endpoint Admin_IKED matches both the Admin_KeyExRule1 and ZoneA_KeyExRule1 rules, the Admin_KeyExRule1 rule should be placed ahead of the ZoneA_KeyExRule1 rule in the key exchange policy as follows:

```
KeyExchangePolicy
{
  KeyExchangeRuleRef         Admin_KeyExRule1
  KeyExchangeRuleRef         ZoneA_KeyExRule1
  KeyExchangeRuleRef         ZoneB_KeyExRule1
  KeyExchangeRuleRef         ZoneC_KeyExRule1
}
```

Local dynamic VPN policy

A local dynamic VPN policy is required only if the IPSec negotiation is started through command-line activation using the **ipsec** command, or through automatic activation due to a local dynamic VPN policy update. IPSec negotiations can be initiated in one of four ways:

- On-demand

  The negotiation initiates when an outbound IP packet matches a filter rule with an ipsec action.
- Remotely

  The remote peer initiates the request, and the local IKE daemon responds.
- Command-line activation

  The **ipsec** command enables you to manually initiate an IPSec negotiation. (Not to be confused with manual tunnels, which do not use the IKE daemon at all.)
- Autoactivation

  The negotiation begins when either the stack or the IKE daemon initializes and both are active, or when the local dynamic VPN policy is updated.

A local dynamic VPN policy is required only in the last two cases.

A local dynamic VPN policy consists of an unordered list of local dynamic VPN rules. The negotiation for a phase 2 Security Association requires that the two communicating hosts agree on two data endpoints that the Security Association covers, the protocols the Security Association covers, and the ports that the Security Association covers. This information is then stored in the phase 2 Security Association, which is consulted each time relevant IPSec traffic needs to be encapsulated or decapsulated. The purpose of the local dynamic VPN rule is to define these requirements for each Security Association that is configured.

Following is a sample LocalDynVpnRule statement that defines the parameters for the negotiation of a phase 2 Security Association for TN3270E Telnet server traffic between a server (9.1.1.1) and a client (9.4.4.100). A description of each line follows the sample.

```
1  LocalDynVpnRule      TelnetSA
2  {
3           LocalIP           9.1.1.1
4           RemoteIP          9.4.4.100
5           LocalDataPort     23
```

```
6          RemoteDataPort    0
7          Protocol          tcp
8          Autoactivate      yes
9  }
```

Line	Description
1	The LocalDynVpnRule keyword and user-defined name.
2	An open brace ({) marks the start of the LocalDynVpnRule statement block.
3	The local address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.
4	The remote address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.
5	The local ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.
6	The remote ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.
7	The protocol that this Security Association is to protect. This value can be numeric. It must define a single protocol or all protocols.
8	Indicates that this Security Association is to be activated when the stack and IKE daemon are active. No user intervention is required.
9	A close brace (}) marks the end of the LocalDynVpnRule statement block.

An on-demand Security Association does not require a local dynamic VPN rule definition. All of the parameters for the negotiation of an on-demand phase 2 Security Association can be inferred from one of two places, either the packet that began the on-demand activation or the filter rule on which the packet matched. The packet always provides a single value for address, protocol, port, type, and code. The filter rule, however, can allow for a range of values for IP address, protocol, port, type, or code. The granularity setting of the IpLocalStartAction statement determines whether the information is taken from the packet or from the matching filter rule. For more information regarding the IpLocalStartAction statement, see *z/OS Communications Server: IP Configuration Reference*.

Security Associations can be defined as wide or narrow with respect to IP addresses or ports and protocols. If a Security Association is wide with respect to IP address, the same Security Association is used to protect data between multiple endpoints. If a Security Association is wide with respect to ports and protocols, the same Security Association is used to protect multiple traffic types. Conversely, a narrowly defined Security Association can be used to protect specific data endpoints (based on IP address) or specific traffic types (based on commonly used ports and protocols for network services). Security associations negotiated with IKEv2 can also be narrow with respect to types and codes.

Example 1 - wide Security Association: The following rule allows any type of traffic to flow between PublicServerAddressA1 and SubnetC using the same Security Association. PublicServerAddressA1 and SubnetC can be defined in either

the common or the stack-specific IP security configuration file. The AutoActivate parameter causes the IKE negotiation to initiate when the stack or IKE initializes.

```
LocalDynVpnRule       ZoneC_VPN-All-traffic
{
     LocalIpRef          PublicServerAddressA1
     RemoteIpSetRef      SubnetC
     Protocol            all
     AutoActivate        yes
}

IpAddr                PublicServerAddressA1
{
  Addr                9.3.3.3
}

IpAddrSet             SubnetC
{
  Prefix              9.6.0.0/16
}
```

Example 2 - narrow Security Association: If narrow Security Associations are used for IPSec-protected FTP traffic, two VPN definitions are required, one for the data connection and one for the control connection. The following rules are from the server's perspective. The FTP client connecting from BranchOfficeAddressC1 to the PublicServerAddressA1 ports 20 and 21 uses the respective ZoneC FTP VPNs.

```
LocalDynVpnRule             ZoneC_VPN-FTP-Data
{
     LocalIpRef                PublicServerAddressA1
     RemoteIpRef               BranchOfficeAddressC1
     LocalDataPort             20
     RemoteDataPort            0
     Protocol                  tcp
}

LocalDynVpnRule             ZoneC_VPN-FTP-Control
{
     LocalIpRef                PublicServerAddressA1
     RemoteIpRef               BranchOfficeAddressC1
     LocalDataPort             21
     RemoteDataPort            0
     Protocol                  tcp
}

IpAddr                      PublicServerAddressA1
{
  Addr                      9.3.3.3
}

IpAddr                      BranchOfficeAddressC1
{
  Addr                      9.5.5.5
}
```

Quick start using IP filtering and IPSec host-to-host

The following sample shows a complete IP security policy allowing connections from a secure server (9.1.1.1) to an administrative machine (9.1.1.2) on an internal network. It represents the absolute minimum number of items that need to be configured for the IKED to provide IPSec protection with dynamic key management between two hosts.

Tip: You can modify the quick start sample for IPv6 by replacing all IPv4 addresses with IPv6 addresses.

This IP security policy allows IKE negotiations in the clear (UDP, port 500 traffic), while authenticating and encrypting all other traffic using the ESP IPSec protocol. The policy relies almost exclusively on the z/OS IP security policy defaults, including MD5 and DES for the phase 1 Security Association and ESP/MD5 ESP/DES for the phase 2 Security Association. For a complete description of IP security policy configuration statements and their defaults, see *z/OS Communications Server: IP Configuration Reference*.

```
#------------------------------------------------------
# Quick-Start IP Security policy
#------------------------------------------------------
IpFilterPolicy
{
  PreDecap                    off
  FilterLogging               on
  AllowOnDemand               yes

  IpFilterRule                QuickStartRule1
  {
    IpSourceAddr              9.1.1.1
    IpDestAddr                9.1.1.2
    IpService
    {
      SourcePortRange         500
      DestinationPortRange    500
      Protocol                udp
      Direction               bidirectional
      Routing                 local
    }
    IpGenericFilterActionRef  permit
  }

  IpFilterRule                QuickStartRule2
  {
    IpSourceAddr              9.1.1.1
    IpDestAddr                9.1.1.2
    IpService
    {
      Direction               bidirectional
      Routing                 local
    }
    IpGenericFilterActionRef  ipsec
    IpDynVpnActionRef         TransportMode
  }
}

KeyExchangePolicy
{
  KeyExchangeRule             QuickStart_KeyExRule
  {
     LocalSecurityEndpoint
     {
       Identity               IpAddr 9.1.1.1
       Location               9.1.1.1
     }
     RemoteSecurityEndpoint
     {
       Identity               IpAddr 9.1.1.2
       Location               9.1.1.2
     }
    KeyExchangeActionRef      QuickStart_KeyExAction
    SharedKey                 Ascii TheEagleHasLanded
  }
}

#------------------------------------------------------
```

```
# Reusable actions
#-------------------------------------------------------
IpGenericFilterAction    permit
{
  IpFilterAction         permit
}

IpGenericFilterAction    ipsec
{
  IpFilterAction         ipsec
  IpFilterLogging        yes LogDeny
}

KeyExchangeAction        QuickStart_KeyExAction
{
  KeyExchangeOffer
  {
    HowToAuthPeers       PreSharedKey
  }
}

IpDynVpnAction           TransportMode
{
  IpDataOffer
  {
    HowToEncap           transport
  }
}
```

For all IKE negotiations, there must be a corresponding and consistent configuration on the remote host. In this case, if the remote system is running with z/OS IP security, the corresponding policy for the remote system can be generated merely by transposing all instances of local and remote IP addresses.

Displaying filters, rules, and actions

To display the filter rules for the quick start policy after they have been installed in the stack, enter the following UNIX System Services command:

```
ipsec -f display -r detail -c current

```

Each IP service in the example uses the bidirectional keyword. Therefore, two rules are created for each IP service, one outbound and one inbound. When the IP filter rules are expanded in this way, the specific filter rules are distinguished from each other by a unique numeric value in the FilterNameExtension field.

Note that the last four deny rules are not explicitly coded in the IP security configuration file, but are added by the system in keeping with a default-deny policy.

For more information on displaying active filters with the **ipsec** command, see "Displaying active filters with the ipsec command" on page 1111.

To view the quick start filter rules using the **pasearch** command, issue the following command:

```
pasearch -v f

Activating the quick start Security Association

The quick start policy enables on-demand activation of a Security Association between the two endpoints. The Security Association is a wide Security Association allowing any type of traffic. Therefore, it can be activated by sending any type of traffic from the local host at 9.1.1.1 to the remote host at 9.1.1.2 as follows:

```
ping -s 9.1.1.1 9.1.1.2
CS V1R12: Pinging host 9.1.1.2
sendto(): EDC5111I Permission denied. (errno2=0x74420291)
```

Because the Security Association does not exist, the initial ping attempt fails. After the negotiation for the Security Association has activated and the Security Association is established, a subsequent ping attempt succeeds as follows:

```
ping -s 9.1.1.1 9.1.1.2
CS V1R12: Pinging host 9.1.1.2
Ping #1 response took 0.001 seconds.
```

Displaying the quick start Security Associations

Use the **ipsec** command to display both the phase 1 and phase 2 Security Associations between 9.1.1.1 and 9.1.1.2. The following command displays the phase 1 Security Associations:

```
ipsec -k display -r detail

```

In addition to information relating specifically to the phase 2 Security Association, use the **ipsec -y display** command to find the phase 1 that protects it. The ParentIKETunnelID field shows the associated phase 1, which is the same as the TunnelID from the previous **ipsec -k display** command.

```
ipsec -y display -r detail

Steps for configuring IP security policy

Perform the following steps to configure IP security policy.

1. Determine the number of zones to be protected. A zone typically equates to a subnetwork that is reachable by the host server, but can be any group of IP addresses that are conceptually related. The internal network can be defined in one or several zones, while any external network or group of networks can be placed in separate zones. Each zone should have meaning related to the site's security policy. If a zone maps to a physical interface, optionally assign a security class to all interfaces in that zone.
2. For each zone, determine what services are allowed and define an IpService statement for each desired service. Services are defined by the protocols and well-known ports that they use.
3. Determine the data endpoints to be protected. Typically, this is both a local and remote IP address, or subnetwork.
4. Determine what level of security is needed between each set of data endpoints. The level of security can be deny, permit, or ipsec.
5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged.
6. If IPSec is required between any two endpoints:
   a. Configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation:
      1) Determine the required type and strength of protection for the phase 1 Security Association.
      2) Decide what type of peer authentication will be used:
         - If digital signature, set up RACF certificates and certificate authority information.
         - If pre-shared key, create a secret key that is known to both peers.

3) Decide whether NAT traversal will be allowed. If the network topology contains one or more NAT devices that must be traversed by the phase 1 Security Association, NAT traversal should be allowed.
4) Configure a KeyExchangeOffer statement.
5) Determine negotiation mode, IKEv1 Main, IKEv1 Aggressive, or IKEv2.
6) Configure a KeyExchangeAction statement.
7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement.
8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action.
9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block.

b. Configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation:
1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.
2) Determine whether tunnel or transport mode is required. For an IKEv2 negotiation, the appropriate mode is chosen based on topology.
3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation.
4) Determine which peer should be allowed to initiate the negotiation.

c. Decide how the Security Association is to be activated:
1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.
2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.
3) Either create an IpFilterRule statement that allows IPSec traffic (AH and ESP), or set the global PreDecap parameter of the IpFilterPolicy statement to off.

7. Define an IpFilterRule statement for each set of data endpoints. The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.

   Rule: To allow IKE negotiations for Security Associations, IKE traffic (port 500, and optionally port 4500 for NAT traversal) must be permitted in the clear.

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.
9. Include the IpFilterRule statements in the IpFilterPolicy block.
10. Include all configured statements in the IP security configuration file. For more information, see the following:

- "Steps for configuring local IP security policy using only a common IP security configuration file" on page 993
- "Steps for configuring remote IP security policy using only a common IP security configuration file" on page 993
- "Steps for configuring local IP security policy using only a stack-specific IP security configuration file" on page 994
- "Steps for configuring remote IP security policy using only a stack-specific IP security configuration file" on page 994
- "Steps for configuring local IP security policy using both a stack-specific file and a common file" on page 995
- "Steps for configuring remote IP security policy using both a stack-specific file and a common file" on page 996

For examples of the use of these steps, see "Configuring specific security models."

Configuring specific security models

Setting up IP security configuration files can be a complex task, as there are many powerful features, options, and controls. However, after the security needs of the business are identified, implementing an IP security policy becomes a matter of translating the requirements to a Policy Agent configuration file.

The choice of protection model primarily depends on the network topology. Although it is perfectly permissible to follow a single model when configuring IP security policy, the z/OS IP security function enables any number of models to be installed concurrently. Commonly, one set of rules governs internal network traffic, another protects traffic from connected networks, and a third provides security for traffic that is routed over the Internet. The following scenarios presume that you are configuring a secure server that is a multihomed host that is connected to an internal, an external, and a wide-area network that traverses the Internet. The configuration guidelines that are presented in the following subtopics are based on three business models:

- Trusted internal network (permit, deny)

  In the trusted internal network model, the server is protecting traffic that originates from hosts inside a privately controlled network. IP packets on the internal network are not generally subject to the stringent restrictions that are placed on traffic that is generated from outside the business. This model is usually more tolerant, given that users inside the company need access to internal network resources and services, such as the Web, FTP, and Telnet.
- Partner company (permit, deny, strong IPSec protection)

  The partner company model consists of two interconnected networks, with the server protecting traffic that originates from hosts outside the internal network. Typically, two separate networks are physically connected to the z/OS server. Because the traffic is not restricted to internal hosts, security is usually somewhat tighter than in the trusted internal network model. Each partner company has no physical control over the machine of the other partner company. The services that are provided are determined by the needs of the business, but typically include many of the same services that are provided to the internal network, such as access to a Web server, FTP, and Telnet. Though many services might be allowed between partner companies, the need for confidentiality and authentication of data is more stringent than in the trusted

internal network model, because there is little to no control over the other network. IPSec is often specified to authenticate and optionally encrypt data that flows between the two networks.

- Branch office (permit, deny, strong tunnel-mode IPSec protection)

  The branch office model consists of two networks whose IP connectivity relies on the Internet. The server is protecting traffic that originates from hosts outside the internal network, which at some point is routed over the Internet. Because there is no control over any data that traverses the Internet, the need for security is greatest in this model. The services that are provided are based on business need, but typically include a subset of what is available internally. All traffic that traverses the Internet carrying vital information should be secured using some form of authentication and encryption.

Figure 100 shows a sample network for all three security models.

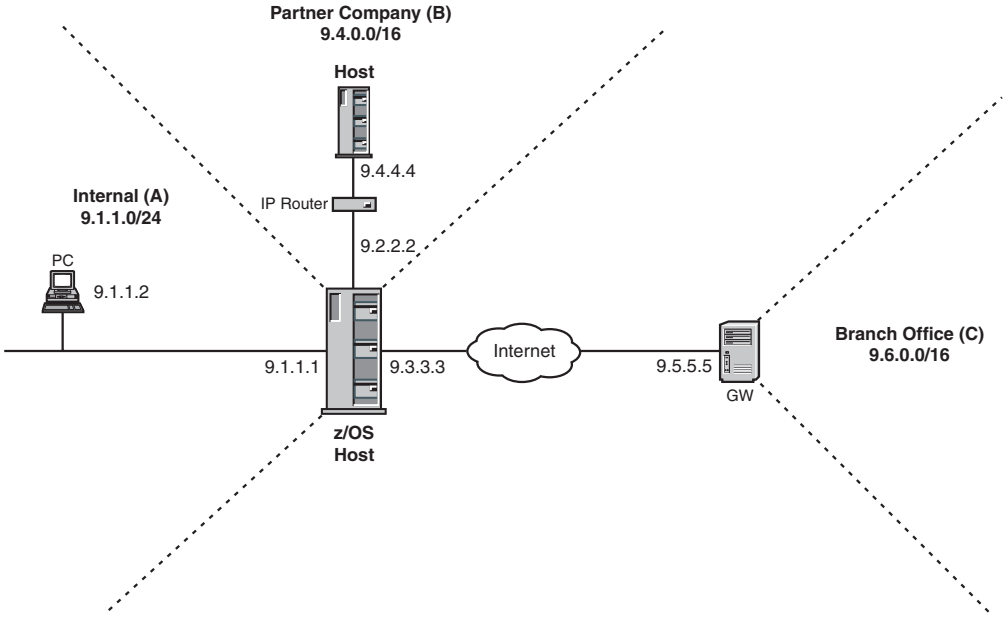

Figure 100. Security model network

The following subtopics describe how to configure these models using the steps described in "Steps for configuring IP security policy" on page 1026. The policy examples assume that a default-deny policy is in place. Any traffic not explicitly permitted is blocked.

Steps for configuring the trusted internal network model (simple IP filtering)

The following statements, concepts, and files are covered in the discussion of this model:

- IpFilterRule
- IpService
- IpGenericFilterAction
- References
- Groups
- Stack-specific IP security configuration file
- Common IP security configuration file

Figure 101 shows the trusted internal network portion of the security model network.

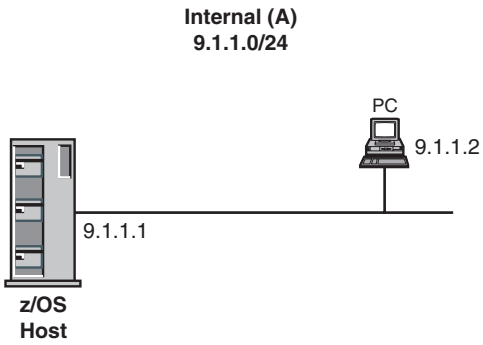

Figure 101. Trusted internal network model

For this example, assume that the following requirements must be met to control traffic on the internal network:

- Give FTP access to an administrator from a host inside the internal network (9.1.1.2) to the secure server (9.1.1.1). Log any traffic that matches this traffic pattern.
- Allow Web access (HTTP, port 80) to the secure server from any host on the internal network (9.1.1.0/24). Do not log any traffic that matches this traffic pattern.
- Deny all other traffic.

Perform the following steps to meet these requirements and configure the trusted internal network model.

1. Determine the number of zones to be protected.

   There is only one zone for this example, the internal network 9.1.1.0/24.

2. For each zone, determine what services are allowed and define an IpService block for each desired service. Optionally, assign a security class to all interfaces in each zone.

   There are two services stated in the example requirements, HTTP and FTP. The traffic is local to this host and, therefore, the routing is designated as local. No forwarding of these services is allowed.

   Because the entire internal network is defined in one zone, you can define a unique security class for the interface with address 9.1.1.1. For this example, the SECCLASS parameter of all internal network interfaces is assigned the arbitrary value of 1, which can be interpreted to mean a trusted network. If you specify the SecurityClass parameter in the IpService block, the related interface must be assigned the same value on the SECCLASS parameter of the LINK or INTERFACE statement in the TCP/IP profile. In this example, the traffic is allowed only over an interface with a SECCLASS parameter value of 1, presumed to be the interface connected to the internal network.

   ```
   IpService
   {
     SourcePortRange       80
     DestinationPortRange  1024 65535
     Protocol              tcp
     Direction             bidirectional InboundConnect
     Routing               local
     SecurityClass         1
   }
   ```

Because normal FTP uses two well-known ports, two services are required, one for the control connection and one for the data connection:

```
IpService
{
  SourcePortRange       21
  DestinationPortRange  1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1

}

IpService
{
  SourcePortRange       20
  DestinationPortRange  1024 65535
  Protocol              tcp
  Direction             bidirectional OutboundConnect
  Routing               local
  SecurityClass         1

}
```

The InboundConnect keyword is used for services that are not allowed to initiate a TCP connection. The OutboundConnect keyword is used for services that are not allowed to receive a TCP connection request. If neither keyword is specified, either side can initiate a TCP connection.

3. Determine the data endpoints to be protected.

   There are two sets of data endpoints to be protected in this example, representing the connection from the administrative machine, and all the other hosts on the subnetwork:

   ```
   Local  Address of secure server: 9.1.1.1
   Remote Address of administrative machine: 9.1.1.2

   Local  Address of secure server: 9.1.1.1
   Remote Address of all hosts on internal network: 9.1.1.0/24
   ```

4. Determine what level of security is needed between each set of data endpoints.

   In this example, only permit is required. Therefore, no IPSec information is needed. Because z/OS IP security policy implicitly provides a default-deny policy, all other traffic is denied.

5. Configure an IpGenericFilterAction statement for the level of security (permit, deny, ipsec) that is required, including whether the connection is logged.

   Because the example requirement is to permit two types of traffic with different logging requirements, two actions are needed as follows:

   ```
   IpGenericFilterAction    permit-log
   {
      IpFilterAction       permit
      IpFilterLogging       yes
   }

   IpGenericFilterAction    permit-nolog
   {
      IpFilterAction       permit
      IpFilterLogging       no
   }
   ```

6. If IPSec is required between any two endpoints, configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation, configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation, and decide how the Security Association is to be activated.

   IPSec is not required in this example. If there was sensitive data flowing through the internal network that needed to be confidential, IPSec could be specified to encrypt some IP packets, thereby effectively securing information that travels between two hosts on the internal network.

7. Define an IpFilterRule block for each set of data endpoints. Each rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.

   In this example, the source address refers to an address on the secure host. The destination address refers to remote hosts. The IpService statements are the ones defined in step 2 on page 1030. Note that the IpGenericFilterAction statement must reference a previously defined action.

```
IpFilterRule             AdminFTP
{
   IpSourceAddr          9.1.1.1
   IpDestAddr            9.1.1.2
   IpService
   {
      SourcePortRange       21
      DestinationPortRange  1024 65535
      Protocol              tcp
      Direction             bidirectional InboundConnect
      Routing               local
      SecurityClass         1

   }
   IpService
   {
      SourcePortRange       20
      DestinationPortRange  1024 65535
      Protocol              tcp
      Direction             bidirectional OutboundConnect
      Routing               local
      SecurityClass         1
   }
   IpGenericFilterActionRef  permit-log
}
IpFilterRule             InternalNetWeb
{
   IpSourceAddr          9.1.1.1
   IpDestAddrSet         9.1.1.0/24
   IpService
   {
      SourcePortRange       80
      DestinationPortRange  1024 65535
      Protocol              tcp
      Direction             bidirectional InboundConnect
      Routing               local
      SecurityClass         1
   }
   IpGenericFilterActionRef  permit-nolog
}

IpGenericFilterAction        permit-log
```

```
{
  IpFilterAction             permit
  IpFilterLogging            yes
}

IpGenericFilterAction        permit-nolog
{
  IpFilterAction             permit
  IpFilterLogging            no
}
```

Because IPSec is not required in this example, no filters for IKE traffic are needed.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

   The IP filter rules and their relative placement within the IpFilterPolicy block should be from most specific to least specific. Because the AdminFTP rule controls traffic from a specific host, it should be placed before the InternalNetWeb rule. Note that to enable logging of the individual rules, filter logging must be enabled at the global level of the IP filter policy with the FilterLogging parameter.

```
IpFilterPolicy
{
   FilterLogging            on

   IpFilterRule             AdminFTP
   {
      IpSourceAddr          9.1.1.1
      IpDestAddr            9.1.1.2
      IpService
      {
         SourcePortRange       21
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }
      IpService
      {
         SourcePortRange       20
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional OutboundConnect
         Routing               local
         SecurityClass         1
      }
      IpGenericFilterActionRef  permit-log
   }
   IpFilterRule             InternalNetWeb
   {
      IpSourceAddr          9.1.1.1
      IpDestAddrSet         9.1.1.0/24
      IpService             WebServer
      {
         SourcePortRange       80
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }
      IpGenericFilterActionRef  permit-nolog
   }
}
```

9. Include all configured statements in the stack-specific IP security configuration file.

   The IpFilterPolicy statement and the IpGenericFilterAction statements are placed in the file in no particular order, although the file is easier to read if logically related items are placed close together. For further ease of reading and maintenance, document the file with comments, which begin with the number sign (#).

   The completed stack-specific IP security configuration file for the internal network with two filter rules follows:

```
# IP Security policy for Secure Server
#########################
# IpFilterPolicy block   #
#########################
IpFilterPolicy
{
   FilterLogging            on
   #Allow admin FTP; log traffic
   IpFilterRule             AdminFTP
   {
      IpSourceAddr          9.1.1.1
      IpDestAddr            9.1.1.2
      IpService
      {
         SourcePortRange       21
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }
      IpService
      {
         SourcePortRange       20
         DestinationPortRange  1024 65535
         Protocol              tcp
         Routing               local
         SecurityClass         1
         Direction             bidirectional OutboundConnect
      }
      IpGenericFilterActionRef  permit-log
   }
   #Allow LAN Web traffic; don't log
   IpFilterRule             InternalNetWeb
   {
      IpSourceAddr          9.1.1.1
      IpDestAddrSet         9.1.1.0/24
      IpService
      {
         SourcePortRange       80
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }
      IpGenericFilterActionRef  permit-nolog
}

##########################
# Generic Filter Actions   #
##########################
IpGenericFilterAction    permit-log
{
   IpFilterAction        permit
```

```
   IpFilterLogging       yes
}

IpGenericFilterAction    permit-nolog
{
   IpFilterAction        permit
   IpFilterLogging       no
}
```

10. Define an IP filter group for each zone, and include the IP filter rules that belong to that zone.

    In step 9 on page 1034, both IpFilterRule statements include a reference to statements defined outside of the IpFilterRule block, the IpGenericFilterAction statements. Some other information, such as IP addresses and services, is undoubtedly to be needed more than once. Changing these occurrences to reference objects eliminates repeated typing of the same information and adds clarity to the configuration file. To take advantage of references, the reusable statements must be given a name.

    - Single IP addresses are defined by the IpAddr statement, which contains one parameter, Addr:

      ```
      IpAddr         InternalNetServerAddress
      {
         Addr        9.1.1.1
      {

      IpAddr         InternalNetAdminAddress
      {
         Addr        9.1.1.2
      }
      ```

    - Ranges or subnetworks are defined by the IpAddrSet statement, which contains either a Range or Prefix attribute:

      ```
      IpAddrSet      InternalNet
      {
         Prefix      9.1.1.0/24
      }
      ```

    - To be referenced, each IpService statement needs a name:

      ```
      IpService      WebServer
      {
         SourcePortRange       80
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }

      IpService     FTPServer-Control
      {
         SourcePortRange       21
         DestinationPortRange  1024 65535
         Protocol              tcp
         Direction             bidirectional InboundConnect
         Routing               local
         SecurityClass         1
      }
      IpService     FTPServer-Data
      {
         SourcePortRange       20
         DestinationPortRange  1024 65535
         Protocol              tcp
      ```

```
   Direction             bidirectional OutboundConnect
   Routing               local
   SecurityClass         1
}
```

- FTP is composed of two individual services, and both can be condensed into an IpServiceGroup that references the two FTP services:

```
IpServiceGroup    FTPServer
{
   IpServiceRef   FTPServer-Control
   IpServiceRef   FTPServer-Data
}
```

- The IP filter rules can be grouped as well. Because the filter rules that apply to the internal network naturally relate to each other in the sense that they apply to the same security zone, they can be combined into an IpFilterGroup statement:

```
IpFilterGroup     InternalNetZoneA
{
   IpFilterRef    AdminFTP
   IpFilterRef    InternalNetWeb
}
```

  Notice that just as the list of IpFilterRule statements in the IpFilterPolicy block is ordered, the list of IpFilterRef statements in the IpFilterGroup block is also ordered. The InternalNetWeb rule applies to all of the IP addresses in the network, including the administrative machine. However, the AdminFTP rule is more specific because it applies only to a specific address within that network. The more specific rule is placed first in the list.

Now that all reusable statements have been identified and separately defined, they can be incorporated into any statement that requires that reusable statement type. The modified stack-specific IP security configuration file using references follows. Note that by adding names and organizing related statements, the purpose of the IpFilterPolicy statement is clarified.

```
# IP Security policy for Secure Server
##########################
# IpFilterPolicy block   #
##########################
IpFilterPolicy
{
   FilterLogging            on
   IpFilterGroupRef     InternalNetZoneA
}

##########################
# Security Zones         #

{
```

```
   IpServiceRef   FTPServer-Control
   IpServiceRef   FTPServer-Data
}

##########################
# Reusable IP Addresses    #
##########################
IpAddr         InternalNetServerAddress
{
   Addr        9.1.1.1
}

IpAddr         InternalNetAdminAddress
{
   Addr        9.1.1.2
}

IpAddrSet      InternalNet
{
   Prefix      9.1.1.0/24
}
```

This stack-specific IP security configuration file gives FTP access to the administrator and Web access to everyone in the internal network. By relying heavily on the abstracted use of references, the policy is not only more self-explanatory, but changes to any referenced object are propagated to any statement that references it. So, if the IP address of the administrative machine or internal subnetwork changes, you merely have to make one change to an IpAddr or IpAddrSet statement, rather than modify a large number of instances in multiple rules.

Using a common IP security configuration file for reusable statements: The stack-specific IP security configuration file should be tailored to the specific stack to which it belongs. However, as the policy files for IP security are being constructed, a large number of statements can be reused. Reusable statements can be placed in a common file, which is available to all stacks. Statements in the common IP security configuration file are read by all stacks on the system, providing a convenient way to store common definitions that they can all share. If you are operating in a sysplex, you can also place a common IP security configuration file on shared DASD or in a shared zSeries File System directory so that stacks in a multiple sysplex image have access to the same common configuration file.

Assuming that all statements that might be used later are placed in a common IP security configuration file, the stack-specific IP security configuration file from step 10 now reads as follows:

```
# IP Security policy for Secure Server
#########################
# IpFilterPolicy block   #
#########################
IpFilterPolicy
{
   FilterLogging            on
   IpFilterGroupRef     InternalNetZoneA
}

#########################
# Security Zones         #
#########################
IpFilterGroup     InternalNetZoneA
{
   IpFilterRuleRef    AdminFTP
   IpFilterRuleRef    InternalNetWeb
```

```
}

########################
# Filter rules         #
########################
#Allow admin FTP; log traffic
IpFilterRule                AdminFTP
{
   IpSourceAddrRef          InternalNetServerAddress
   IpDestAddrRef            InternalNetAdminAddress
   IpServiceGroupRef        FTPServer
   IpGenericFilterActionRef permit-log
}

#Allow LAN Web traffic; don't log
IpFilterRule                InternalNetWeb
{
   IpSourceAddrRef          InternalNetServerAddress
   IpDestAddrSetRef         InternalNet
   IpServiceRef             WebServer
   IpGenericFilterActionRef permit-nolog
}
```

This stack-specific IP security configuration file references the following reusable statements:

- InternalNetServerAddress
- InternalNetAdminAddress
- InternalNet
- FTPServer
- FTPServer-Control
- FTPServer-Data
- permit-log
- permit-nolog
- WebServer

IpFilterRule statements can also be placed in the common IP security configuration file, because some IP filter rules apply to all addresses. If certain IpFilterRule statements are to apply globally to all stacks on the system, they can go into the common file. Use a value of `all` for the IpSourceAddr and IpDestAddr attributes. For instance, if all stacks on a z/OS system need rules permitting dynamic routing traffic (OSPF or RIP, for example), the statements that define this type of traffic can be placed in the common file and referenced in the stack-specific file:

```
IpFilterRule                  AllowOmprouteLocalNolog
{
  IpSourceAddr                all
  IpDestAddr                  all
  IpServiceGroupRef           Omproute-local
  IpGenericFilterActionRef    Permit-nolog
}

IpServiceGroup                Omproute-local
{
  IpServiceRef                OSPF-local
  IpServiceRef                RIP-local
}

IpService                     OSPF-local
{
  Protocol                    OSPF
  Direction                   bidirectional
```

```
  Routing                     local
}

IpService                     RIP-local
{
  Protocol                    UDP
  SourcePortRange             520
  DestinationPortRange        520
  Direction                   bidirectional
  Routing                     local
}
```

With these definitions in the common IP security configuration file, any stack needing global permission to send and receive routing information merely needs to include the following statement in the IpFilterPolicy block of its stack-specific IP security configuration file:

```
IpFilterRuleRef  AllowOmprouteLocalNolog
```

Steps for configuring the partner company model (host-to-host with IPSec)

The following statements and concepts are covered in the discussion of this model:

- Dynamic host-to-host IKE negotiations
- Key exchange rules
- Local and remote security endpoints
- Use of wildcards in Location and Identity
- IpLocalStartAction
- Granularity
- RSA signature peer authentication
- Certificates and certificate authorities
- On-demand activation
- Remote activation

Figure 102 shows the partner company portion of the security model network.

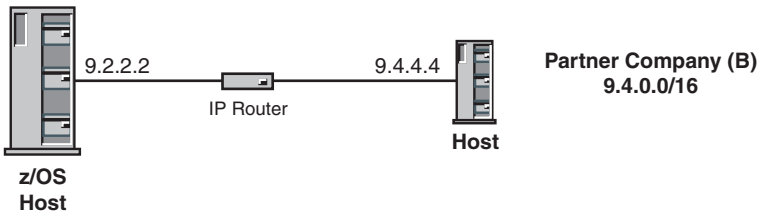

Figure 102. Partner company model

The partner company model is similar to that of the internal network, but an increased need for security means that a greater number of connections rely on data authentication and encryption. Although some services are allowed in the clear, sensitive data needs IPSec protection. To apply IPSec to a connection, the traffic that flows over that connection must match an IP filter rule that has an ipsec action.

For this example, assume you must meet the following requirements to allow network communications from a partner company in an untrusted zone B over a connected network (9.4.0.0/16) to a public IP address (9.2.2.2) on this host:

- Allow IKE traffic from untrusted zone B to this host.

- Allow secure FTP traffic (using TLS/SSL) from untrusted zone B to a secure FTP server running on this host.

  Secure FTP has its own security mechanism. Although IPSec can be used together with TLS/SSL, using both adds processing expense. For this example, secure FTP is allowed without IPSec protection.
- Allow Enterprise Extender (EE) traffic from untrusted zone B to an EE service running on this host using a dynamic IPSec tunnel with strong encryption and authentication.

  Because there is no encryption mechanism used in this example for EE, IPSec provides the secure service.
- Allow FTP traffic from untrusted zone B to an FTP server running on this host using a dynamic IPSec tunnel with strong AH authentication.
- The dynamic IPSec tunnel for EE comes up when outbound EE traffic is detected (on-demand activation).
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each outbound data connection to a remote host (local activation).
- Peers authenticate themselves using the RSA signature method.

Perform the following steps to meet these requirements and configure the partner company model.

1. For each zone, determine what services are allowed:
   - IKE traffic
   - Normal FTP traffic
   - Secure FTP traffic
   - Enterprise Extender traffic
2. Define an IpService statement for each desired service.
   - IKE uses UDP, port 500 for message exchanges:

     ```
     IpService                   IKE-local
     {
       SourcePortRange           500
       DestinationPortRange      500
       Protocol                  UDP
       Direction                 bidirectional
       Routing                   local
       SecurityClass             0
     }
     ```
   - For normal FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection:

     ```
     IpService                   FTPServer-Control
     {
       SourcePortRange           21
       DestinationPortRange      1024 65535
       Protocol                  tcp
       Direction                 bidirectional InboundConnect
       Routing                   local
       SecurityClass             0
     }

     IpService                   FTPServer-Data
     {
       SourcePortRange           20
     ```

```
  DestinationPortRange       1024 65535
  Protocol                   tcp
  Direction                  bidirectional OutboundConnect
  Routing                    local
  SecurityClass              0
}
```

- For secure FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection.

```
IpService                    SecureFTPServer-Control
{
  SourcePortRange            990
  DestinationPortRange       1024 65535
  Protocol                   tcp
  Direction                  bidirectional InboundConnect
  Routing                    local
  SecurityClass              0
}

IpService                    SecureFTPServer-Data
{
  SourcePortRange            989
  DestinationPortRange       1024 65535
  Protocol                   tcp
  Direction                  bidirectional OutboundConnect
  Routing                    local
  SecurityClass              0
}
```

- For Enterprise Extender traffic, allow both inbound and outbound traffic:

```
IpService                    Enterprise-Extender
{
  SourcePortRange            12000 12004
  DestinationPortRange       12000 12004
  Protocol                   UDP
  Direction                  bidirectional
  Routing                    local
  SecurityClass              0
}
```

IP services can be grouped together for convenience, flexibility, and reuse of configuration. Any IP filter rule that includes an IP service group will be expanded to include all of the services from that group. The following IP service groups include the IP services that define the FTPServer and the SecureFTPServer:

```
IpServiceGroup FTPServer
{
   IpServiceRef FTPServer-Control
   IpServiceRef FTPServer-Data
}
IpServiceGroup SecureFTPServer
{
   IpServiceRef Secure-FTPServer-Control
   IpServiceRef Secure-FTPServer-Data
}
```

3. Determine the data endpoints to be protected. In this example, the local data endpoint is the public address of the server, and the remote data endpoint is the entire subnetwork in zone B:

```
Local public IP address:  9.2.2.2
Remote subnet: 9.4.0.0/16
```

4. Determine what level of security is needed between each set of data endpoints:

```
IKE traffic - permit
Secure FTP traffic - permit
EE traffic - IPSec encryption and authentication
FTP traffic - IPSec authentication
```

5. Configure an IpGenericFilterAction statement for the level of security that is required. The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Notice that the parameters of the IpGenericFilterAction statement include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec:

```
IpGenericFilterAction    permit-nolog
{
   IpFilterAction       permit
   IpFilterLogging       no
}

IpGenericFilterAction    ipsec-nolog
{
   IpFilterAction       ipsec
   IpFilterLogging       no
}
```

6. If IPSec is required between any two endpoints, do the following:

   a. Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

      1) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

         ```
         Authentication, SHA1 algorithm
         Encryption, 3DES algorithm
         DHGroup, Diffie-Hellman Group2
         ```

         Tip: The greater the Diffie-Hellman group specified, the greater the protection provided.

      2) Decide what type of peer authentication is used:

         ```
         RSA signature
         ```

         Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

         The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see Appendix E, "Steps for preparing to run IP security," on page 1505. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see *z/OS Security Server RACF Security Administrator's Guide*.

         In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label

CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

```
SupportedCertAuth CA4PartnerCompany
```

Guideline: For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.

3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication, strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

```
KeyExchangeOffer RSA-SHA1-3DES-DH2
{
   HowToEncrypt    3DES
   HowToAuthMsgs   SHA1
   HowToAuthPeers  RsaSignature
   DHGroup         Group2
   RefreshLifetimeProposed  480
   RefreshLifetimeAccepted  240 1440
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

4) Decide whether NAT traversal will be allowed.

   In this example, the following parameter is used:

```
AllowNat No
```

5) Determine the negotiation mode. Main mode is used for phase 1, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.

6) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured in step 6a3:

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{
   HowToInitiate       main
   HowToRespondIKEv1   main
   KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint  Public_IKED
{
   Identity      IpAddr  9.2.2.2
   Location      9.2.2.2
}
```

   Similarly, the same information is needed for remote hosts. Notice that in the RemoteSecurityEndpoint statement, an IP address range is specified for both identity and location. Although it is possible to configure a RemoteSecurityEndpoint statement for every host in the remote subnetwork, unless they have unique key exchange

requirements, it is not necessary. Wildcards can be used for the Identity and Location parameters. Any of the identity types can potentially contain wildcards to include a group of remote hosts with similar identities.

```
RemoteSecurityEndpoint   ZoneB_IKED
{
   Identity      IpAddr   9.4.0.0/16
   Location      9.4.0.0/16
   CaLabel       CA4PartnerCompany
}
```

The use of an IPv4 address on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the IPv4 address in the Subject Alternative Name field of the certificate. The use of an IPv4 subnet on the Identity parameter for the ZoneB_IKED security endpoint requires that an IPv4 address within that subnet (9.4.0.0/16) appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.

Rule: For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the RemoteSecurityEndpoint statement, see *z/OS Communications Server: IP Configuration Reference*.

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action:

```
KeyExchangeRule              ZoneB_KeyExRule1
{
   LocalSecurityEndpointRef  Public_IKED
   RemoteSecurityEndpointRef ZoneB_IKED
   KeyExchangeActionRef      Main-RSA-SHA1-3DES-DH2
}
```

9) Include the key exchange rule in the KeyExchangePolicy statement:

```
KeyExchangePolicy
{
   KeyExchangeRuleRef    ZoneB_KeyExRule1
}
```

b. Configure an IpDynVpnAction statement that defines the parameters of the phase 2 negotiation as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

```
EE traffic - strong encryption: ESP, 3DES
             strong ESP authentication: Hmac SHA1
Normal FTP traffic - strong AH authentication, Hmac SHA1
```

This information eventually translates into two IpDataOffer statements.

2) Determine whether tunnel or transport mode is required.

Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

3) Configure IpDataOffer statements that define the parameters of the phase 2 negotiation.
   - Authenticated offer for FTP:

```
IpDataOffer TRAN-AHSHA-NOENCR
{
   HowToEncap Transport
   HowToEncrypt DoNot
   HowToAuth    AH HMAC_SHA1
   RefreshLifetimeProposed 240
   RefreshLifetimeAccepted 120 480
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

   - Encrypted and authenticated offer for EE:

```
IpDataOffer TRAN-ESPSHA-3DES
{
   HowToEncap Transport
   HowToEncrypt 3DES
   HowToAuth    ESP HMAC_SHA1
   RefreshLifetimeProposed 240
   RefreshLifetimeAccepted 120 480
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

4) Determine which peer is allowed to initiate the negotiation.

   Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. The remote host initiates the negotiation of the Security Association for the FTP control connection, so local initiation is not required. The FTP data connection is initiated from the local host, so to activate the Security Association, local initiation is required.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation.

   The IpDynVpnAction statement can control which host is allowed to initiate the negotiation. You must allow the IPSec VPN for the FTP control connection to be initiated by the remote peer, and the data connection by the local host. EE should be allowed to initiate an IKE negotiation locally.
   - Authenticated VPN action for FTP:

```
IpDynVpnAction FTP-vpnaction
{
   Initiation           either
   InitiateWithPfs      group2
   AcceptablePfs        group2
   VpnLife              1440
   IpDataOfferRef       TRAN-AHSHA-NOENCR
}
```

   - Encrypted and authenticated VPN action for EE traffic:

```
IpDynVpnAction EE-vpnaction
{
   Initiation           localonly
   InitiateWithPfs      group2
```

```
   AcceptablePfs        group2
   VpnLife              1440
   IpDataOfferRef       TRAN-ESPSHA-3DES
}
```

c. Decide how the Security Association is to be activated as follows:

   1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

      Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

   2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

      Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

      ```
      IpLocalStartAction           ZoneB-Start-Action
      {
         AllowOnDemand             yes
         LocalPortGranularity      packet
         RemotePortGranularity     packet
         ProtocolGranularity       packet
         LocalIpGranularity        packet
         RemoteIpGranularity       packet
         LocalSecurityEndpointRef  Public_IKED
         RemoteSecurityEndpointRef ZoneB_IKED
      }
      ```

      In this example, specifying `packet` is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of `rule`. Specifying `packet` is required, however, if the EE and FTP rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

   3) Set the global PreDecap parameter of the IpFilterPolicy statement to `off`, or create an IpFilterRule statement that allows IPSec traffic (AH and ESP).

      When the system begins to process encapsulated traffic, the encapsulated packets are subject to filtering. The encrypted and authenticated packets are denied unless they are explicitly allowed. There are two options to configure this that are subtly different. The first is less restrictive, allowing AH and ESP packets from anywhere and not subjecting them to filtering until after the packets have had their IPSec headers removed. The second method is to add an IpFilterRule statement that explicitly permits the IPSec-encapsulated traffic. This option adds an additional layer of security, in that you can control exactly who is allowed to send encrypted traffic. This protects system resources by preventing the processing of IPSec packets unnecessarily, such as might happen in the case of a malicious

attack of IPSec packets. Although more secure, this solution is less efficient because it requires additional processing resources to filter all IPSec-encapsulated traffic.

For the first option, in the main IpFilterPolicy block, code `PreDecap off` as follows:

```
IpFilterPolicy
{
   PreDecap off

:
}
```

For the second option, configure a filter rule in the IpFilterPolicy block that explicitly allows AH and ESP traffic as follows:

```
IpFilterRule           Allow-IPSec-traffic
{
   IpSourceAddr        9.2.2.2
   IpDestAddrSet       9.4.0.0/16
   IpService                   AH-traffic
   {
      Protocol                 AH
      Direction                bidirectional
      Routing                  local
      SecurityClass            0
   }
   IpService                   ESP-traffic
   {
      Protocol                 ESP
      Direction                bidirectional
      Routing                  local
      SecurityClass            0
   }
   IpGenericFilterRef    permit-nolog
}
```

Tip: In most cases, unless the extra security is deemed a necessity, use the `PreDecap off` global option to allow IPSec packets to flow with minimum overhead.

7. Define an IpFilterRule statement for each set of data endpoints.

   The secure host and subnetwork B represent the data endpoints. The IpService statements were defined in step 2 on page 1041. Place the IpDynVpnAction statements that were created in step 6 on page 1043 with the appropriate rule.

```
IpFilterRule              ZoneB-Permitted-traffic
{
   IpSourceAddrRef           PublicServerAddress
   IpDestAddrSetRef          ZoneB-subnet
   IpServiceRef              IKE-local
   IpServiceGroupRef         SecureFTPServer
   IpGenericFilterActionRef  permit-nolog
}

IpFilterRule              FTPServer-ZoneB
{
   IpSourceAddr              9.2.2.2
   IpDestAddrSet             9.4.0.0/16
   IpServiceGroupRef         FTPServer
   IpGenericFilterActionRef  ipsec-nolog
   IpDynVpnAction            FTP-vpnaction
   IpLocalStartActionRef     ZoneB-Start-Action
}
IpFilterRule             EE-ZoneB
```

```
{
   IpSourceAddr          9.2.2.2
   IpDestAddrSet         9.4.0.0/16
   IpService
   {
      SourcePortRange       12000 12004
      DestinationPortRange  12000 12004
      Protocol              udp
      Direction             bidirectional
      Routing               local
      SecurityClass         0
   }
   IpGenericFilterActionRef  ipsec-nolog
   IpDynVpnAction            EE-vpnaction
   IpLocalStartActionRef     ZoneB-Start-Action
}
```

Because both IKE and Secure FTP need to be permitted without IPSec protection, an IpFilterRule statement for both is not needed. The two services can be combined into one rule.

Tip: Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

   The IpFilterRule statement allowing IKE traffic should always be at the top of the list. The rest of the IpFilterRule statements are disjointed, and their relative placement within the IpFilterPolicy is irrelevant.

   Tip: If it is known that one particular type of traffic is the most frequent, placing that rule near the top of the list results in faster filter lookups.

9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone. Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.

   A completely configured policy, including all objects and their references, is as follows:

```
# IpFilterPolicy for secure public server

IpFilterPolicy
{
   PreDecap             off
   IpFilterGroupRef     ZoneB
}

KeyExchangePolicy
{
   KeyExchangeRuleRef   ZoneB_KeyExRule1
}

###### All reusable statements follow #######
IpFilterGroup           ZoneB

10. Include all configured statements in the stack-specific IP security configuration file.

Steps for configuring the partner company with NAT model (host-to-host with IPSec)

The following statements and concepts are covered in the discussion of this model:

- AllowNat and NatKeepAliveInterval parameters on the KeyExchangePolicy and KeyExchangeAction statements
- IKE traffic on UDP port 4500, in addition to port 500
- NAT implications for host-to-host dynamic IKE negotiations:
  - Local and remote data endpoints
  - Local and remote security endpoints
  - IKE initiator and responder roles
  - Restriction on HowToAuth protocol (AH not supported)
- Using wildcards for location and identity
- RSA signature peer authentication
- Certificates and certificate authorities
- CaLabel
- SupportedCertAuth

"Steps for configuring the partner company model (host-to-host with IPSec)" on page 1040 assumed a network topology with both partner companies using public IP addresses in their internal networks. Often one or both businesses have an internal network utilizing IETF-defined private IP addresses (10.0.0.0/8, 172.16.0.0./12, and 192.168.0.0/16). Private IP addresses cannot be routed outside an internal network. Network address translation (NAT) is used to create a mapping of private addresses to public addresses and perform the necessary translation as packets traverse the NAT device.

When IPSec Security Associations traverse a NAT, there are problems because the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). The IETF has defined a solution known as NAT traversal (NATT) that allows IPSec Security Associations to successfully traverse a NAT device.

Figure 103 on page 1055 shows the partner company with NAT topology when the partner company model topology has been modified to include private addressing in each partner company's private network with a NAT device in front of each private network.

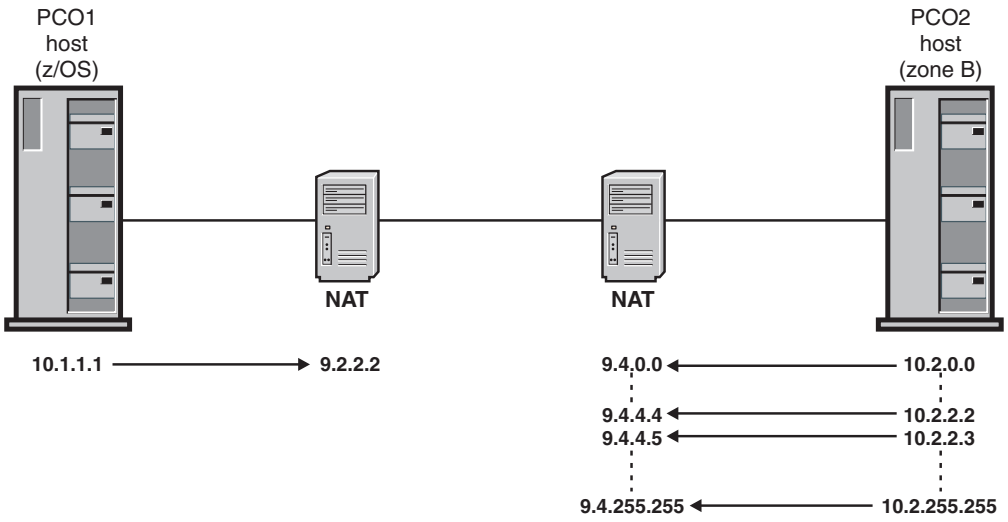

Figure 103. Partner company with NAT model

The steps in this topic will describe the configuration considerations and requirements when the NATT solution is implemented to traverse NAT devices in a host-to-host environment. The partner company with NAT model has the same basic security requirements as the partner company model. Configuration statements added or changed for the partner company with NAT model are shown in **bold**. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to allow network communications from a partner company (PCO2) in an untrusted zone B behind a NAT over a connected network (9.4.0.0/16) to a server on this host that is behind a NAT:

- IKE traffic from untrusted zone B that is behind a NAT is allowed to this host that is behind a NAT.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- Enterprise Extender (EE) traffic from untrusted zone B is allowed to an EE service running on this host using a dynamic IPSec tunnel with strong encryption and authentication.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPSec tunnel with strong authentication.
- The dynamic IPSec tunnel for EE is activated when outbound EE traffic is detected (on-demand activation).
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

Perform the following steps to meet these requirements and configure the partner company with NAT model.

1. For each zone, determine what services are allowed:
   - IKE traffic
   - Normal FTP traffic
   - Secure FTP traffic

- Enterprise Extender traffic

2. Define an IpService statement for each desired service.
   - IKE traffic

     When NAT traversal is allowed, IKE uses UDP port 500 and port 4500 for message exchanges. NAT traversal is controlled by the AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements.

```
IpService                   IKE-local-500
{
  SourcePortRange           500
  DestinationPortRange      500
  Protocol                  UDP
  Direction                 bidirectional
  Routing                   local
  SecurityClass             0
}

IpService                   IKE-local-4500
{
  SourcePortRange           4500
  DestinationPortRange      4500
  Protocol                  UDP
  Direction                 bidirectional
  Routing                   local
  SecurityClass             0
}
```

   - Normal FTP traffic

     When a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not outbound connection requests. For more information on active and passive mode FTP, see "Considerations for IPSec-encapsulated FTP traffic when traversing a NAT" on page 1098.

     Two services are required, one for the control connection and one for the data connection. The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server's FTP.DATA file. For more information on PASSIVEDATAPORTS, see *z/OS Communications Server: IP Configuration Reference*.

     The following definitions show the services required for the FTP server for EPSV mode:

```
IpService                   FTPServer-Control
{
  SourcePortRange           21
  DestinationPortRange      1024 65535
  Protocol                  tcp
  Direction                 bidirectional InboundConnect
  Routing                   local
  SecurityClass             0
}

IpService                   FTPServer-Data-Passive
{
  SourcePortRange           50000 50200
  DestinationPortRange      1024 65535
  Protocol                  tcp
  Direction                 bidirectional InboundConnect
  Routing                   local
  SecurityClass             0
}
```

- Secure FTP traffic

  Again, when a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not outbound connection requests. Two services are required, one for the control connection and one for the data connection.

```
IpService                   SecureFTPServer-Control
{
  SourcePortRange           990
  DestinationPortRange      1024 65535
  Protocol                  tcp
  Direction                 bidirectional InboundConnect
  Routing                   local
  SecurityClass             0
}

IpService                   SecureFTPServer-Data-Passive
{
  SourcePortRange           50201 50400
  DestinationPortRange      1024 65535
  Protocol                  tcp
  Direction                 bidirectional InboundConnect
  Routing                   local
  SecurityClass             0
}
```

- Enterprise Extender traffic

  Allow both inbound and outbound connections.

```
IpService                   Enterprise-Extender
{
  SourcePortRange           12000 12004
  DestinationPortRange      12000 12004
  Protocol                  UDP
  Direction                 bidirectional
  Routing                   local
  SecurityClass             0
}
```

3. Determine the data endpoints that are to be protected.

   In this case, the local data endpoint is the private address of the server, local IP address 10.1.1.1.

   The remote data endpoint is the partner company's internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public addresses should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address range 9.4.0.0/16. Thus, the remote subnetwork is 9.4.0.0/16.

4. Determine what level of security is needed between each set of data endpoints.

```
IKE traffic - permit
Secure FTP traffic - permit
EE traffic - IPSec encryption and authentication
FTP traffic - IPSec authentication
```

5. Configure an IpGenericFilterAction statement for the level of security that is required. The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Because no logging requirements were specified, two actions are needed, permit and ipsec.

```
IpGenericFilterAction    permit-nolog
{
   IpFilterAction       permit
   IpFilterLogging       no
}

IpGenericFilterAction    ipsec-nolog
{
   IpFilterAction       ipsec
   IpFilterLogging       no
}
```

6. If IPSec is required between any two endpoints, do the following:
   a. Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:
      1) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

         ```
         Authentication, SHA1 algorithm
         Encryption, 3DES algorithm
         DHGroup, Diffie-Hellman Group2
         ```

         Tip: The greater the Diffie-Hellman group specified, the greater the protection provided.
      2) Decide what type of peer authentication is used:

         ```
         RSA signature
         ```

         Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

         The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see Appendix E, "Steps for preparing to run IP security," on page 1505. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see *z/OS Security Server RACF Security Administrator's Guide*.

         In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

         ```
         SupportedCertAuth CA4PartnerCompany
         ```

         Guideline: For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.
      3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication,

strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

```
KeyExchangeOffer RSA-SHA1-3DES-DH2
{
   HowToEncrypt    3DES
   HowToAuthMsgs   SHA1
   HowToAuthPeers  RSAsignature
   DHGroup         Group2
   RefreshLifetimeProposed  480
   RefreshLifetimeAccepted  240 1440
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

4) Decide whether NAT traversal will be allowed.

   The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements allows IKE to advertise NAT traversal support. When a phase 1 Security Association is being negotiated, if both IKE peers support NAT traversal, several IKE payloads are exchanged that allow the peers to determine if one or more NAT devices are being traversed. If a NAT is being traversed, the IKE peers negotiate a UDP-Encapsulated-Transport or UDP-Encapsulated-Tunnel mode phase 2 Security Association to allow IPSec traffic to traverse the NATs successfully. If a NAT is not being traversed, a standard transport or tunnel mode phase 2 Security Association is negotiated.

   The AllowNat parameter can be specified on the overall KeyExchangePolicy statement or for a specific KeyExchangeAction statement. If AllowNat is No, IKE does not advertise its support for NAT traversal. You might want to disable NAT traversal for interoperability purposes (certain remote resources might not be able to tolerate NAT traversal protocols) or security concerns (for example, NAT traversal exposes private internal addresses to the IKE peer). If NAT traversal is disabled and there is a NAT device in the path, ipsec processing might fail to negotiate the Security Association or fail to send data over the Security Association.

   For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by coding the following on the KeyExchangePolicy statement:

   ```
   AllowNat Yes
   ```

   A NatKeepAliveInterval parameter is also provided on the KeyExchangePolicy statement. A NAT keep-alive timer is maintained to ensure that NAT mappings do not expire. If z/OS is behind a NAT, a NAT keep-alive timer is started with the interval specified on the NatKeepAliveInterval parameter. If z/OS is behind a NAT that is using static mappings that will not expire, the NatKeepAliveInterval parameter should be set to 0. It is not necessary to run a NAT keep-alive timer in this case.

   For this model, since static mapping is being used for the NAT in front of PCO1, the NatKeepAliveInterval parameter is set to 0:

   ```
   NatKeepAliveInterval   0
   ```

5) Determine the negotiation mode. Main mode is used for phase 1 in this example, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.

6) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action

determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured previously:

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{
   HowToInitiate       main
   HowToRespondIKEv1   main
   KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint  Local_IKED
{
   Identity      Fqdn  Server.PCO1.example.com
   Location      10.1.1.1
}
```

The value specified for Identity on the LocalSecurityEndpoint statement is sent to the remote peer to identify this endpoint. The remote peer uses this value to determine if a Security Association can be negotiated and which policy should be used. Identity can be specified in different formats, such as an IP address or fully qualified domain name.

The partner company model specified an IP address for Identity, and an IP address could be used in this model. However, PCO1's private IP address 10.1.1.1 is not meaningful in the PCO2 configuration, so one of the other Identity types was chosen. The fully qualified domain name (Fqdn) identifies the local security endpoint.

An identity and IP address are also needed for the remote hosts. Notice that in the following RemoteSecurityEndpoint statement, the Identity and Location attributes use a wildcard to include a group of remote hosts with similar identities. It is possible to use a wildcard for the values because the key exchange requirements are the same for the hosts included in the specified range.

The Identity attribute is specified as `Fqdn` (fully qualified domain name), and the Location attribute is the range of public IP addresses used by the PCO2 internal network. PCO2 internal private addresses are not coded because they have no meaning for PCO1.

```
RemoteSecurityEndpoint   ZoneB_IKED
{
   Identity      Fqdn   *.PCO2.example.com
   Location      9.4.0.0/16
   CaLabel       CA4PartnerCompany
}
```

The use of a fully qualified domain name on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the fully-qualified domain name in the Subject Alternative Name field of the certificate. The use of a wild-carded domain name on the Identity parameter for the ZoneB_IKED security endpoint requires that a fully-qualified domain name ending with .PCO2.example.com appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.

Rule: For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the RemoteSecurityEndpoint statement, see *z/OS Communications Server: IP Configuration Reference*.

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action:

```
KeyExchangeRule              ZoneB_KeyExRule1
{
   LocalSecurityEndpointRef  Local_IKED
   RemoteSecurityEndpointRef ZoneB_IKED
   KeyExchangeActionRef      Main-RSA-SHA1-3DES-DH2
}
```

9) Include the key exchange rule in the KeyExchangePolicy statement block. Also include the AllowNat parameter:

```
KeyExchangePolicy
{
   AllowNat              Yes
   KeyExchangeRuleRef    ZoneB_KeyExRule1
}
```

b. Configure an IpDynVpnAction statement that defines the parameters of the phase 2 negotiation as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

```
EE traffic - strong encryption: ESP, 3DES
             strong ESP authentication: Hmac SHA1
Normal FTP traffic - strong ESP authentication, Hmac SHA1
```

The partner company model used AH authentication for normal FTP traffic, but the NATT solution defined by the IETF is based on the ESP protocol. The AH protocol is not supported for NATT, and ESP authentication is used in this model.

This information eventually translates into two IpDataOffer statements.

2) Determine whether tunnel or transport mode is required.

Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

3) Configure IpDataOffer statements that define the parameters of the phase 2 negotiation.

- Authenticated offer for FTP:

```
IpDataOffer TRAN-ESPSHA-NOENCR
{
   HowToEncap Transport
   HowToEncrypt DoNot
   HowToAuth    ESP HMAC_SHA1
   RefreshLifetimeProposed 240
```

```
   RefreshLifetimeAccepted 120 480
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

- Encrypted and authenticated offer for EE:

```
IpDataOffer TRAN-ESPSHA-3DES
{
   HowToEncap Transport
   HowToEncrypt 3DES
   HowToAuth    ESP HMAC_SHA1
   RefreshLifetimeProposed 240
   RefreshLifetimeAccepted 120 480
   RefreshLifesizeProposed  none
   RefreshLifesizeAccepted  none
}
```

4) Determine which peer is allowed to initiate the negotiation.

   When an IKE peer is behind a NAT device, there are implications regarding which peer can initiate. In a host-to-host configuration, IKE should only initiate to a peer whose IP address is unambiguous. If the peer is not behind a NAT, or if the peer's NAT mapping is static, the address is unambiguous. In this model, assume that static mapping is being used for both PCO1 and PCO2.

   Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. For PASV mode or EPSV mode FTP, both the FTP control connection and the FTP data connection initiate the negotiation of the Security Association remotely, so local initiation is not required.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation.

   The IpDynVpnAction statement can control which host is allowed to initiate the negotiation. Both the FTP control connection and data connection will be initiated remotely. EE should be allowed to initiate an IKE negotiation locally.

   - Authenticated VPN action for FTP:

```
IpDynVpnAction FTP-vpnaction
{
   Initiation           remoteonly
   InitiateWithPfs      group2
   AcceptablePfs        group2
   VpnLife              1440
   IpDataOfferRef       TRAN-ESPSHA-NOENCR
}
```

   - Encrypted and authenticated VPN action for EE traffic:

```
IpDynVpnAction EE-vpnaction
{
   Initiation           localonly
   InitiateWithPfs      group2
   AcceptablePfs        group2
   VpnLife              1440
   IpDataOfferRef       TRAN-ESPSHA-3DES
}
```

c. Decide how the Security Association is to be activated as follows:

1) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

   Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivated) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

   Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

```
IpLocalStartAction           ZoneB-Start-Action
{
   AllowOnDemand             yes
   LocalPortGranularity      packet
   RemotePortGranularity     packet
   ProtocolGranularity       packet
   LocalIpGranularity        packet
   RemoteIpGranulatiry       packet
   LocalSecurityEndpointRef  Local_IKED
   RemoteSecurityEndpointRef ZoneB_IKED
}
```

   In this example, specifying `packet` for LocalPortGranularity and RemotePortGranularity is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of `rule`. Specifying `packet` is required, however, if the EE rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

3) Set the global PreDecap parameter of the IpFilterPolicy statement to `off`, or create an IpFilterRule statement that allows IPSec traffic (AH and ESP).

   In this example, set `PreDecap off` in the IpFilterPolicy statement

7. Define an IpFilterRule statement for each set of data endpoints.

   The secure host and zone B represent the data endpoints. The IpService statements were defined previously. Place the IpDynVpnAction statements that were created previously with the appropriate rule. Notice that the parameters of the IpGenericFilterAction statement include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec.

```
IpFilterRule              ZoneB-Permitted-traffic
{
   IpSourceAddrRef           PrivateServerAddress
   IpDestAddrSetRef          ZoneB-subnet
   IpServiceRef              IKE-local-500
   IpServiceRef              IKE-local-4500
   IpServiceGroupRef         SecureFTPServer
   IpGenericFilterActionRef  permit-nolog
}

IpFilterRule                 FTPServer-ZoneB
{
   IpSourceAddr              10.1.1.1
```

```
   IPDestAddrSet             9.4.0.0/16
   IpServiceRef              FTPServer-Control
   IpServiceRef              FTPServer-Data-Passive
   IpGenericFilterActionRef  ipsec-nolog
   IpDynVpnAction            FTP-vpnaction
}

IpFilterRule             EE-ZoneB
{
   IpSourceAddr              10.1.1.1
   IPDestAddrSet             9.4.0.0/16
   IpServiceRef              Enterprise-Extender
   IpGenericFilterActionRef  ipsec-nolog
   IpDynVpnAction            EE-vpnaction
   IpLocalStartActionRef     ZoneB-Start-Action
}
```

Because IKE port 500, IKE port 4500, and secure FTP without IPSec protection are permitted, a separate IpFilterRule statement for each is not needed. The services can be combined into one IpFilterRule statement.

Tip: Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.
9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone. Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.
10. Include all configured statements in the stack-specific IP security configuration file.

A completely configured policy, including all objects and their references, is as follows:

```
# IpFilterPolicy for secure public server

IpFilterPolicy
{
   PreDecap             off
   IpFilterGroupRef     ZoneB
}

KeyExchangePolicy
{
   AllowNat             Yes
   NatKeepAliveInterval 0
   KeyExchangeRuleRef   ZoneB_KeyExRule1
}

###### All re-usable statements follow #######
IpFilterGroup           ZoneB
{
   IpFilterRuleRef      ZoneB-Permitted-traffic
   IpFilterRuleRef      FTPServer-ZoneB  #IPSec-protected
   IpFilterRuleRef      EE-ZoneB         #IPSec-protected
}

Steps for configuring the partner company with NAPT model (host-to-host with IPSec)

The following statements and concepts are covered in the discussion of this model:

- Using wildcard values for the remote port for IKE traffic
- NAPT implications for host-to-host dynamic IKE negotiations:
  - Local and remote data endpoints
  - Local and remote security endpoints
  - IKE initiator and responder roles

The partner company model assumed a network topology with both partner companies using public IP addresses in their internal networks. The partner company with NAT model modified the partner company model to include private addressing in the private network of each partner company, with a NAT device in front of each private network. Both NAT devices used static one-to-one address mappings.

The partner company with NAPT model modifies the partner company with NAT model, replacing the NAT device in front of the partner company's internal network with a NAPT device. The NAPT device uses many-to-one address and port mappings. The NAT in front of the z/OS host continues to use static one-to-one address mappings.

Figure 104 shows the partner company with NAPT topology.

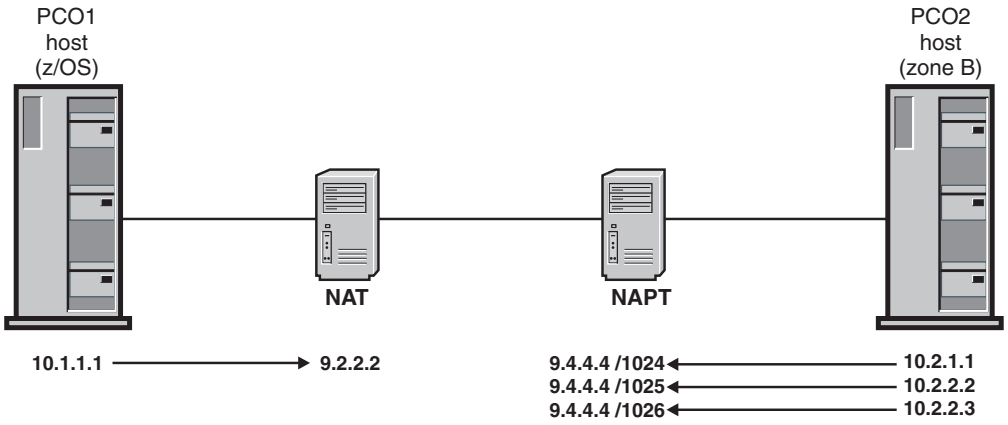

Figure 104. Partner company with NAPT model

The partner company with NAPT model has the same basic security requirements as the partner company with NAT model. One difference is that IPSec protection for Enterprise Extender (EE) traffic has been eliminated from the example. EE

traffic is not compatible with the use of NAPT, with or without IPSec protection. For more information, see "Enterprise Extender considerations when traversing a NAT" on page 1099.

This example includes only the configuration steps that are impacted by a change from static one-to-one address mappings to NAPT mappings. Configuration statements added or changed for the partner company with NAPT model are shown in **bold**. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to enable network communications from a partner company (PCO2) in an untrusted zone B behind a NAPT (9.4.4.4), over a connected network, to a server on this host that is behind a NAT, using static one-to-one address mapping:

- IKE traffic from untrusted zone B is allowed to this host.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPSec tunnel with strong authentication.
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

Starting with the partner company with NAT policy, the following changes need to be made to meet these requirements when there is a NAPT in front of the partner company's internal network (Zone B):

- Modify the IpService statements for the IKE traffic to specify a wildcard value for the remote port. The NAPT will update both the IP address and port values of an IKE packet, so that the traffic can no longer be described with a constant value of 500 or 4500.

```
IpService                     IKE-local-500
{
  SourcePortRange             500
  DestinationPortRange        0
  Protocol                    UDP
  Direction                   bidirectional
  Routing                     local
  SecurityClass               0
}

IpService                     IKE-local-4500
{
  SourcePortRange             4500
  DestinationPortRange        0
  Protocol                    UDP
  Direction                   bidirectional
  Routing                     local
  SecurityClass               0
}
```

- Modify the remote data endpoint to reflect the NAPT's single IP address, 9.4.4.4. The remote data endpoint is the partner company's internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public address should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address 9.4.4.4. Thus, the remote data endpoint is 9.4.4.4.

```
IpAddr    ZoneB
{
   Addr   9.4.4.4
}
```

- Modify the remote security endpoint.

```
RemoteSecurityEndpoint   ZoneB_IKED
{
   Identity      Fqdn  *.PCO2.example.com
   Location      9.4.4.4
   CaLabel       CA4PartnerCompany
}
```

A completely configured policy, including all objects and their references, is as follows:

```
# IpFilterPolicy for secure public server

IpFilterPolicy
{
   PreDecap             off
   IpFilterGroupRef     ZoneB
}

KeyExchangePolicy
{
   AllowNat             Yes
   NatKeepAliveInterval 0
   KeyExchangeRuleRef   ZoneB_KeyExRule1
}

Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)

The following topics are covered in the discussion of this model:

- Host-to-gateway
- Gateway-to-gateway
- Autoactivation
- Command-line activation
- Using wildcards for location and identity
- Pre-shared key peer authentication

Figure 105 shows the branch office portion of the security model network.

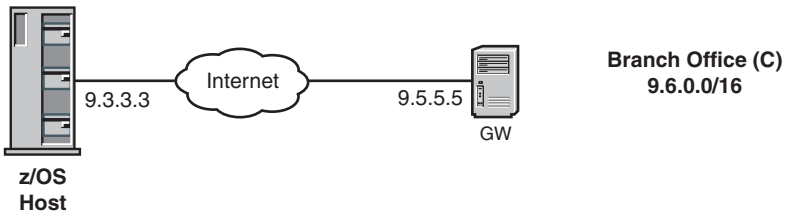

Figure 105. Branch office model

Transport-mode IPSec is used exclusively for transporting encrypted data directly between two hosts. Tunnel-mode IPSec encapsulation must be used if one of the security endpoints is a security gateway routing traffic for any number of hosts. In the branch office model, there can be multiple hosts behind a security gateway that is providing the security mechanism for all hosts that reside behind the security gateway. The base assumption is that the local secure server represents a single data endpoint and a single security endpoint, whereas the remote subnetwork represents multiple data endpoints which share a common security endpoint, namely the security gateway host. Traffic from the local server to the branch office gateway is IPSec protected, while traffic from the branch office gateway to the hosts behind the security gateway need not be encrypted or even filtered.

As in the previous models, a complete IP security policy defines the traffic that is allowed between the local server and the zone representing the branch office. However, the difference lies primarily in where the remote security endpoint is situated. In the previous examples, all of the IPSec protection was provided on a host-to-host basis. Each set of communicating endpoints had a single dynamic VPN that represented a secure channel of communication between two hosts, local and remote. In contrast, any scenario that involves an IPSec security gateway can require that one VPN carry traffic for multiple hosts. This difference is highlighted in this branch office example.

For this example, assume the following requirements to allow network communications from zone C, a branch office network (9.6.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the public branch office gateway server (9.5.5.5).

- Allow IKE traffic from branch office zone C to this host.

- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. The VPN should be up when the stack initializes.
- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. The VPN is command-line activated. Only one VPN should be established to carry all FTP traffic. There will not be one VPN per connection, but rather one Security Association will be negotiated for all of the remote FTP clients.

  Restriction: Negotiating a single Security Association for multiple remote clients is possible only when the remote security endpoint is acting as a secure gateway.
- Peers authenticate themselves using the pre-shared key method.

Perform the following steps to meet these requirements and configure part 1 of the branch office model.

1. Determine the number of zones to be protected.

   The branch office represents one zone, zone C.

2. For each zone, determine what services are allowed and define an IpService block for each desired service. Services are defined by their protocols and the well-known ports they use.

   The definitions that describe FTP traffic can be combined in an IP service group as follows:

```
IpServiceGroup               FTPServer
{
  IpService                  FTPServer-Control
  {
    SourcePortRange            21
    Protocol                   tcp
    Direction                  bidirectional InboundConnect
    Routing                    local
    SecurityClass              0
  }
  IpService                  FTPServer-Data
  {
    SourcePortRange            20
    Protocol                   tcp
    Direction                  bidirectional OutboundConnect
    Routing                    local
    SecurityClass              0
  }
  IpService                  FTPServer-Data-Passive
  {
    SourcePortRange            50000 50200
    Protocol                   tcp
    Direction                  bidirectional InboundConnect
    Routing                    local
    SecurityClass              0
  }
}
```

   The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

```
IpService                    Enterprise-Extender
{
  SourcePortRange            12000 12004
  DestinationPortRange       12000 12004
  Protocol                   udp
  Direction                  bidirectional
  Routing                    local
  SecurityClass              0
}
```

3. Determine the data endpoints to be protected. Typically, this is both a local and remote IP address or subnetwork.

   In this example, for the local host's public IP address, 9.3.3.3, define the following:

```
IpAddr                      PublicServerAddressA1
{
  Addr                      9.3.3.3
}
```

   For the remote subnet, 9.6.0.0/16, the following is defined:

```
IpAddrSet                   SubnetC
{
  Prefix                    9.6.0.0/16
}
```

   Because it is necessary to permit IKE traffic between the local public server and the remote branch office gateway, the IP address of the remote gateway must also be defined as follows:

```
IpAddr                      BranchOfficeGateway
{
  Addr                      9.5.5.5
}
```

4. Determine what level of security is needed between each set of data endpoints.

   In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:

```
IpGenericFilterAction       ipsec
{
  IpFilterAction            ipsec
}
```

6. If IPSec is required between any two endpoints, do the following:

   a. Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

      1) Determine the required type and strength of protection for the phase 1 Security Association.

         In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used because it is stronger than DES and equivalent to 3DES. Diffie-Hellman Group5 and Group14 are considered strong enough to generate keying material for AES using a 128 bit key. Group14 is used in this example..

      2) Decide what type of peer authentication to use.

         In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

      3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

```
KeyExchangeOffer              SHA1-AES-PSK
{
  HowToEncrypt                AES_CBC KeyLength 128
  HowToAuthMsgs               SHA1
  HowToAuthPeers              PresharedKey
  DHGroup                     Group14
}
```

4) Decide whether NAT traversal will be allowed.

   In this example, the following parameter is used:

   ```
   AllowNat No
   ```

5) Determine the negotiation mode, Main or Aggressive.

   Because security is a priority in the branch office model, the more secure Main mode is used for the phase 1 negotiation.

6) Configure a KeyExchangeAction statement as follows:

   ```
   KeyExchangeAction             Gold-PSK
   {
     HowToInitiate               main
     HowToRespondIKEv1           main
     KeyExchangeOfferRef         SHA1-AES-PSK
   }
   ```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

   ```
   LocalSecurityEndpoint         Public_IKED
   {
     Identity                    IpAddr 9.3.3.3
     LocationRef                 PublicServerAddressA1
   }

   RemoteSecurityEndpoint        ZoneC_IKED
   {
     Identity                    Fqdn gateway.BO.example.com
     LocationRef                 BranchOfficeGateway
   }
   ```

8) Configure a KeyExchangeRule statement that includes the two endpoints, the key exchange action, and the pre-shared key as follows:

   ```
   KeyExchangeRule               ZoneC_KeyExRule1
   {
     LocalSecurityEndpointRef    Public_IKED
     RemoteSecurityEndpointRef   ZoneC_IKED
     KeyExchangeActionRef        Gold-PSK
     PresharedKey                abracadabra
   }
   ```

9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

   ```
   KeyExchangePolicy
   {
       KeyExchangeRuleRef          ZoneC_KeyExRule1
   }
   ```

b. Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

   1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

      In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

   2) Determine whether tunnel or transport mode is required.

Tunnel mode is required when one of the security endpoints is a security gateway.

3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```
IpDataOffer                 SHA-AES-Tunnel
{
  HowToEncap                tunnel
  HowToEncrypt              AES_CBC KeyLength 128
  HowToAuth                 ESP HMAC_SHA1
}
```

4) Determine which peer is allowed to initiate the negotiation.

   Because the EE VPN is up when the stack starts, you need to be able to start the negotiation locally (that is, autoactivate it). The FTP VPN is command-line activated, so you need to be able to start the negotiation locally.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```
IpDynVpnAction              Gold-TunnelMode
{
  Initiation                either
  InitiateWithPfs           group2
  AcceptablePfs             group2
  IpDataOfferRef            SHA-AES-Tunnel
}
```

c. Decide how the Security Association is activated.

1) Optionally, configure a local dynamic VPN policy, if command-line activated or autoactivated.

   A LocalDynVpnRule statement is required for each Security Association because none are on-demand activated, five for the EE traffic and two for the FTP traffic, as follows:

```
LocalDynVpnRule             ZoneC_VPN-EE1
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             12000
   RemoteDataPort            12000
   Protocol                  UDP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-EE2
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             12001
   RemoteDataPort            12001
   Protocol                  UDP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-EE3
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             12002
   RemoteDataPort            12002
   Protocol                  UDP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-EE4
```

```
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             12003
   RemoteDataPort            12003
   Protocol                  UDP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-EE5
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             12004
   RemoteDataPort            12004
   Protocol                  UDP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-FTP-Data
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             20
   RemoteDataPort            0
   Protocol                  TCP
   AutoActivate              Yes
}

LocalDynVpnRule             ZoneC_VPN-FTP-Control
{
   LocalIpRef                PublicServerAddressA1
   RemoteIpSetRef            SubnetC
   LocalDataPort             21
   RemoteDataPort            0
   Protocol                  TCP
   AutoActivate              Yes
}
```

2) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

   If the local secure server initiates an IKE negotiation, it must be able to identify a remote IKE peer. However, in this case, the remote data endpoint is not a single host, but multiple endpoints in a subnetwork, ZoneC. The IpLocalStartAction statement is used to identify the remote IKE peer, and is required if the local IKE daemon initiates an ipsec connection with a remote security gateway.

```
IpLocalStartAction            StartZoneC
{
   RemoteSecurityEndpointRef  ZoneC_IKED
}
```

3) Create an IpFilterRule statement that allows IPSec traffic (AH and ESP), or set the global IpFilterPolicy statement parameter PreDecap to `off`.

   In this example, `PreDecap off` is used in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints. The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to

the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500. See the IpAddr and IpAddrSet statements configured in step 3 on page 1077.

```
IpFilterRule                Rule1C
{
   IpSourceAddrRef           PublicServerAddressA1
   IpDestAddrRef             BranchOfficeGateway
   IpServiceRef              IKE
   IpGenericFilterActionRef  permit
}

IpFilterRule                Rule2C
{
   IpSourceAddrRef           PublicServerAddressA1
   IpDestAddrSetRef          SubnetC
   IpServiceRef              Enterprise-Extender
   IpServiceGroupRef         FTPServer
   IpGenericFilterActionRef  ipsec
   IpDynVpnActionRef         Gold-TunnelMode
   IpLocalStartActionRef     StartZoneC
}
```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.
9. Include all IpFilterGroup references and, optionally, any additional IpFilterRule statements as needed, in the IpFilterPolicy block.
10. Include all configured statements in the stack-specific IP security configuration file.

Following is a complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements have been included in the common IP security configuration file:

```
#------------------------------------------------------
# Filter Policy for Secure Server
#------------------------------------------------------
IpFilterPolicy
{
  PreDecap                  off
  FilterLogging             on
  AllowOnDemand             no
  IpFilterGroupRef          ZoneC
}

#------------------------------------------------------
# KeyExchange Policy for Secure Server
#------------------------------------------------------
KeyExchangePolicy
{
  KeyExchangeRuleRef        ZoneC_KeyExRule1
}

#------------------------------------------------------
# LocalDynVpn Policy for Secure Server
#------------------------------------------------------
LocalDynVpnPolicy
{
  LocalDynVpnGroupRef       ZoneC_BranchOfficeVPNs
}

######################################################

      AutoActivate              Yes
    }
}
```

Steps for configuring the branch office with NAT model (host-to-gateway with IPSec)

The following NAT implications for host-to-gateway dynamic IKE negotiations are covered in the discussion of this model:

- Local and remote data endpoints
- Local and remote security endpoints
- IKE initiator and responder roles
- Restriction on HowToAuth protocol (AH not supported)

"Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)" on page 1075 assumed a network topology with both the host and the security gateway, as well as the hosts behind the security gateway, using public IP addresses. Often one or both security endpoints are behind a NAT utilizing a private IP address.

Modifying the branch office model topology to include a NAT in front of the security gateway, the branch office with NAT topology becomes as shown in Figure 106:

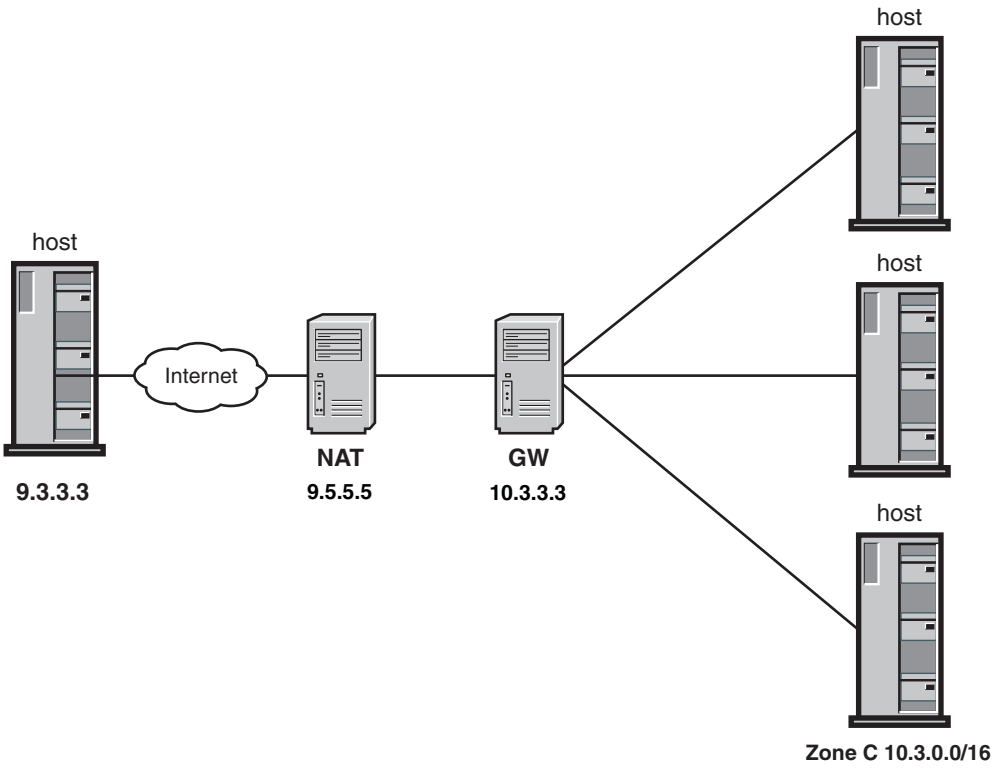

Figure 106. Branch office with NAT model

This example will describe the configuration considerations and requirements when the NATT solution is implemented to traverse NAT devices in a

host-to-security gateway environment. The branch office with NAT model has the same basic security requirements as the branch office model. Configuration statements added or changed for the branch office with NAT model are shown in **bold**. The example describes the policy for host 9.3.3.3.

For this example, assume the following requirements to enable network communications from zone C, a branch office network using private IP addresses (10.3.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the branch office gateway server, which is behind a NAT. In this model, the NAT has a static mapping of the security gateway's private address 10.3.3.3 to the public address 9.5.5.5.

- Allow IKE traffic from the branch office zone C security gateway to this host.
- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. Only one host behind the security gateway (branch office zone C) will be able to send EE traffic.

  Guideline: In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.

  In "Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)" on page 1075, the VPN was brought up when the z/OS stack initialized by setting the AutoActivate parameter to Yes on the LocalDynVpnRule statement. In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-Encapsulated-Tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.
- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. In "Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)" on page 1075, the VPN was activated by an administrator from the z/OS UNIX command line. Again, z/OS does not allow initiation of a UDP-Encapsulated-Tunnel mode Security Association to a security gateway. The Security Associations between the security gateway and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as the responder.
- Peers authenticate themselves using the pre-shared key method.

Perform the following steps to meet these requirements and configure the branch office with NAT model.

1. Determine the number of zones to be protected.

   The branch office represents one zone, zone C.

2. For each zone, determine what services are allowed and define an IpService block for each desired service. Services are defined by their protocols and the well-known ports that they use.

   The definitions that describe FTP traffic can be combined in an IP service group. Typically, FTP clients use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server when the client is behind a NAT. For more information on active and passive mode FTP, see "Considerations for IPSec-encapsulated FTP traffic when traversing a NAT" on page 1098.

The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server's FTP.DATA file. For more information on PASSIVEDATAPORTS, see *z/OS Communications Server: IP Configuration Reference*.

The following definitions show the services required for the server for PASV or EPSV:

```
IpServiceGroup              FTPServer
{
  IpService                 FTPServer-Control
  {
    SourcePortRange           21
    Protocol                  tcp
    Direction                 bidirectional InboundConnect
    Routing                   local
    SecurityClass             0
  }
  IpService                 FTPServer-Data-Passive
  {
    SourcePortRange           50000 50200
    Protocol                  tcp
    Direction                 bidirectional InboundConnect
    Routing                   local
    SecurityClass             0
  }
}
```

The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

```
IpService                   Enterprise-Extender
{
  SourcePortRange           12000 12004
  DestinationPortRange      12000 12004
  Protocol                  udp
  Direction                 bidirectional
  Routing                   local
  SecurityClass             0
}
```

3. Determine the data endpoints to be protected.

   In this example, for the local host's public IP address, 9.3.3.3, define the following:

```
IpAddr                      PublicServerAddressA1
{
  Addr                      9.3.3.3
}
```

   In this case, the remote data endpoints are in the branch office's internal network. The z/OS NATT implementation does not require the coding of private addresses for the remote endpoints. Instead, the security gateway's public address is treated as the remote data endpoint. The NAT is using a static mapping for the security gateway, so the public address of the gateway is specified. If the NAT was using dynamic mappings, the range of public IP addresses to which the security gateway could be mapped would need to be included in this definition.

```
IpAddr                      BranchOfficeGateway
{
  Addr                      9.5.5.5
}
```

   This IP address is also needed to permit IKE traffic between the local public server and the remote branch office gateway.

4. Determine what level of security is needed between each set of data endpoints.

   In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used. ESP must be used when NAT traversal support is being used.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:

```
IpGenericFilterAction        ipsec
{
  IpFilterAction             ipsec
}
```

6. If IPSec is required between any two endpoints, do the following:

   a. Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

      1) Determine the required type and strength of protection for the phase 1 Security Association.

         In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used because it is as secure as 3DES.

      2) Decide what type of peer authentication to use.

         In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

      3) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

```
KeyExchangeOffer             SHA1-AES-PSK
{
  HowToEncrypt               AES_CBC KeyLength 128
  HowToAuthMsgs              SHA1
  HowToAuthPeers             PresharedKey
  DHGroup                    Group14
}
```

      4) Decide whether NAT traversal will be allowed.

         The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements enables the IKED to advertise NAT traversal support. For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by specifying Yes on the AllowNat parameter on the KeyExchangePolicy statement:

```
AllowNat Yes
```

         For this model, use the NatKeepAliveInterval parameter default value, 20 seconds. When z/OS is behind a NAT, a NAT keep-alive timer is started, with the interval specified in NatKeepAliveInterval parameter on the KeyExchangePolicy statement. Because z/OS is not behind a NAT in this model, a NAT keep-alive is not kept regardless of the value specified or the default for NatKeepAliveInterval.

      5) Determine the negotiation mode, Main or Aggressive.

Because security is a priority in the branch office with NAT model, the more secure Main mode is used for the phase 1 negotiation.

6) Configure a KeyExchangeAction statement as follows:

```
KeyExchangeAction            Gold-PSK
{
  HowToInitiate              main
  HowToRespondIKEv1          main
  KeyExchangeOfferRef        SHA1-AES-PSK
}
```

7) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

```
LocalSecurityEndpoint        Public_IKED
{
  Identity                   IpAddr 9.3.3.3
  LocationRef                PublicServerAddressA1
}

RemoteSecurityEndpoint       ZoneC_IKED
{
  Identity                   Fqdn gateway.BO.example.com
  LocationRef                BranchOfficeGateway
}
```

8) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action, as follows:

```
KeyExchangeRule              ZoneC_KeyExRule1
{
  LocalSecurityEndpointRef   Public_IKED
  RemoteSecurityEndpointRef  ZoneC_IKED
  KeyExchangeActionRef       Gold-PSK
  PresharedKey               abracadabra
}
```

9) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

```
KeyExchangePolicy
{
    AllowNat                 Yes
    KeyExchangeRuleRef       ZoneC_KeyExRule1
}
```

b. Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

1) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

2) Determine whether tunnel or transport mode is required.

Tunnel mode is required when one of the security endpoints is a security gateway.

3) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```
IpDataOffer                  SHA-AES-Tunnel
{
  HowToEncap                 tunnel
  HowToEncrypt               AES_CBC KeyLength 128
  HowToAuth                  ESP HMAC_SHA1
}
```

4) Determine which peer is allowed to initiate the negotiation.

In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-Encapsulated-Tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.

5) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```
IpDynVpnAction              Gold-TunnelMode
{
  Initiation                remoteonly
  InitiateWithPfs           group2
  AcceptablePfs             group2
  IpDataOfferRef            SHA-AES-Tunnel
}
```

c. Decide how the Security Association is activated.

1) Only remote initiation of the Security Association is allowed, as specified for the Initiation parameter on the Gold-TunnelMode IpDynVpnAction statement. No LocalDynVpnRule or IpLocalStartAction statements are needed.

2) Create an IpFilterRule statement that allows IPSec traffic (ESP), or set the global IpFilterPolicy statement parameter PreDecap to `off`.

In this example, `PreDecap off` is used in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints. The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500 and 4500). See the IpAddr and IpAddrSet statements configured previously.

```
IpFilterRule                Rule1C
{
   IpSourceAddrRef           PublicServerAddressA1
   IpDestAddrRef             BranchOfficeGateway
   IpServiceRef              IKE-local-500
   IpServiceRef              IKE-local-4500
   IpGenericFilterActionRef  permit
}

IpFilterRule                Rule2C
{
   IpSourceAddrRef           PublicServerAddressA1
   IpDestAddrRef             BranchOfficeGateway
   IpServiceRef              Enterprise-Extender
   IpServiceGroupRef         FTPServer
   IpGenericFilterActionRef  ipsec
   IpDynVpnActionRef         Gold-TunnelMode
}
```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.

9. Include all IpFilterGroup references and, optionally, any additional IpFilterRule statements as needed, in the IpFilterPolicy block.

10. Include all configured statements in the stack-specific IP security configuration file.

The following is the complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements have been included in the common IP security configuration file:

```
#------------------------------------------------------
# Filter Policy for Secure Server
#------------------------------------------------------
IpFilterPolicy
{
  PreDecap                  off
  FilterLogging             on
  AllowOnDemand             no
  IpFilterGroupRef          ZoneC
}

#------------------------------------------------------
# KeyExchange Policy for Secure Server
#------------------------------------------------------
KeyExchangePolicy
{
  AllowNat                  Yes
  KeyExchangeRuleRef        ZoneC_KeyExRule1
}

######################################################
#               Connectivity Profile
#              Secure Server To Zone C
#
#   Server to Trusted Branch Office Network
#
######################################################
IpFilterGroup               ZoneC
{
   #-----------------------------------------------------
   # Permitted Zone C traffic:
   #    Allow IKE traffic from the gateway IKE Server
   #    for branch office to this host.
   #
   #    IKE  (UDP port 500/4500) - IKE negotiations
   #-----------------------------------------------------

   IpFilterRule               Rule1C
   {
     IpSourceAddrRef          PublicServerAddressA1
     IpDestAddrRef            BranchOfficeGateway
     IpServiceGroupRef        IKE
     IpGenericFilterActionRef permit
   }

   #-----------------------------------------------------
   # IPSec-protected Zone C traffic:
   #
   #    Enterprise Extender (ports 12000-12004)
   #    FTP Server - SubnetC to PublicServerAddressA
   #-----------------------------------------------------

   IpFilterRule               Rule2C
   {
     IpSourceAddrRef          PublicServerAddressA1
     IpDestAddrRef            BranchOfficeGateway
     IpServiceRef             Enterprise-Extender
     IpServiceGroupRef        FTPServer
     IpGenericFilterActionRef ipsec
     IpDynVpnActionRef        Gold-TunnelMode
   }
}
```

```
KeyExchangeRule              ZoneC_KeyExRule1
{
  LocalSecurityEndpointRef   Public_IKED
  RemoteSecurityEndpointRef  ZoneC_IKED
  KeyExchangeActionRef       Gold-PSK
  PresharedKey               abracadabra
}
```

Steps for configuring the branch office model: Part 2 (gateway-to-gateway with IPSec)

It is not likely that the z/OS system will function strictly as a router or a firewall at the network perimeter, but it is possible to configure the z/OS system to provide the IPSec functionality that many secure gateway devices provide. This topic includes instructions on how to configure a scenario in which the z/OS system is routing network traffic from inside the internal network. This functionality is similar to the functionality that is provided by the branch office gateway in "Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)" on page 1075. Here, there are multiple data endpoints on both the local side and the remote side, but only one pair of security endpoints, one local and one remote.

In this example, assume that the local z/OS system is acting as a secure gateway for hosts on an internal network A, and tunneling the IPSec-protected traffic to a remote secure gateway for subnetwork C. The following summarizes the requirements for this example:

- Permit IKE negotiations between the two security gateways, the secure local host and the secure remote gateway for subnetwork C.
- Permit traffic from the internal network to the internal interface on the secure local host.
- Add IPSec protection to any traffic that flows between the two secure gateways.

In this scenario, the z/OS system is a secure forwarding agent for the internal hosts, rather than a data endpoint. Traffic from the internal hosts that is destined for the remote network first comes to the secure local gateway in the clear. Before it is sent out to the remote network, it is IPSec encapsulated. The process is reversed for traffic that comes from the remote network. Traffic that comes from the remote network to the local secure gateway is IPSec decapsulated on the local secure host and forwarded to the internal host in the clear.

Perform the following steps to meet the above requirements and configure part 2 of the branch office model.

1. Permit IKE negotiations between the two secure gateways.

   UDP port 500 traffic must be allowed for IKE negotiations.

   ```
   IpFilterRule                 Rule1AtoC
   {
        IpSourceAddrRef           PublicServerAddressA1
        IpDestAddrRef             BranchOfficeGateway
        IpServiceRef              IKE
        IpGenericFilterActionRef  permit
   }
   ```

2. Permit traffic from the internal network to the internal interface on the secure host.

   ```
   IpFilterRule                 Rule2AtoC
   {
        IpSourceAddrSetRef        SubnetC
   ```

```
    IpDestAddrSetRef           InternalNetworkA
    IpServiceGroupRef          All-traffic-routed
    IpGenericFilterActionRef   permit
}
```

The bidirectional keyword on the IpService statement creates two filter rules, one inbound and one outbound. Expansion of this IpFilterRule statement is shown in Table 47.

Table 47. Expanded filter rule for internal traffic

Source	Destination	Routing	Direction	Action
SubnetC	InternalNetworkA	Routed	Outbound	permit
InternalNetworkA	SubnetC	Routed	Inbound	permit

As required, traffic that enters the secure server from InternalNetworkA that is destined for SubnetC is permitted by the secure host as an inbound routed packet. Traffic that leaves the secure server from SubnetC destined for InternalNetworkA is permitted by the secure host as an outbound routed packet.

3. Add IPSec protection to any traffic that flows between the two secure gateways.

```
IpFilterRule                Rule3AtoC
{
    IpSourceAddrSetRef         InternalNetworkA
    IpDestAddrSetRef           SubnetC
    IpServiceGroupRef          All-traffic-routed
    IpGenericFilterActionRef   ipsec-log
}
```

Expansion of this rule is shown in Table 48.

Table 48. Expanded filter rule for remote traffic

Source	Destination	Routing	Direction	Action
InternalNetworkA	SubnetC	Routed	Outbound	ipsec
SubnetC	InternalNetworkA	Routed	Inbound	ipsec

Traffic that leaves the secure server from InternalNetworkA that is destined for SubnetC is permitted with ipsec. Traffic that enters the secure server from SubnetC that is destined for InternalNetworkA is permitted with ipsec.

Additional topologies

There are alternative security models that might be suitable for particular networks. Each of these configurations is supported by z/OS IP security.

Cascaded tunnels: If there are multiple hops from data endpoint to data endpoint, there might be Security Associations between any two hosts along the path. For example, the data might be authenticated from a host to the secure gateway, then encrypted for transportation over the Internet, then possibly authenticated and encrypted from the second secure gateway to the host on the other side, as shown in Figure 107 on page 1093:

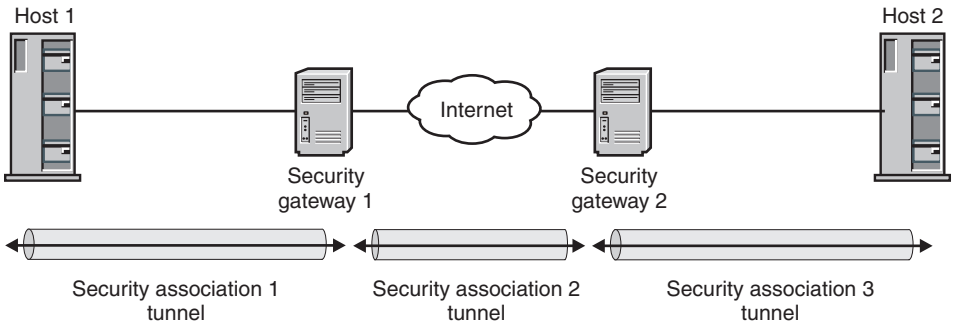

Figure 107. Cascaded tunnels

Nested tunnels: In a nested environment, data is encapsulated multiple times over multiple hops. If the local and remote hosts are both behind a secure gateway, there could be a tunnel-mode Security Association that carries the traffic from one secure gateway to the other. Meanwhile, a transport-mode Security Association could carry the traffic from one host to the other, end-to-end. In this case, the transport-mode Security Association is nested in the tunnel-mode Security Association. Data from the local host is encapsulated once when leaving the local machine, encapsulated again at the secure gateway, decapsulated at the other secure gateway, and decapsulated one final time at the remote host, leaving only the original packet.

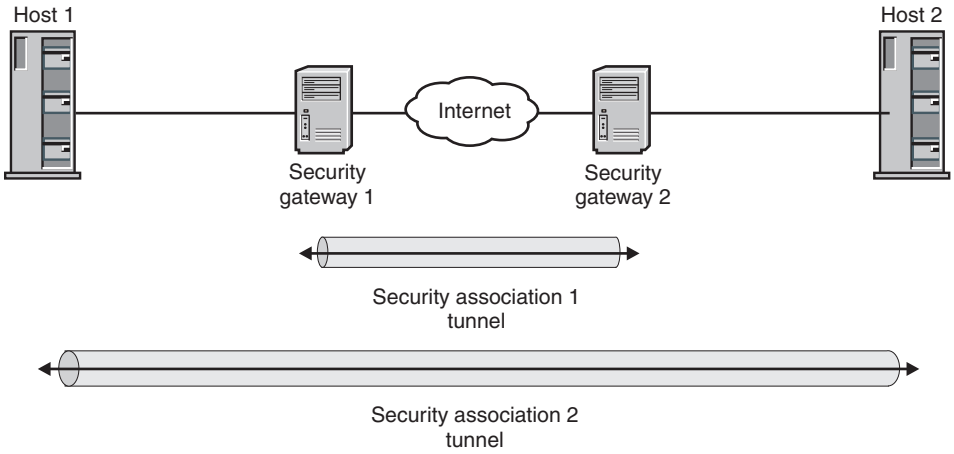

Figure 108. Nested tunnels

Mobile users: Mobile users represent a unique security model, because their IP address is not fixed and can be unpredictable. Instead of selecting traffic based on remote IP address, the mobile user's IKE identity can be used to select traffic. IPSec protection is required so that the IKE identity is known. You configure this security model similarly to other security models that require IPSec protection, except that the peer's remote identity is indicated on the RemoteIdentity parameter of the IpFilterRule statement, and the IpDestAddr parameter typically uses a wildcard value to indicate all addresses.

Multicast traffic: Multicast traffic can be protected by IPSec, but only manual tunnels are supported because the IKED supports negotiating dynamic tunnels with only a single peer rather than with a group of peers.

Multicast traffic is one-to-many (sent by individual nodes but received by multiple nodes) and is normally both sent and received; therefore, to use manual tunnels for

multicast, you must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. You must coordinate the SPI values and keys that are used with all multicast peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify `any` or `any6` for the local and remote security endpoint locations. The following example shows AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```
IpManVpnAction tunnel-multicast
   {
     LocalSecurityEndpointAddr  any
     RemoteSecurityEndpointAddr any
     HowToAuth                  AH HMAC_SHA1
       AuthOutboundSa      2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
       AuthInboundSa       2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
     HowToEncrypt               DES
       EncryptOutboundSa   2701 0x3e6dcf72459ef551
       EncryptInboundSa    2701 0x3e6dcf72459ef551
     HowToEncap                 transport
   }
```

Requirement: You must define two filter rules for the multicast traffic. The first rule matches outbound multicast traffic, which has a unicast source address and a multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is unicast, and a local (source) address that is multicast. The addresses of the inbound rule are reversed from those that you might expect, because bidirectional rules are written from an outbound perspective. These rules are as follows:

```
IpFilterRule outbound-multicast
   {
     IpSourceAddrSetRef       lan-home-address
     IpDestAddr               224.0.0.1
     IpServiceRef             service-udp
     IpGenericFilterActionRef ipsec-nolog
     IpManVpnActionRef        tunnel-multicast
   }
   IpFilterRule inbound-multicast
   {
     IpSourceAddr             224.0.0.1
     IpDestAddr               lan-subnet
     IpServiceRef             service-udp
     IpGenericFilterActionRef ipsec-nolog
     IpManVpnActionRef        tunnel-multicast
   }
```

It is possible to restrict the tunnel to the multicast address that is being used. Define separate tunnels for different multicast addresses while using the same SPI value (the combination of address and SPI makes the tunnel unique). Because the local system is expected to participate in both sending and receiving multicast messages, you must create two manual tunnels. Following is an example of this approach. In this example, one endpoint address is known for each tunnel, so you specify that address for the given security endpoint address.

```
IpManVpnAction tunnel-multicast-outbound
   {
     LocalSecurityEndpointAddr  any
     RemoteSecurityEndpointAddr 224.0.0.1
     HowToAuth                  AH HMAC_SHA1
       AuthOutboundSa      2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
       AuthInboundSa       2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
     HowToEncrypt               DES
       EncryptOutboundSa   2701 0x3e6dcf72459ef551
       EncryptInboundSa    2701 0x3e6dcf72459ef551
```

```
  HowToEncap                 transport
}
IpManVpnAction tunnel-multicast-inbound
{
  LocalSecurityEndpointAddr  224.0.0.1
  RemoteSecurityEndpointAddr any
  HowToAuth                  AH HMAC_SHA1

  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-multicast-inbound
}
```

Tip: Configuration of manual tunnels for IPv6 multicast is similar. For specific examples of configuring this for OSPFv3 security, see “Considerations for IPv6 OSPF security” on page 942.

Configuration scenarios supported for NAT traversal

Communications Server can act as a host Security Association endpoint for UDP-encapsulated mode Security Associations that are negotiated to enable IPSec traffic to traverse a NAT. The partner company with NAT model and the partner company with NAPT model describe Communications Server's host-to-host support. The branch office with NAT model describes Communications Server's host-to-security gateway support.

Rule: Communications Server does not support acting as a security gateway endpoint for UDP-Encapsulated-Tunnel mode Security Associations. This is different than the Communications Server support provided for tunnel mode Security Associations, where Communications Server can act as a security gateway, although Communications Server is not typically deployed in this manner.

The figures in the subtopics show z/OS configuration support for UDP-encapsulated Security Associations. A Security Association is negotiated by two IKE peers, with one initiating the negotiation and the other acting in responder mode. The location of the NAT, and the NAT's functionality, affect which IKE peer can initiate the Security Association. A traditional dynamic NAT implementation requires outbound traffic to be sent first to create an address mapping, before inbound traffic can be accepted. The dynamic NAT can be creating one-to-one address mappings from a dynamic pool of public IP addresses, or creating many-to-one address port mappings using a single public IP address and a pool of port values. When an IKE responder is behind a NAT, the NAT's address mapping must be static, allowing inbound traffic for the address to be received prior to outbound traffic being sent.

Host-to-host scenario 1 — z/OS-to-z/OS: Figure 109 shows a NAT in front of both z/OS hosts. A configuration with a NAT in front of only one of the z/OS hosts is supported as well. If there is a NAT device in front of the responder, the NAT's address mapping must be static. If there is a NAT device in front of the initiator, the NAT's address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

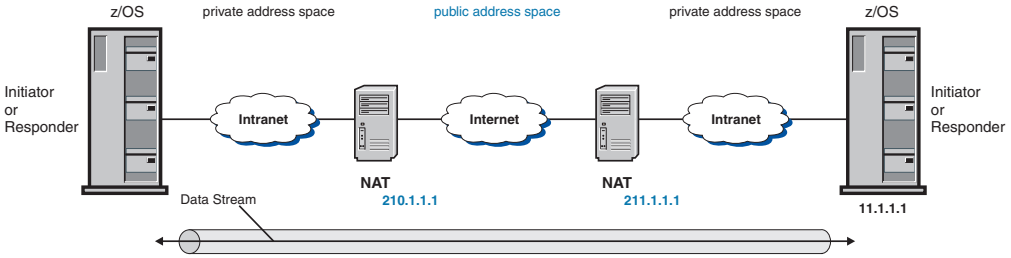

Figure 109. z/OS host to z/OS host, double NAT

Either UDP-Encapsulated-Transport mode or UDP-Encapsulated-Tunnel mode can be negotiated in a z/OS host-to-z/OS host configuration.

Rule: The z/OS host is limited to acting in responder mode when the remote endpoint is behind a NAPT. The negotiation of the phase 1 and phase 2 Security Associations must be initiated by the client behind the NAPT. Data must be initiated by the client behind the NAPT.

Host-to-host scenario 2 — z/OS-to-non-z/OS: Figure 110 shows a NAT in front of the z/OS host and the non-z/OS host. A configuration with a NAT in front of only one of the hosts is supported as well. If there is a NAT device in front of the responder, the NAT's address mapping must be static. If there is a NAT device in front of the initiator, the NAT's address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

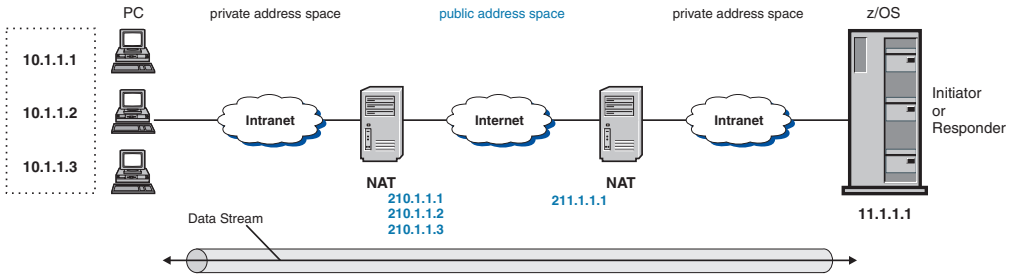

Figure 110. z/OS host to non-z/OS host, double NAT

Either UDP-Encapsulated-Transport mode or UDP-Encapsulated-Tunnel mode can be negotiated in a z/OS host-to-non-z/OS host configuration.

Rule: The z/OS host is limited to acting in responder mode when the remote endpoint is behind a NAPT. The negotiation of the phase 1 and phase 2 Security Associations must be initiated by the client behind the NAPT. Data must be initiated by the client behind the NAPT.

Interoperability Considerations: z/OS is typically used to provide a server function. The client initiates the phase 2 Security Association and data, with z/OS acting in

the role of IKE responder and data responder. z/OS provides robust NAT traversal responder support, allowing it to interoperate with a variety of clients.

z/OS can also act as the initiator of the phase 2 Security Association and data. Potential incompatibilities exist in the following cases, depending on the support of the non-z/OS peer:

- Phase 2 Security Associations that protect specific ports, protocols, or both. When initiating such a phase 2 Security Association, z/OS represents the data being protected by the Security Association with the following:
  - The local IP address as it appears in the home list. This could be a private IP address if z/OS is behind a NAT.
  - The client's public IP address. If the client is behind a NAT, this would be the client's public address.
  - The specific port and protocol values.

  The Phase 2 Security Association negotiation should succeed if the non-z/OS peer supports receiving this specification.
- Tunnel mode phase 2 Security Associations that protect all ports and protocols. When initiating such a phase 2 Security Association, z/OS does not explicitly include the IP addresses of the data being protected in the negotiation of the Security Association. This allows the non-z/OS peer to view the protected data in terms of the IP addresses that it understands, the public address of the remote endpoint and the private address of the local endpoint. The phase 2 Security Association negotiation is expected to be successful.

  If data is initiated from z/OS over the Security Association, the data packet contains:
  - The local IP address as it appears in the home list. This could be a private IP address if z/OS is behind a NAT.
  - The client's public IP address. If the client is behind a NAT, this would be the client's public address.

  If the non-z/OS peer supports receiving a packet with these IP addresses, the data flow should be successful. Once z/OS receives data packets from the non-z/OS peer, z/OS will send packets containing the IP addresses used by the peer.

Host-to-security gateway scenario: Figure 111 on page 1098 shows both the security gateway and the host behind a NAT. z/OS also supports acting in responder mode when only one endpoint (either the security gateway or the z/OS host) is behind a NAT. When there is a NAT device in front of the z/OS host (acting as responder), the address mapping of the NAT must be static. If there is a NAT device in front of the security gateway, the address mapping of the NAT can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

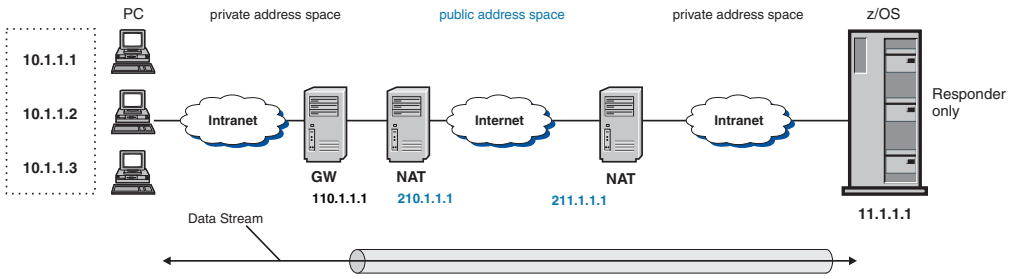

Figure 111. z/OS in a host-to-security gateway configuration

Rule: The z/OS host is limited to acting in responder mode in a host-to-security gateway configuration when a NAT is traversed. The phase 2 Security Association negotiation must be initiated by the security gateway. Data must be initiated by the client behind the security gateway.

Figure 111 shows the clients and the security gateway as separate devices. However, whenever a Security Association is negotiated to protect something other than a single IP address (for example, a range of IP addresses), that IKE daemon negotiating the Security Association is acting as a security gateway.

When the security gateway is behind a NAT, the individual hosts behind the NAT cannot be distinguished. If only one NAT address is available, all Security Associations negotiated between the security gateway (GW) and z/OS are negotiated using the NAT address, and have the same security characteristics. If multiple security characteristics are required to protect the traffic behind the security gateway, more NAT addresses are needed so that z/OS can locate different policies based on the NAT address.

Considerations for IPSec-encapsulated FTP traffic when traversing a NAT: FTP requires both a control connection and a data connection. For active-mode FTP, the client initiates the control connection and provides IP address and port information for the server to initiate the data connection. If the client is behind a NAT, the client provides its private IP address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

Rule: When the FTP client is behind a NAT, you must use passive-mode FTP.

For passive-mode FTP, the client initiates the control connection. When a file transfer is to be started, the client sends a passive (PASV) command to the server. In response to the PASV command, the server provides the IP address and port information for establishing the data connection. The client is then able to initiate the data connection to the IP address and port.

When the FTP server is behind a NAT, the IP address provided in the PASV response is its private address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

Rule: When the FTP server is behind a NAT, you must use extended passive-mode FTP.

Extended passive-mode FTP eliminates the IP address from the FTP data. The server provides the port for the data connection, and the client connects to the same IP address that was used for the control connection.

The z/OS FTP client and server support extended passive-mode FTP using the EPSV command. If you are using the z/OS FTP client and the FTP server that you are accessing does not support the EPSV command, you can configure the PASSIVEIGNOREADDR statement for the z/OS FTP client and use passive-mode FTP, which is widely supported. The PASSIVEIGNOREADDR statement directs the z/OS FTP client to ignore the IP address in the PASV reply, and to connect to the same IP address used for the control connection.

For more information about FTP, see Chapter 12, "Transferring files using FTP," on page 659. For a sample FTP.DATA data set, or for information about the LOCSIte subcommand, see *z/OS Communications Server: IP User's Guide and Commands*.

Enterprise Extender considerations when traversing a NAT: The implementation of Enterprise Extender (EE) requires that the EE connection endpoints be defined by unique static VIPA addresses. NAT functions are limited in the EE environment as follows:

- The NAT mapping must be a one-to-one address mapping. NAPT is not supported.
- Dynamic mappings are generally unreliable for an EE connection. A static mapping of internal IP address to external IP address should be defined when an EE endpoint is behind a NAT.
- When IPSec protection is added for EE traffic that traverses a NAT, only one host that is behind a security gateway that is behind a NAT will be able to send EE traffic. In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.

Additional configuration concerns for NAT traversal: Following are some additional configuration concerns for NAT traversal:

- When using NAT traversal, z/OS views its own address as the one configured in the z/OS home list. If the z/OS host is behind a NAT, this address is a private address. Otherwise, it is the public address of the z/OS host.

  The z/OS implementation does not use private addresses in its configuration to describe the remote IKE peer or remote IP connection endpoint. z/OS views its IPSec peer and the remote IP connection endpoint as a public IP address. If a NAT is in front of the IPSec peer, the z/OS host perceives the IPSec peer and connection endpoint addresses to be that of the NAT.
- You should not configure pre-shared keys in Main mode when multiple remote peers reside behind a NAT and the peers do not map to unique RemoteSecurityEndpoint specifications. RFC 3947 states that pre-shared keys cannot be used with Main mode, unless group shared keys for all those behind the NAT are deployed. The use of group pre-shared keys is considered a security risk.
- If a NAT address is coming out of a dynamic NAT pool, addresses assigned to a host from the pool can be assigned any of the pooled addresses. In this case, there are additional considerations. When z/OS is the responder, the IPSec policy intended for a host must be broad enough to cover the entire range of IP addresses in the dynamic NAT pool. When z/OS is the initiator and the responder is behind a NAT, the identity of the target host can be ambiguous. A z/OS should not be configured to initiate to an ambiguous target host.

- When a remote security endpoint resides behind a NAT, its identity must be unique. During a phase 1 negotiation, the remote security endpoint sends its identity in an ID payload. The IKE daemon can manage multiple remote security endpoints using the same ID when those endpoints are not behind a NAT. However, when a remote security endpoint is behind a NAT, it must use a unique ISAKMP identity.
- When the remote security endpoint is a security gateway behind a NAT or a host behind a NAPT, only TCP, UDP, and ICMP traffic is supported. ICMP traffic has limited support.
- z/OS allows traffic for a TCP connection to continue as long as the integrity of the connection can be verified. Two cases where z/OS can no longer verify the integrity of the connection are:
  - Adding or removing IPSec protection for a TCP connection

    When a TCP connection traverses a NAT, the TCP connection must be restarted after a filter policy change that causes the connection's traffic to change from IPSec-protected traffic to clear text, or from clear text to IPSec-protected traffic.
  - NAT IP address remapping

    If the peer's IP address is remapped by a NAT due to a timeout or reboot of the NAT device, the TCP connection must be restarted.

Configuring the IKE daemon

This topic describes considerations and steps for configuring the IKE daemon.

The IKE daemon's purpose is to manage dynamic IPSec tunnels and to provide a network management interface (NMI) for monitoring and controlling IP filtering and IPSec. The IKE daemon is not involved in the actual filtering, encapsulation, or decapsulation of packets. The IKE daemon is not required for the configuration or use of IP filters when no IpDynVpnAction statements are used. However, because the IKE daemon processes NMI monitoring requests, it must be running to gather monitoring data for IP filters, manual Security Associations, or dynamic Security Associations. To start the IKE daemon, it must be able to connect to the Policy Agent. For information about this requirement, see “Policy Agent considerations” on page 1102. For more information about the IPSec network management interface, see *z/OS Communications Server: IP Programmer’s Guide and Reference*.

Multiple TCP/IP stacks

A one-to-many relationship can exist between an instance of the IKE daemon and stacks configured with IPCONFIG IPSECURITY. A single instance of the IKE daemon can service all stacks configured with IPCONFIG IPSECURITY on a single z/OS image. Only one instance of the IKE daemon can run on a single z/OS image.

Each stack can be configured as a network security services (NSS) client. An NSS client makes use of network security services offered by the NSS server. For details about configuring an NSS server, see Chapter 20, “Network security services,” on page 1149.

“TCP/IP stack initialization access control” on page 126 describes a time interval during which limited stack access is available for stacks that have been configured for AT-TLS using the TCPCONFIG statement with the TTLS parameter. To enable the IKE daemon for a stack during this interval, the IKE daemon user ID must be

permitted to the EZB.INITSTACK.*sysname.tcpname* resource profile. For examples of the security product commands needed to grant access to this profile, see member EZARACF in sample data set SEZAINST.

Run-time environment

The IKE daemon is a z/OS UNIX application, and it requires a z/OS UNIX file system such as zSeries File System. The IKE daemon can be started from an MVS started procedure, from the z/OS shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMNDxx member of PARMLIB. The IKE daemon must be started by a RACF-authorized user ID, and it must reside in an APF-authorized library. For more information about how to start the IKE daemon, see "Starting the IKE daemon" on page 1109.

The IKE daemon uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to dynamic IPSec tunnel management. CTRACE is used for detailed tracing and debugging.

The IKE daemon uses a standard message catalog. The message catalog must be in the z/OS UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

Language Environment run-time considerations

When starting the IKE daemon from a started or cataloged procedure, you should usually start the IKE daemon directly from the SEZALOAD data set using PGM=IKED. However, there is a situation where you might want to start the IKE daemon using BPXBATCH.

When the IKE daemon is started using PGM=IKED, the STDENV DD card, if used, is passed directly to the IKE daemon program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS= environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM= parameter and the options must be specified before any IKE daemon options. However, the PARM= statement allows a maximum of 100 characters. If the desired Language Environment run-time options plus IKE daemon parameters exceeds 100 characters, consider using BPXBATCH to start the IKE daemon. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

IKE daemon configuration source information

The IKE daemon obtains configuration information from two sources.

- IKE daemon configuration file

  The IKE daemon configuration file contains the IkeConfig statement. Parameters on the IkeConfig statement are global IKE daemon operational parameters. For details on the IKE daemon configuration file and the IkeConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

  The IKE daemon configuration file is read when the IKE daemon initializes and can be reread dynamically. For more information, see "Controlling the IKE daemon" on page 1110.

- Policy Agent

  IP security policy includes dynamic IPSec tunnel configuration information required by the IKE daemon. The IKE daemon obtains IP security policy from the Policy Agent. The IKE daemon obtains IP security policy when connecting to the Policy Agent and whenever the Policy Agent informs the IKE daemon of a change in IP security policy. The IKE daemon connects only to stacks configured with IPCONFIG IPSECURITY, if there is an IP security policy defined for a stack. For details on configuring IP security policy, see "Configuring specific security models" on page 1028.

Policy Agent considerations

The IKE daemon cannot perform management of dynamic IPSec tunnels until it has obtained IP security policy from the Policy Agent. While the Policy Agent is running, it can inform the IKE daemon of dynamic changes to IP security policy. Once the IKE daemon has obtained an IP security policy, the Policy Agent can be stopped without impacting the IKE daemon. However, any changes to the IP security policy will not be detected until the Policy Agent is restarted, nor will IKE detect newly activated or reactivated stacks. The IKE daemon reconnects to the Policy Agent when the Policy Agent is restarted. For information about starting and monitoring policy related applications using the Policy Agent, see "Step 7: Configuring Policy Agent to automatically monitor applications" on page 861.

Using network security services

The IKE daemon allows a stack to be defined as a network security services (NSS) client. When a stack is defined as an NSS client, the IKE daemon uses at least one network security service on behalf of that stack. Network security services are provided by an NSS server. An NSS server provides a certificate service and a remote management service. For details about the configuration of an NSS server, see Chapter 20, "Network security services," on page 1149.

The certificate service of the NSS server is used to create and verify digital signatures on behalf of an NSS client. Certificates for stacks that are configured to use the NSS certificate service must reside on the key ring of the NSS server. For details about configuring the IKE daemon to use the NSS certificate service, see "Step 5: Setting up the IKE daemon for digital signature authentication (optional)" on page 1510.

Restriction: If you want the IKED to use a digital signature authentication method to negotiate an IKEv2 Security Association for a stack, the stack must be configured to use the NSS certificate service.

The remote management service of the NSS server enables the IP filter rules and Security Associations of an NSS client to be monitored and managed from the system on which the NSS server is executing. For details about using the **ipsec** command to monitor and manage NSS clients, see *z/OS Communications Server: IP System Administrator's Commands*. For details about using the IPSec NMI to monitor and manage NSS clients, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

The NSS server does not need to reside on the same system as the IKE daemon. The location of the NSS server is specified by the NetworkSecurityServer parameter and optionally by the NetworkSecurityServerBackup parameter of the IkeConfig statement. For additional details about the IkeConfig statement, see *z/OS Communications Server: IP Configuration Reference*

The NssStackConfig statement in the IKE daemon configuration file is used to define a stack as an NSS client. The ServiceType parameter of the NssStackConfig statement identifies what network security services are to be used by a stack. When a ServiceType value Cert is specified, the NSS certificate service is used. When a ServiceType value RemoteMgmt is specified, the NSS remote management service is used. The ServiceType parameter can be specified multiple times. For complete details about the NssStackConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

When a stack is configured to use the NSS remote management service, the NSS server can send the IKE daemon a request to switch between default IP filter policy and IP security filter policy. To change filter sets, the IKE daemon creates or deletes a specific marker file that the stack accesses. This marker file is the same marker file that is created or deleted by the **ipsec** command when the **ipsec -f reload** or **ipsec -f default** IP filter options are specified locally without the **-z** option. For details about the marker file, see *z/OS Communications Server: IP System Administrator's Commands*.

The ClientName parameter of the NssStackConfig statement associates an NSS client name with a stack. This is the name by which the NSS server knows the stack. The UserId parameter of the NssStackConfig statement associates the NSS client name with a user ID defined on the NSS server's system. The NSS server uses both the client name and user ID when checking SERVAUTH profiles to verify that an NSS client is authorized to request a specific action. For details about SERVAUTH profiles checked by the NSS server, see Chapter 20, "Network security services," on page 1149.

The AuthBy parameter of the NssStackConfig statement defines how the user ID associated with a stack that is acting as an NSS client is to be authenticated. This user ID can be authenticated using a password or a PassTicket. When a PassTicket is used, the application key is stored in the local external security manager database.

Tip: Using a PassTicket is more secure than specifying a password.

To store the application key in the local external security manager database, the secure signon function must be enabled and a PTKTDATA profile must be created. This key must be associated with an application ID of the NSSD. For specific information about enabling the secure signon function and defining profiles to be utilized by the single signon function, see *z/OS Security Server RACF Security Administrator's Guide*.

The following is an example of a RACF command that you can issue to store the application key for the NSS server and NSS clients:

```
RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E001193519561977)) UACC(NONE)
```

Figure 112 on page 1104 shows a partial configuration for the IKE daemon on system SYSTEMA. The NetworkSecurityServer parameter on the IkeConfig statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. One NssStackConfig statement is shown. The ClientName parameter associates stack STACK1 with an NSS client name SYSTEMA_STACK1. This is the name by which the NSS server knows this stack. The UserId parameter associates the client name with the user ID A1S1. The A1S1 user ID must be defined on the NSS server's system. Both the client name and user ID are used by the NSS server when verifying the authorization of an NSS client. The multiple ServiceType parameters

indicate that the IKE daemon uses both the NSS certificate service and the NSS remote management service.

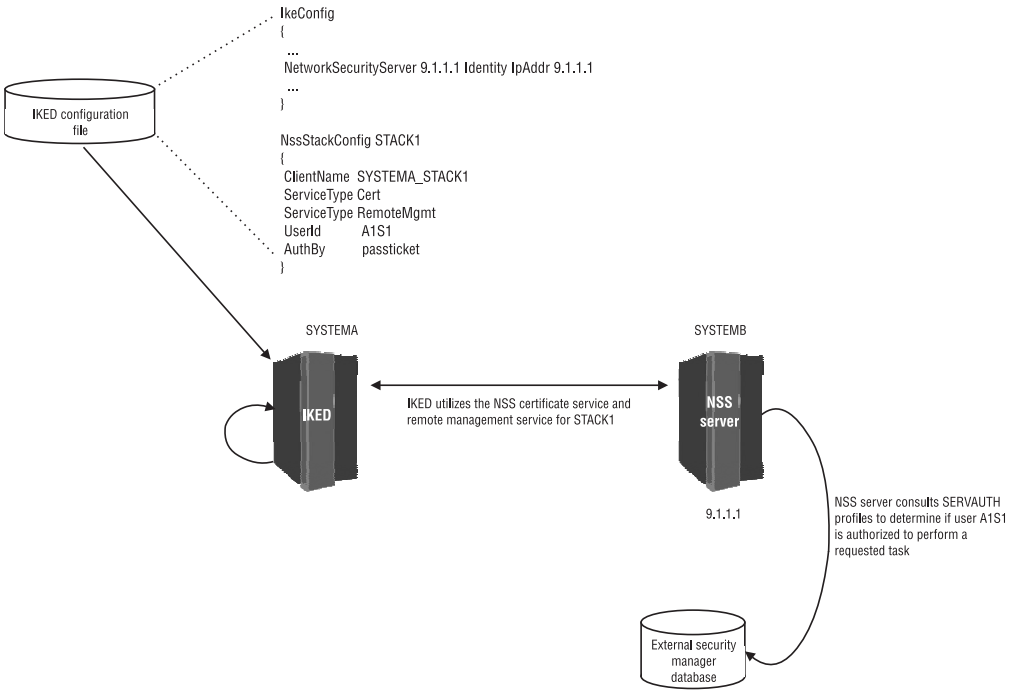

Figure 112. Enabling network security services

The IKE daemon requires that communication with the NSS server be protected using AT-TLS. During the AT-TLS handshake, the NSS server provides a certificate that can be used to authenticate its identity. The IKE daemon examines this certificate and verifies that the identity in the certificate matches the identity specified on the NetworkSecurityServer parameter of the IkeConfig statement.

The IKE daemon does not perform any SERVAUTH checks when processing an IPSec monitoring request or an IPSec management request from the NSS server. The NSS server performs SERVAUTH checks to make sure that the requester of an IPSec monitoring or management request is authorized. For details about the SERVAUTH requirements imposed by the NSS server, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

The IKE daemon does perform a SERVAUTH check for the EZB.NETMGMT.*sysname*.*sysname*.IKED.DISPLAY profile when processing a local NMI request to display information about current NSS client state. For additional details, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Certificate revocation checking

Certificate revocation checking is applicable only to digital signature authentication methods. The RevocationChecking parameter in the IPSec policy file controls the level of certificate revocation checking that is performed during an IKE negotiation. The following three levels of revocation checking are supported:

- Strict
- Loose
- None

You can specify the RevocationChecking parameter on the KeyExchangePolicy statement and the KeyExchangeAction statement. For more information about the KeyExchangePolicy statement and the KeyExchangeAction statement, see *z/OS Communications Server: IP Configuration Reference*.

The native IKED certificate service does not support the retrieval and checking of certificate revocation information. When the IKED is configured to use the native IKE daemon certificate service, the RevocationChecking parameter is ignored.

The NSS certificate service does support the retrieval and checking of certificate revocation information in the form of certificate revocation lists (CRLs). For information about the NSS server requirements for retrieving CRLs, see "NSS server certificate revocation support" on page 1172. Ensure that these requirements can be met before you enable strict revocation checking in the IPSec policy file.

Steps for configuring the IKE daemon

Perform the following steps to configure the IKE daemon:

1. Create the IKE daemon configuration file.

   A sample configuration file is provided in /usr/lpp/tcpip/samples/iked.conf.

   Following is the search order used by the IKE daemon to locate the configuration data set or file:

   a. If the environment variable IKED_FILE has been defined, the IKE daemon uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
   b. /etc/security/iked.conf

   You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the IKED_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

2. Set the _BPX_JOBNAME environment variable (optional).

   When starting the IKE daemon from the z/OS shell, the environment variable _BPX_JOBNAME should be set. This enables a specific job name to be used when reserving ports for the IKE daemon. This name can also be used with the STOP or MODIFY console commands.

   For more information on _BPX_JOBNAME, see *z/OS UNIX System Services Planning*

3. Reserve the ports.

   Update the PORT statement in PROFILE.TCPIP to reserve ports 500 and 4500 for the IKE daemon. Add the name of the member containing the IKE daemon cataloged procedure or the name as set using _BPX_JOBNAME:

   ```
   PORT
                  500 UDP IKED
                  4500 UDP IKED
   ```

4. Update the IKE daemon cataloged procedure.

   If the IKE daemon is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(IKED) to your system or recognized PROCLIB. Specify IKE daemon parameters and change the data set names to suit your local configuration. Following is a copy of the sample:

```
//IKED     PROC
//*
//* IBM Communications Server for z/OS
//* SMP/E distribution name: EZBIKPRC
//*
//* 5694-A01 Copyright IBM Corp. 2005, 2009
//* Licensed Materials - Property of IBM
//* "Restricted Materials of IBM"
//* Status = CSV1R11
//*
//*
//IKED     EXEC PGM=IKED,REGION=0K,TIME=NOLIMIT,
//       PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//*
//* Provide environment variables to run with the desired
//* configuration.  As an example, the data set or file specified by
//* STDENV could contain:
//*
//*   IKED_FILE=/etc/security/iked.conf2
//*   IKED_CTRACE_MEMBER=CTIIKE01
//*   IKED_CODEPAGE=IBM-1047
//*
//* For information on the above environment variables, refer to the
//* IP Configuration Reference.
//*
//STDENV   DD DUMMY
//* Sample MVS data set containing environment variables:
//*STDENV   DD DSN=TCPIP.IKED.ENV(IKED),DISP=SHR
//* Sample HFS file containing environment variables:
//*STDENV   DD PATH='/etc/security/iked.env',PATHOPTS=(ORDONLY)
//*
//* Output written to stdout and stderr goes to the data set or
//* file specified with SYSPRINT or SYSOUT, respectively.
//SYSPRINT DD SYSOUT=*
//SYSOUT   DD SYSOUT=*
```

Figure 113. IKE cataloged procedure

5. Authorize the IKE daemon to the external security manager.

   See "Step 2: Authorizing the IKE daemon to the external security manager" on page 1505.

6. Configure and start syslogd.

   The IKE daemon uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use zSeries File System as its underlying file system. For more information on syslogd, see "Configuring the syslog daemon" on page 185.

   Tip: The system logging daemon (syslogd) can be configured to forward messages from the IKE daemon to a syslogd on another host. For information about forwarding syslog messages to another host, see *z/OS Communications Server: IP Configuration Reference*. When a stack is configured as an NSS client, it can be advantageous to forward syslog messages from the IKE daemon to the syslogd running on the NSS server's system. Configuring syslogd in this manner allows all IKE messages relating to an NSS client to reside in the same log file as the NSS server's messages.

7. Update the IKE daemon environment variables (optional).

   The following environment variables are used by the IKE daemon and can be tailored to a particular installation:

   IKED_CODEPAGE
   Use the IKED_CODEPAGE variable to specify the EBCDIC code page

to be used when reading the configuration file. For more information about IKE environment variables and the supported code pages, see *z/OS Communications Server: IP Configuration Reference*.

IKED_CTRACE_MEMBER
The IKED_CTRACE_MEMBER variable is used by the IKE daemon to locate a parmlib member for IKE daemon CTRACE customization. For more information on the TCP/IP services component trace for the IKE daemon, see *z/OS Communications Server: IP Diagnosis Guide*.

IKED_FILE
The IKED_FILE variable is used by the IKE daemon in the search order for the IKE daemon configuration file. For details on the search order used for locating this configuration file, see step 1 on page 1105.

8. Setup the IKE daemon for TCP/IP stack initialization access control (optional).

   See "Multiple TCP/IP stacks" on page 1100.

9. Setup the IKE daemon for digital signature mode authentication (optional).

   See "Step 5: Setting up the IKE daemon for digital signature authentication (optional)" on page 1510.

10. Define AT-TLS policy to protect communication with an NSS server.

    The IKE daemon requires that communication between the NSS server and the IKE daemon be secured using Application Transparent Transport Layer Security (AT-TLS). If a stack is configured as an NSS client, AT-TLS rules must be defined to secure this communication. Enable AT-TLS processing for a stack by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

    Tip: Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with the NSS server. Failure to restrict the cipher suites to those requiring encryption can result in sensitive information flowing in the clear across an untrusted network.

    Rule: AT-TLS policy must be defined for each stack through which the IKE daemon communicates with the NSS server.

    A sample AT-TLS policy is located in /usr/lpp/tcpip/samples/pagent_TTLS.conf.

    Rule: The RemotePortRange value in the TTLSRule statement must include the value specified on the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

11. Define IP filter policy to enable communication with an NSS server (optional).

    If a stack is configured as an NSS client, IP filter policy for that stack must be defined to enable this communication. The IKE daemon communicates with the NSS clients using the TCP protocol. By default, the NSS server listens on port 4159. The IKE daemon connects to the NSS client using an ephemeral port. Ephemeral ports are generally in the range 1024 – 65355.

    Two types of IP filter policy can be defined for a z/OS stack:

- Default IP filter policy is defined in the TCP/IP profile. Updating default IP filter policy to permit communications between the IKE daemon and the NSS server is optional. Default IP filter policy is in effect only when IP security filter policy cannot be loaded or when the **ipsec -f default** command has been issued. For details about how to define default IP filter policy, see *z/OS Communications Server: IP Configuration Reference*.

  Following is an example of a default policy containing IPSECRule definitions allowing IKE daemon traffic with the NSS server:

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr   Logging Protocol   SrcPort    DestPort     Routing Secclass

; OSPF protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO OSPF

; IGMP protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO 2

; DNS queries to UDP port 53
  IPSECRule *       *         NOLOG   PROTO UDP  SRCPort *  DESTport 53

; Administrative access
  IPSECRule *       9.1.1.2   LOG                                                SECCLASS 100

; IKE daemon access to the Network Security Server
  IPSECRule *       *         LOG     TCP        SRCPort *  DESTport 4159

; IKE daemon access to the Network Security Server
  IPSEC6Rule *      *         LOG     TCP        SRCPort *  DESTport 4159

ENDIPSEC
```

  Rule: The DESTport value in the filter rules must include the value specified for the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

- IP security filter policy is defined in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the IKE daemon and the NSS server. For details about how to define IP security policy files, see *z/OS Communications Server: IP Configuration Reference*.

  Following is an example of an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement allowing the IKE daemon to communicate with the NSS server:

```
IpFilterRule             NssTrafficIPv4
{
    IpSourceAddr             all4
    IpDestAddr               all4
    IpService
    {
       SourcePortRange        1024 65535
       DestinationPortRange   4159
       Protocol               tcp
       Direction              bidirectional OutboundConnect
       Routing                local
    }
    IpGenericFilterActionRef  permit-nolog
}

IpFilterRule             NssTrafficIPv6
{
   IpSourceAddr             all6
   IpDestAddr               all6
   IpService
   {
      SourcePortRange        1024 65535
      DestinationPortRange   4159
      Protocol               tcp
```

```
      Direction              bidirectional InboundConnect
      Routing                local
   }
   IpGenericFilterActionRef  permit-nolog
}

IpGenericFilterAction     permit-nolog
{
   IpFilterAction           permit
   IpFilterLogging          no
}
```

Rule: The DestinationPortRange value on the IpService statement must include the value specified on the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

Starting the IKE daemon

After the necessary external security manager authorization has been defined (see "Step 2: Authorizing the IKE daemon to the external security manager" on page 1505), the IKE daemon can be started from an MVS procedure, from the z/OS shell, or using the AUTOLOG statement.

- You can start the IKE daemon procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(IKED).
- You can start the IKE daemon from the z/OS shell by starting OMVS and then issuing the iked command.
- You can use the AUTOLOG statement to start the IKE daemon automatically during TCP/IP initialization by inserting the name of the IKE daemon start procedure into the AUTOLOG statement in the PROFILE.TCPIP data set:

  ```
  AUTOLOG
    IKED
  ENDAUTOLOG
  ```

  Tips:

  – When implementing multiple stacks enabled for IP security, adding an AUTOLOG statement for the IKE daemon might not be optimal. If the IKE daemon is listed in an AUTOLOG statement of a stack's profile, the IKE daemon is cancelled if it is already running when that stack starts. In a multiple IP security stack environment, this could disrupt traffic on other IP security stacks. Use another method to automate starting the IKE daemon when the system is IPLed, such as using the COMMNDxx member of PARMLIB. For more information about the use and configuration of the COMMNDxx member of PARMLIB, see *z/OS MVS Initialization and Tuning Reference*.

  – If you start the IKE daemon from the z/OS shell and you stop the shell environment from scrolling, then when the daemon needs to display data to the shell it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

When running from an MVS procedure, the environment variables can be set using the STDENV DD statement in the IKE daemon procedure. For information concerning the environment variables used by IKE daemon, see step 7 on page 1106 in "Steps for configuring the IKE daemon" on page 1105.

Stopping the IKE daemon

The IKE daemon can be stopped as follows:

- From MVS, issue:

  `STOP procname`

  If the IKE daemon was started from a cataloged procedure, *procname* is the member name of that procedure. If the IKE daemon was started from the z/OS shell and the environment variable _BPX_JOBNAME was set, *procname* is the same as _BPX_JOBNAME. If the IKE daemon was started from the z/OS shell and _BPX_JOBNAME was not set, *procname* is *useridX*, where X is the sequence number set by the system. To determine the sequence number, from the SDSF LOG window on TSO, issue:

  `/d omvs,u=userid`

  This command shows the programs running under this user ID. For more information on _BPX_JOBNAME, see *z/OS UNIX System Services Planning*.
- From a superuser ID in the z/OS shell, issue the kill command to the process ID (PID) associated with the IKE daemon. The IKE daemon PID is recorded in /var/ike/iked.pid.

Controlling the IKE daemon

You can control the IKE daemon from the operator's console using the MODIFY command. MODIFY commands are available to perform the following functions:

- Rereading the configuration file

  The MODIFY *procname*,REFRESH command is used to reread the IKE daemon configuration file. Not all IkeConfig statement parameters can be updated using this command. For information on which parameters can be dynamically changed, see the parameter descriptions for the IkeConfig statement of the IKE daemon configuration file in the *z/OS Communications Server: IP Configuration Reference*.
- Displaying the configuration file parameters

  The MODIFY *procname*,DISPLAY command is used to display configuration values currently being used by the IKE daemon.

For more information on the MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying policy installation

This topic describes the console messages and commands that are used to verify policy installation.

Console messages

After the IP security policy has been configured, start the TCP/IP stacks, Policy Agent, and the IKED. A series of console messages is issued if the installation of IP security policy was successful.

The following console messages indicate that Policy Agent and IKE have completed initialization:

```
EZZ8432I PAGENT INITIALIZATION COMPLETE
EZD1046I IKE INITIALIZATION COMPLETE
```

The following console messages indicate that the processing of IP security policy is complete:

```
EZZ8771I PAGENT CONFIG POLICY PROCESSING COMPLETE FOR TCPCS : IPSEC
EZD1068I IKE POLICY UPDATED FOR STACK TCPCS
```

If there were errors in the configuration files, Policy Agent issues the following message to the console:

```
EZZ8438I PAGENT POLICY DEFINITIONS CONTAIN ERRORS FOR TCPCS : IPSEC
```

Look at the Policy Agent log to find and correct the error.

Displaying TCP/IP configuration

To display whether the TCP/IP stack is configured with IPCONFIG IPSECURITY, issue the **netstat -f** command and look for the following field in the `IPv4 Configuration Table` section:

```
IpSecurity: Yes
```

To display whether the TCP/IP stack is configured with IPCONFIG6 IPSECURITY, issue the **netstat -f** command and look for the following field in the `IPv6 Configuration Table` section:

```
IpSecurity: Yes
```

To display whether the TCP/IP stack is configured for sysplex-wide Security Associations, issue the **ipsec -f display** command. The DVIPSec field in the header of the command display shows whether or not the DVIPSEC keyword has been coded in the TCP/IP profile:

```
ipsec -f display | head -n 7

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 10:52:03 2010
Primary:  Filter          Function: Display            Format:   Detail
Source:   Stack Policy    Scope:    Current            TotAvail: 137
Logging:  On              Predecap: Off                DVIPSec:  Yes
NatKeepAlive:  20         FIPS140:  No
Defensive Mode: Inactive
```

Displaying active filters with the ipsec command

Use the **ipsec -f display** command to display active filter rules, configured filter rules from IP security policy configuration files, and the default IP filter rules from the TCP/IP profile. The scope on the command, as indicated by the **-c** option, determines which source is queried:

-c policy
Shows IP filters as configured in the IP security policy configuration files.

-c profile
Shows default IP filters as configured in the TCP/IP profile.

-c current
Shows active IP filters in the stack. The active filters that are shown can be the default IP filters as defined in the TCP/IP profile, or IP filters as configured in the IP security policy configuration files, depending on which policy is active at the time the command is issued. The output of the display indicates the source of the current active filters.

The output of the command can be quite voluminous, so you might want to redirect the output of the display to a file.

The information in the report header of the report output indicates how many filters are active, and also indicates the source of the filters, whether from the default IP filter policy or the IP security policy from the Policy Agent.

```
ipsec -f display

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 10:53:12 2010
Primary:  Filter          Function: Display           Format:   Detail
Source:   Stack Profile   Scope:    Current           TotAvail: 14
Logging:  On              Predecap: Off               DVIPSec:  Yes
NatKeepAlive:  20         FIPS140:  No
Defensive Mode: Inactive
```

If the source field shows `Stack Policy`, the IP security policy is installed and active.

If the source field shows `Stack Profile`, the IP security policy is either not installed or the **ipsec -f default** command was issued. Either issue the **ipsec -f reload** command, or correct the IP security policy configuration.

Filter displays can be abbreviated to include only specific named rules. To view a named filter rule, use the **-n** option as follows:

```
ipsec -f display -n Rule2Admin

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 10:54:36 2010
Primary:  Filter          Function: Display           Format:   Detail
Source:   Stack Policy    Scope:    Current           TotAvail: 137
Logging:  On              Predecap: Off               DVIPSec:  Yes
NatKeepAlive:  20         FIPS140:  No
Defensive Mode: Inactive

FilterName:                   Rule2Admin
FilterNameExtension:          1
GroupName:                    Admin
LocalStartActionName:         n/a

Anchor filters and dynamic filters

After a Security Association is negotiated, the **ipsec -f display** command shows the addition of two dynamic filters that were created when the Security Association was created, corresponding to the inbound and outbound anchor filters. Dynamic filters are placed ahead of the anchor filters in the filter table, so dynamic filters are searched first when IP filtering is performed. In the following sample output, note that two dynamic filters have been added to the filter table subsequent to the activation of a phase 2 Security Association. The Type field indicates whether the filter is a dynamic anchor filter or a dynamic filter:

```
ipsec -f dis -n Rule2Admin

NATT anchor and NATT dynamic filters

Using the **ipsec -f** command after the activation of two phase 2 Security Associations in the branch office with NAT model, the filter structure looks like the following:

```
CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:38:37 2010
Primary:  Filter          Function: Display           Format:   Detail
Source:   Stack Policy    Scope:    Current           TotAvail: 139
Logging:  On              Predecap: Off               DVIPSec:  No
NatKeepAlive:  20         FIPS140:  No
Defensive Mode: Inactive

FilterName:                 Rule2C
FilterNameExtension:        1
GroupName:                  n/a
LocalStartActionName:       StartZoneC
VpnActionName:              Gold-TunnelMode
TunnelID:                   Y2
Type:                       NATT Dynamic
```

```

The inbound dynamic anchor filter protects TCP traffic from source address 9.6.0.0/16, source port any, to destination address 9.3.3.3, destination port 21. The inbound NATT anchor filter protects TCP traffic from source address 9.5.5.5, source port any, to destination address 9.3.3.3, destination port 21. The two inbound NATT dynamic filters also protect TCP traffic from source address 9.5.5.5, source port any, to destination address 9.3.3.3, destination port 21. However, the two NATT dynamic filters were negotiated for separate clients behind the security gateway. You can see that the first inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.1.1 (value in the RmtIDpayload field).

The second inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.2.2. The internal address of the data endpoint is what makes each NATT dynamic unique.

NAT resolution filters

Use the **-h** option on the **ipsec -f** command to display any NRFs associated with the displayed filters. After two clients behind the security gateway have connected to host 9.3.3.3 using FTP, the NRFs could look like the following (The display has been truncated to include only the NRFs):

```
FilterName:                   Rule2C
FilterNameExtension:          1
GroupName:                    n/a

|                       ************************************************************************
```

There are two NRF inbound/outbound entry pairs associated with the NATT anchor. In this example, two clients behind the security gateway have an FTP connection with host 9.3.3.3. The first outbound NRF entry is for:

```
source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 34732
protocol TCP
```

The destination port is shown in the DestPort field. This value can be a translated value. The OrigRmtConnPort field indicates the original remote connection port, prior to remote port translation by Communications Server. In this example, the first outbound NRF shows that DestPort and OrigRmtConnPort are both 34732. For more information, see “Remote port translation” on page 984.

The second outbound NRF entry is for:

```
source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 65535
protocol TCP
```

The original remote connection port (OrigRmtConnPort) is 34732. Because the values in DestPort and OrigRmtConnPort do not match, you can tell that the value was translated by Communications Server's remote port translation function. For more information, see “Remote port translation” on page 984.

The TunnelID field provides information on which phase 2 Security Association the traffic will be sent over. In this example, the phase two Security Associations are identified by the labels Y2 and Y3 respectively.

Displaying remote port translation with the ipsec command

As seen in “NAT resolution filters” on page 1124, the remote data endpoint is represented by the security gateway's public IP address (9.5.5.5), not the client's IP address (10.3.1.1 or 10.3.2.2). Using the **ipsec -o display** command after the activation of two FTP connections in the branch office with NAT model, the port mappings look like the following:

```
CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:43:55 2010
Primary:  NATT Port Trans Function: Display           Format:   Detail
Source:   Stack           Scope:    Current           TotAvail: 2

RmtIpAddress:         9.5.5.5
Protocol:             TCP(6)
TransRmtConnPort:     34732
OrigRmtConnPort:      34732
RmtInnerIpAddress:    10.3.1.1
*************************************************************************
RmtIpAddress:         9.5.5.5
Protocol:             TCP(6)
TransRmtConnPort:     65535
OrigRmtConnPort:      34732
RmtInnerIpAddress:    10.3.2.2
*************************************************************************

2 entries selected
```

In both entries, you can see that the remote IP address (RmtIpAddress) value is 9.5.5.5, the IP address of the branch office gateway, the protocol is TCP (6), and the original remote connection port (OrigRmtConnPort) is 34732. The first entry shows that the translated remote connection port (TransRmtConnPort) is also 34732. The remote inner IP address contains the private address of the client behind the security gateway that initiated the connection, 10.3.1.1. The second entry shows

that the remote connection port was translated to a value of 65535 (TransRmtConnPort), and that the client initiating the connection is using private IP address 10.3.2.2.

Table 49 details several places where one or both of the remote port values are displayed or used for a selection.

Table 49. Original and translated port values

Function	How remote port values are used	Which remote port, original or translated?
Netstat displays of connection data, such as Netstat ALL/-A, Netstat ALLConn/-a, and Netstat COnn/-c	The Netstat command has many options to display connection information, including the remote port value. In some cases, the Netstat command takes a remote port value as a selector.	Translated remote port
Netstat display of the VIPA connection routing table (netstat VCRT/-V)	This command displays the remote port value in the sport or Source field, depending on the flavor of the report generated, and allows you to select based on port.	Translated remote port
Packet trace	Packet trace displays packet data as it was received or sent. If the packet is authenticated but not encrypted, the port is visible in the packet trace data.	Original remote port
IPSecurity syslog messages: • `EZD0814I packet permitted` • `EZD0815I packet denied by policy` • `EZD0821I packet denied, no tunnel` • `EZD0822I packet denied, tunnel inactive` • `EZD0832I packet denied by NAT traversal processing` • `EZD0833I packet denied, tunnel mismatch` • `EZD0836I packet permitted` Defensive filtering syslog messages: • `EZD1721I packet denied by defensive filter` • `EZD1722I packet would have been denied by defensive filter`	For an inbound packet, the sport field in these messages contains a remote port value. For an outbound packet, the dport field in these messages contains a remote port value. These messages also have an origport field.	The sport and dport fields contain the translated remote port, and the origport field contains the original remote port.

Table 49. Original and translated port values (continued)

Function	How remote port values are used	Which remote port, original or translated?
Dynamic anchor, displayed with the **ipsec -f** command and the **ipsec -t** command	The dynamic anchor that is configured in the Policy Agent configuration file can specify the remote port as a single port, a range of ports, or all ports. This specification of the remote port controls the range of ports that the original port can be translated to. Both the original port and the translated port for a connection will fit the range of ports coded.	The configured remote port value is displayed. A packet's original port is used to match on this rule. Both the original port and translated port are included in the remote port value displayed.
NATT anchor, displayed with the **ipsec -f** command and the **ipsec -t** command	The NATT anchor, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports.	Original remote port if specific port displayed
NATT dynamic, displayed with the **ipsec -f** command and the **ipsec -t** command	The NATT dynamic, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports.	Original remote port if specific port displayed
NAT resolution filter (NRF), displayed with the **ipsec -f** command with the **-h** option	The NAT resolution filter is a connection level filter, and contains both the translated remote port and the original remote port.	Translated remote port and original remote port. A packet's translated port is used to match on this rule.
ipsec -t command	The **ipsec** traffic test command allows a remote port value to be specified as a filter selection criteria.	Original remote port

Displaying Security Associations with the ipsec command

Use the **ipsec** command to verify Security Associations.

Displaying IKE tunnel information with the ipsec command

Use the **ipsec -k display** command to display IKE tunnel information.

```
ipsec -k display

```

The setting of the AllowNat field indicates whether or not NAT traversal support was advertised to the IKE peer. If AllowNat is Yes, the negotiation might or might not have detected a NAT. If the NATInFrntLclScEndPnt field is Yes, a NAT device was detected in front of the local security endpoint. If the NATInFrntRmtScEndPt field is Yes, a NAT device was detected in front of the remote security endpoint.

Displaying IPSec tunnel information with the ipsec command

Use the **ipsec -y display** command to display IPSec tunnel information.

```
ipsec -y display -a Y39

TunnelID:                     Y39
Generation:                   1
IKEVersion:                   1.0
ParentIKETunnelID:            K11

```

The NAT Traversal Topology fields show additional information when a NAT was detected in the path between the IKE peers. The setting of the UdpEncapMode field indicates whether a UDP-encapsulated mode Security Association has or has not been negotiated. If NAT Traversal is supported by both IKE peers and one or more NATs are detected, UdpEncapMode is set to Yes. The RmtNATDetected field is Yes if a NAT is detected in front of the remote peer. The RmtIsGW field is Yes if the remote peer is acting as a security gateway.

Tip: Use the **-b** option of the **ipsec -y display** command to show the ports and protocols of the dynamic filter that are associated with the phase 2 Security Association. The following excerpt from the **ipsec -y display** using the **-b** option indicates a Telnet connection from a remote host:

```
AssociatedFiltProtocol:     TCP(6)
AssociatedFiltSrcPort:      23
AssociatedFiltDestPort:     0
```

Displaying filter rules with the pasearch command

The configured IP filter rules and associated actions can also be viewed from the perspective of the Policy Agent. The **pasearch** command provides a way to view all Policy Agent configuration, of which IP security is a subset. In contrast to the information that is provided by the **ipsec** command, the detailed information that

is provided by the **pasearch** command does not reflect the stack's active use of the IP security policy, but offers a relatively static view of configured IP security values that were generated from the IP security configuration file. For more information on displaying policy based networking information, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying filter action

To quickly determine which filter rule applies to a specific type of traffic, use the **ipsec** traffic test command (**ipsec -t**). This command returns all of the rules in the current filter table that match the given traffic type.

For example, to test which filter rule matches an incoming FTP connection request from remote IP address 9.1.1.2 to local IP address 9.1.1.1, issue the following command. The input values represent the remote address, local address, protocol, remote port, local port, direction, and security class of the packet.:

```
ipsec -t  9.1.1.2 9.1.1.1 tcp 0 21 in 0

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:59:45 2010

An incoming FTP connection request matches all of the rules shown in the example. The first rule that is returned does not always match a specific packet, depending on how much detail you provide as the input to the **ipsec -t** command. However, the Rule2Admin rule is the best match in this case, so the search for a matching filter ends there. The matching rule in this case is an ipsec rule, as indicated by the designation `Dynamic Anchor`. Therefore, IPSec processing is applied to this packet.

Tip: When using the **ipsec -t** command, provide as much detailed input as possible. The more detailed the input to the command, the more narrow the results of the search will be.

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Security Associations

This topic includes the following:

- Activating a Security Association
- Verifying the activation of a Security Association
- Verifying the use of an active Security Association
- Refreshing Security Associations
- Deactivating Security Associations

Activating a Security Association

Negotiations can be initiated in one of four ways:

- Remote activation

  When a remote IKE peer initiates a negotiation with the local IKE daemon, no action is required. If the IP security policy has been configured correctly and is consistent with the policy of the remote IKE peer, a Security Association is

established. No operator message is issued when a remote activation has occurred, but the syslog does contain a record of all IKE activity. The **ipsec -y display** command can also be used to view all of the active Security Associations.

- On-demand activation

  An on-demand Security Association is activated when some outbound traffic matches an ipsec rule that allows on-demand activation. The `ondemand` field of the filter display indicates whether or not on-demand activation is allowed for that rule.

- Automatic activation

  The local IKE daemon initiates a negotiation for an autoactivated Security Association when it connects to the TCP/IP stack. IKE also initiates a negotiation for an autoactivated Security Association when the **ipsec -f reload** command is issued, changing the active filter rule set from default IP filter rules to Policy Agent filter rules. No operator message is issued when an autoactivation has occurred, but the syslog does contain a record of all IKE activity. The **ipsec -y display** command can also be used to view all of the active Security Associations.

- Command-line activation

  The **ipsec** command can be used as follows to activate a Security Association that has been defined by a LocalDynVpnRule statement:

```
ipsec -y activate -l ZoneC_VPN-EE1

CS V1R12 ipsec  Stack Name: TCPCS  Wed Feb  3 16:02:05 2010
Primary:  Dynamic tunnel  Function: Activate

Selection Data                                  Status
ZoneC_VPN-EE1                                   Activating
```

  The output of the command indicates the status of the activation.

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying the activation of a Security Association

After a Security Association has been activated, it can be displayed with the **ipsec -y display** command. To view all active Security Associations, issue the following command:

```
ipsec -y display
```

You can use the **ipsec** command to view all of the active phase 1 Security Associations, or limit the report to a single phase 1 Security Association by using the **-a** option.

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Verifying the use of an active Security Association

If filter logging is enabled for the selected filter rule, the log indicates whether a packet has been permitted with IPSec processing applied. Among the information available for a typical filter log entry are the rule name, the action, and the tunnel ID:

```
Feb 13 18:09:11 MVS175/TRMD     TRMD1    TRMD.TCPCS2[28]: EZD0814I Packet
permitted: 02/13/2010 18:09:05.96 filter rule= Rule2Admin ext= 1 sipaddr=
9.1.1.2 dipaddr= 9.1.1.1 proto= tcp(6) sport= 3755 dport= 21 -=
Interface= 9.1.1.1 (I) secclass= 255 dest= local len= 52 vpnaction=
Silver-TransportMode tunnelID= Y58 ifcname= MPC4142L fragment= N
```

The **ipsec -y display** command also outputs a field with the number of bytes of traffic that have been protected by a particular Security Association.

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Refreshing Security Associations

When a Security Association is refreshed, the encryption keys change. Refreshing a Security Association periodically prevents the keys from being compromised by an outside party. Phase 1 and phase 2 Security Associations are refreshed automatically, based on the lifetime or life size that was configured for IKEv2 or negotiated between the two IKE peers for IKEv1. When a lifetime expiration causes an IKEv2 phase 1 Security Association to refresh, the encryption key changes but the peer is not reauthenticated. Changing the key without reauthenticating the peer reduces CPU cost.

Tip: For phase 1, these parameters are specified in the KeyExchangeOffer statement. For phase 2, these parameters are specified in the IpDataOffer statement.

You can also refresh Security Associations from the z/OS UNIX command line, but this should only be necessary in exceptional conditions because the IKE daemon is normally responsible for refreshing the keys at configured intervals. Exceptional conditions might include the compromise of a key or the failure to receive an informational IKE message from a remote host. For both IKEv1 and IKEv2 Phase 1 Security Associations, refreshes from the z/OS UNIX command line include both reauthentication and re-keying.

Phase 1

Each phase 1 Security Association is identified by a tunnel ID, a number with a prefix of *K*. To manually refresh a phase 1 Security Association, issue the **ipsec -k display** command to find the tunnel ID. Then issue the **ipsec -k refresh** command for that ID as follows:

```
ipsec -k refresh -a K1

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
Primary:  IKE tunnel      Function: Refresh

Tunnel ID    Status
K1           Refreshing
```

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Phase 2

Each phase 2 Security Association is identified by a tunnel ID, a number with a prefix of *Y*. To manually refresh a phase 2 Security Association, issue the **ipsec -y display** command to find the tunnel ID. Then issue the **ipsec -y refresh** command for that ID as follows:

```
ipsec -y refresh -a Y2

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
Primary:  Dynamic tunnel  Function: Refresh

Tunnel ID    LocalDynVpnRuleName                              Status
Y2           ZoneC_VPN-EE1                                    Refreshing
```

The phase 2 Security Association can also be identified by the local dynamic VPN rule with which it is associated, if one exists, as follows:

```
ipsec -y refresh -l ZoneC_VPN-EE1

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
Primary:  Dynamic tunnel  Function: Refresh

Tunnel ID    LocalDynVpnRuleName                              Status
Y2           ZoneC_VPN-EE1                                    Refreshing
```

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Deactivating Security Associations

When a Security Association is deleted, all of the information that is stored in the Security Association is deleted from the TCP/IP stack and from the IKED, along with the dynamic filters that were created when the Security Association was created. After deletion, the Security Association is no longer available for use. Traffic that was protected by the old Security Association is denied until a new Security Association is subsequently activated.

When a parent phase 1 Security Association is deactivated, all of the associated phase 2 Security Associations are deleted as well. Be careful when deleting phase 1 Security Associations, because all traffic that uses the Security Association and its associated phase 2 Security Associations are dropped until new Security Associations can be negotiated.

- To delete a phase 1 Security Association and all of the phase 2 Security Associations it is protecting, issue the following command:

  ```
  ipsec -k deactivate -a K1

  CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
  Primary:  IKE tunnel      Function: Deactivate

  Tunnel ID    Status
  K1           Deactivating
  ```

- To delete all phase 1 Security Associations and all phase 2 Security Associations, use the `-a all` option as follows:

  ```
  ipsec -k deactivate -a all

  CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
  Primary:  IKE tunnel      Function: Deactivate

  All IKE tunnels Deactivating
  ```

- To delete a phase 2 Security Association, issue the following command:

  ```
  ipsec -y deactivate -a Y2

  CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
  Primary:  Dynamic tunnel  Function: Deactivate

  Tunnel ID    LocalDynVpnRuleName                                Status
  Y2           n/a                                                Deactivating
  ```

The n/a in the LocalDynVpnRuleName field indicates that no local dynamic VPN rule name is associated with this Security Association. The Security Association was either remotely activated or was activated on-demand.

- To delete all phase 2 Security Associations, use the -a all option as follows:

```
ipsec -y deactivate -a all

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 11:48:04 2010
Primary:  Dynamic tunnel  Function: Deactivate

All dynamic tunnels Deactivating
```

For detailed information about the use of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Modifying active IP security policy

This topic describes the effects of changes to security-related files and of issuing the **ipsec -f default** command.

IP security policy files

The IP security configuration files for a TCP/IP stack that has the IPSECURITY parameter defined can be modified while the stack is active in the following ways:

- Policy Agent configuration, including IP security, is updated at each configured refresh interval that is specified on the TcpImage statement for local policies or on the DynamicConfigPolicyLoad statement for remote policies. The default is 30 minutes.
- If Policy Agent was started with the **-i** option and the configuration files are stored in a z/OS UNIX file, changes to any of the configuration files are detected and updated dynamically without user intervention. The **-i** option has no effect when the policies are stored in remote configuration files on the policy server.
- Policy Agent configuration, including IP security, can be updated at any time by issuing the MODIFY PAGENT,REFRESH command or the MODIFY PAGENT,UPDATE command from the console of the policy client.

Policy Agent image configuration files

For an active TCP/IP stack with IPSECURITY defined, the following conditions apply:

- Changing the file name that is identified by an existing IpSecConfig or DynamicConfigPolicyLoad statement causes Policy Agent to update and install the IP security policy as defined in the new file. If the new IP security policy file contains errors, the policy is not updated and the existing IP security policy remains in effect.
- For local IP security policies, removing an existing IpSecConfig statement from a Policy Agent image configuration file activates the default IP filter policy.
- For remote IP security policies, removing the PolicyServer statement (or the PolicyType IPSec parameter on that statement) from a Policy Agent image configuration file activates the default IP filter policy, assuming that no local IP security policy is defined using the IpSecConfig statement.

Policy Agent main configuration file

For an active TCP/IP stack with IPSECURITY defined, removing an existing TcpImage statement from the Policy Agent configuration file has the following effects on IP security policy:

- Existing IP filters remain.
- Existing Security Associations remain.
- Traffic continues to flow in the same way it did before the TcpImage statement was removed, including IPSec-protected traffic.
- New Security Associations cannot be activated.
- Existing Security Associations cannot be refreshed and are deleted when the refresh period expires.

If the intent of removing the TcpImage statement is to remove IP filters from the stack, an alternative is to modify the IP security policy to install a filter rule that permits all inbound and outbound traffic. Also, before restarting the stack, the IPSECURITY parameter should be removed from the IPCONFIG statement of the relevant stack.

Active Security Associations and the ipsec -f default command

Any active Security Associations that were negotiated for IPSec-protected traffic are not deleted when the **ipsec -f default** command is issued. However, they are deleted if, while the default policy is in effect, any associated IP filter rules from the IP filter policy are deleted or modified in such a way that the filter rule no longer encompasses the scope of the Security Association. In that case, the Security Association will be deleted when the IP security policy is reloaded.

For example, Security Associations are not deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.

   Security Associations remain active in the stack and in IKE, though unavailable for use.
2. No modification is made to the IP filter policy in the IP security configuration files.

   Security Associations remain active in the stack and in IKE, though unavailable for use.
3. The **ipsec -f reload** command is issued.

   Security Associations remain active in the stack and in IKE, and are available for use.

Security Associations are deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.

   Security Associations remain active in the stack and in IKE.
2. The IpFilterRule statement that is associated with an active Security Association is deleted.
3. The IP security policy is updated by issuing the MODIFY PAGENT,REFRESH command from the console.

   Existing Security Associations are deleted.
4. The **ipsec -f reload** command is issued.

   Security Associations have been deleted.

In either case, Security Associations are never available for use when the default IP filter policy is in effect.

Displaying NSS client information

Use the NssStackConfig statement to configure a stack as an NSS client. Use the **-w** primary option on the **ipsec** command to determine which active stacks are configured as NSS clients, as well as their current status.

```
ipsec -w display

For complete details about the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Sysplex-wide Security Associations and IP security

z/OS IP security supports sysplex-wide Security Associations (SWSA) for only IKEv1 Security Associations between IPv4 endpoints. In a sysplex environment, SWSA provides for distribution of IPSec Security Associations to the target stacks of distributed DVIPAs. To enable this support, you must code IPCONFIG IPSECURITY in the TCP/IP profile, as well as DVIPSEC in the IPSEC block.

In NATT configurations where the IKE peer is behind a NAPT, the negotiated UDP-encapsulated mode Security Associations can be distributed only to a V1R8 or later target that supports IP security.

In a sysplex environment, the IKE daemon can detect movement of a DVIPA to or from an IP security or Firewall Technologies stack.

Restriction: A stack configured for Firewall Technologies must be running z/OS V1R7 or earlier.

To re-establish the Security Associations of a DVIPA, the DVIPSEC option must be specified in the TCP/IP profile of both the stack that the DVIPA is being moved from and the stack detecting the movement. For details of this movement, see "Sysplex-wide security associations" on page 388. For information on the IPCONFIG and IPSEC statements that need to be added to the TCP/IP profile to configure this support, see *z/OS Communications Server: IP Configuration Reference*.

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and both stacks have the DVIPSEC option specified, an attempt is made to automatically re-establish Security Associations on the backup stack. The IKE daemon on the system that is assuming control of the DVIPA attempts to renegotiate new Security Associations to replace the ones that were on the system that previously owned the DVIPA. If these attempts fail due to configuration errors or connectivity errors, manual intervention might be required. Phase 1 Security Association or phase 2 Security Association negotiations that were in progress at the time of the DVIPA movement are lost. However, if these negotiations were for a refresh, a new negotiation is started in the process of assuming control of the DVIPA.

In NATT configurations where IKE can act only as the responder, the IKE daemon does not attempt to renegotiate a new Security Association for a UDP-encapsulated mode Security Association. Sysplex distribution is possible in these configurations, but the recovery of the Security Associations when the DVIPA moves is not supported. There are two NATT configurations in which IKE can act only as the responder:

- When the IKE peer is a security gateway and a NAT is being traversed

- When the IKE peer is behind a NAPT

For more information about NATT configurations, as well as interoperability considerations, see "Configuration scenarios supported for NAT traversal" on page 1095.

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the server to detect whether one-to-one address translation or many-to-one address port translation (NAPT) is being done. When multiple clients have active Security Associations, the server can detect that port translation is being done. If z/OS cannot determine that a Security Association is negotiated with a remote peer behind a NAPT, the Security Association is treated as if it is being negotiated with a remote peer using one-to-one address translation.

When IKE is limited to only a responder role, the Security Association must be reestablished by peer initiation. The interoperability considerations for establishing an initial phase 2 Security Association are relevant to the renegotiation of the phase 2 Security Association due to the movement of a DVIPA. For example, a host-to-host UDP-Encapsulated-Tunnel mode Security Association protecting specific protocols or ports that was initially initiated from a non-z/OS client, might not be able to be renegotiated when the z/OS system assuming control of the DVIPA initiates the negotiation. If this is the case, the Security Association must be reestablished by peer initiation.

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and one or both stacks do not have the DVIPSEC option specified, the Security Associations that are associated with that DVIPA must be re-established by issuing the **ipsec** command, on-demand activation, or by a peer initiation.

Guidelines:

- If a DVIPA is manually deleted and that address has no backup, the IKE daemon might not be able to terminate the tunnels in which the DVIPA is a security endpoint. To avoid this problem, use the **ipsec** command to deactivate the DVIPA's IKE tunnels before manually deleting the DVIPA.
- This support does not address the dynamic relocation of static filter rules and VPN policy definitions to the target system in the sysplex. It is up to you to ensure that the necessary filter rules and IP security policy definitions exist on all participating systems in the sysplex. If the necessary filter rules and IP security policy definitions do not exist, the IKE daemon might not be able to re-establish all Security Associations. For a description of the SWSA function, see "Sysplex-wide security associations" on page 388.

Rule: Because the renegotiation of a Security Association after a DVIPA move requires the sysplex stack to initiate an IKE negotiation, the sysplex stack must be allowed to initiate. You must code the Initiation attribute on the IpDynVpnAction statement as `localonly` or `either`.

Restriction: An on-demand tunnel negotiation will fail if it is triggered by a connection request from a stack using a distributed DVIPA as the source address and that stack is not also the owner (distributor) of the DVIPA.

FIPS 140 and sysplex-wide Security Associations

To enable FIPS 140 mode in a sysplex, you should enable FIPS 140 mode for all the TCP/IP stacks, IKE daemons, and network security services (NSS) daemons on all

systems in the sysplex. If the FIPS 140 mode of the distributing TCP/IP stack in the sysplex is different than the FIPS 140 mode of the target TCP/IP stacks, distribution of some of the tunnels across the target TCP/IP stacks might not function as expected.

If the distributor is configured with FIPS 140 support, then all of the tunnels it activates will adhere to the FIPS 140 restrictions (for example, DES encryption will not allowed). All target TCP/IP stacks can use the distributed tunnels and can process the distributed traffic, regardless of their FIPS 140 mode. The targets that are configured without FIPS 140 support might not adhere to the strict cryptographic module boundaries as defined by FIPS 140, but the Security Association will be successfully activated and used.

If the distributor is not configured with FIPS 140 support, it might activate Security Associations that do not adhere to the FIPS 140 restrictions. The distributor can successfully distribute those associations to target TCP/IP stacks that are not configured in FIPS 140 mode. However, if the distributor distributes those associations to target TCP/IP stacks that are configured in FIPS 140 mode, the data flowing over connections to those stacks is discarded because the associated Security Association or tunnel is not installed.

The distributor and its backup can be configured differently with respect to the FIPS 140 mode. When a backup takes over from a distributor, all the IP security tunnels are renegotiated by the backup. The renegotiated tunnels operate at the FIPS 140 mode that is defined on the backup distributor. This can change the operation of the tunnels as they are distributed by the backup. If the distributor is configured with FIPS 140 support and its backup is not, the backup might activate Security Associations that do not adhere to the FIPS 140 restrictions and distribution of them might fail.

For more information about enabling FIPS 140 mode in a sysplex environment, see "Steps for configuring IP security to support FIPS 140 mode" on page 932.

Sysplex-wide Security Associations in a mixed-level environment

This topic includes considerations for using sysplex-wide Security Associations (SWSA) in a mixed-level environment.

Using encryption or authentication algorithms

IP security support includes encryption and authentication algorithms.

Restriction: Tunnels that use encryption or authentication algorithms that were introduced in V1R12 are not distributed to target stacks that are at a release prior to V1R12.

Remote identity support in filter policy

An IP filter rule can specify a remote IKE identity when the remote IP address of a client system is unknown or unpredictable, but its IKE identity is known. If the release level of the distributor, backup, and target stacks is not prior to the z/OS V1R10 level, and if all stacks share a common filter policy, sysplex-wide Security Associations (SWSA) distribution and takeover function correctly for dynamic tunnels associated with these IP filter rules. However, if the release level of the distributor is not prior to V1R10 but the release level of the backup or targets is V1R9 or earlier, the remote identity support will not function correctly.

Guideline: Remote identities in IP filter policy should not be used in combination with SWSA unless no TCP/IP stacks are at a release level prior to V1R10.

Shadow Security Associations

When an IP security stack is the target of a DVIPA, it receives a copy (shadow) of any active Security Associations for the DVIPA. To display the shadow Security Associations, use the following command:

```
ipsec -y display -s

CS V1R12 ipsec  Stack Name: TCPCS  Tue Feb 16 10:39:25 2010

Sample IP security policy files

A sample stack-specific policy is located in /usr/lpp/tcpip/samples/pagent_IPSec.conf.

A sample common policy is located in /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf.

Chapter 20. Network security services

A network security services (NSS) server provides network security services for one or more security disciplines. Supported disciplines are IPSec, which is a set of services that supports IPSec and IKE processing, and XMLAppliance, which is a set of services for XML appliances. For the IPSec discipline, these services include the IPSec certificate service and the IPSec remote management service. For the XMLAppliance discipline, the NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service. For information about configuring the IKE daemon to act as an NSS IPSec client on behalf of a TCP/IP stack, see Chapter 19, "IP security," on page 923.

Terms and concepts for network security services

The following terms and concepts apply to the information about network security services (NSS):

certificate bundle
An x.509 bundle as defined in Section 3.6 of RFC 4306, *Internet Key Exchange Protocol: IKEv2*. A certificate bundle can contain multiple DER encoded certificates and certificate revocation lists (CRLs). You can use the **certbundle** command to create a certificate bundle.

Certificate revocation list (CRL)
A time-stamped list of revoked certificates that is signed by a certificate authority.

CRLDistributionPoints
An optional x.509 certificate extension that identifies one or more locations where the CRL for a certificate resides.

hash and URL encoding
A certificate payload encoding that includes the hash of a certificate or bundle and the URL that identifies where that certificate or bundle can be retrieved from an HTTP server

IPSec certificate service
A service for NSS IPSec clients that provides IPSec digital signature and verification services.

IPSec discipline
A set of services provided to an NSS IPSec client. The services are the IPSec certificate service and the IPSec remote management service.

IPSec remote management service
A service for NSS IPSec clients that provides remote IPSec management capability.

Network security services (NSS)
A set of services that performs security enforcement or management. The services are provided in groupings called security disciplines.

NSS client
A client that requests network security services from an NSS server.

NSS daemon (NSSD)
The z/OS UNIX daemon that implements the NSS server functionality.

NSS IPSec client
An NSS client that is using the IPSec discipline. The z/OS IKE daemon can act as an NSS IPSec client for one or more TCP/IP stacks.

NSS server
Provides network security services for one or more NSS clients.

NSS XMLAppliance client
An NSS client that is using the XMLAppliance discipline.

security discipline
A specific grouping of network security services.

trust chain
The signing sequence of certificates for any particular certificate back to a root certificate authority.

XML appliance
A network appliance that processes XML messages efficiently and securely. XML appliances often offload XML parsing and transformations from host systems and implement a variety of XML security features.

XMLAppliance certificate service
A service for NSS XMLAppliance clients that provides key ring listing and certificate retrieval capability.

XMLAppliance discipline
A set of services provided to an NSS XMLAppliance client. The NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service.

XMLAppliance private key service
A service for NSS XMLAppliance clients that provides private key retrieval of private keys that are not protected by Integrated Cryptographic Service Facility (ICSF), RSA signature generation using ICSF-protected private keys, and RSA message decryption using ICSF-protected private keys.

XMLAppliance SAF access service
A service for NSS XMLAppliance clients that provides SAF user authentication and access control capability.

For additional IP security-related terms, see Chapter 19, “IP security,” on page 923.

Network security services overview

Network security services (NSS) includes services that perform security enforcement or management. As shown in Figure 114 on page 1151, NSS includes services provided by the NSS IPSec discipline and NSS XMLAppliance discipline. Each discipline includes a subset of services provided by NSS and is intended for use by a specific type of NSS client.

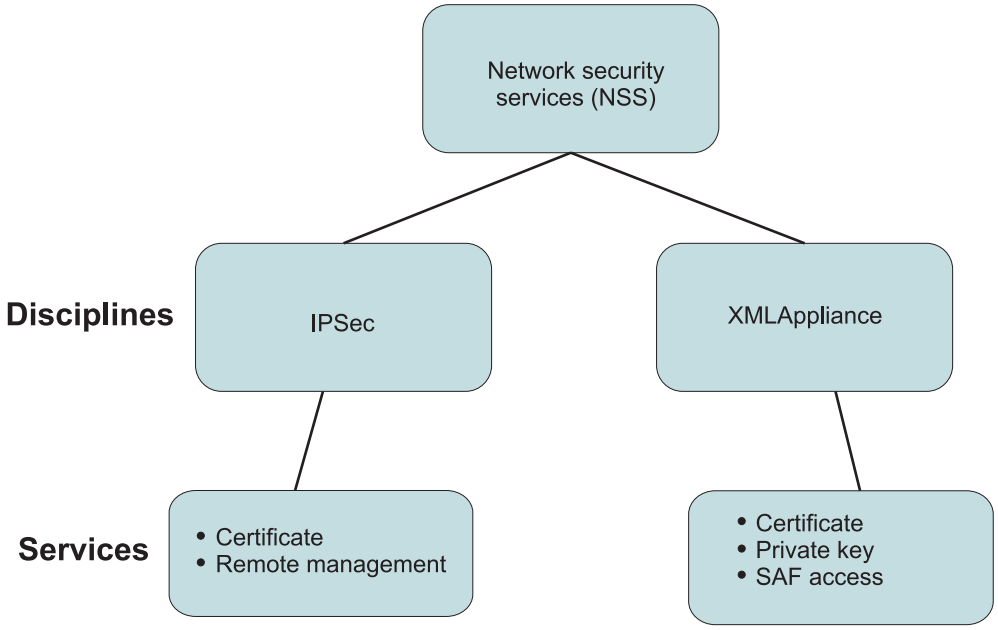

Figure 114. NSS services by discipline

NSS IPSec discipline overview

The NSS IPSec discipline includes the NSS IPSec certificate service and NSS IPSec remote management service.

The NSS server provides the NSS IPSec certificate service to perform digital signature and verification operations on behalf of an NSS IPSec client. The NSS IPSec certificate service is used by an NSS IPSec client during a phase 1 negotiation when digital signature authentication is required. Certificates and private keys for all NSS IPSec clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. When providing the NSS IPSec certificate service, the NSS server consults SERVAUTH profiles to verify that an NSS IPSec client is authorized to access the certificates that are involved. For details about these profiles, see step 7d on page 1155 and step 7e on page 1156, under “Steps for authorizing resources for NSS” on page 1152.

The NSS server uses the NSS IPSec remote management service to request IPSec monitoring data from an NSS IPSec client and to make IPSec control requests to an NSS IPSec client. Control requests include the ability to activate, deactivate, or refresh a Security Association, and to switch between default IP filter policy and IP security filter policy. Use the **ipsec** command and the IPSec network management interface (NMI) to make these requests. For details about the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*. For details about the IPSec NMI, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

NSS XMLAppliance discipline

The NSS XMLAppliance discipline includes the NSS XMLAppliance SAF access service, the NSS XMLAppliance certificate service, and the NSS XMLAppliance private key service.

An NSS XMLAppliance client uses the NSS XMLAppliance SAF access service to perform SAF user authentication and access control checks. The NSS server consults SERVAUTH profiles for access control checks. For details about these profiles, see step 7d on page 1155 and step 7e on page 1156, under "Steps for authorizing resources for NSS."

The NSS XMLAppliance certificate service enables an NSS server to provide a list of authorized certificates on its key ring. Those certificates can then be retrieved on behalf of an NSS XMLAppliance client. Certificates for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates on this key ring. When the NSS server provides the NSS XMLAppliance certificate service, it consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates involved. For details about these profiles, see step 7d on page 1155 and step 7e on page 1156, in "Steps for authorizing resources for NSS."

An NSS XMLAppliance client uses the NSS XMLAppliance private key service to retrieve authorized private keys stored in the SAF database of the NSS server. The private key service also enables the NSS server to perform RSA signature and RSA decryption operations using private keys protected by Integrated Cryptographic Service Facility (ICSF) on behalf of an NSS XMLAppliance client. An NSS XMLAppliance client can use a retrievable private key to sign and decrypt XML messages locally. XML appliances that are in less-trusted network zones can use a centralized NSS server to perform critical RSA operations using ICSF-protected private keys on behalf of the appliance. Certificates and private keys for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. Retrieval of the private key is not allowed if the private key is stored in the ICSF public key data set (PKDS). When providing NSS XMLAppliance private key service, the NSS server consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates and associated keys involved. For details about these profiles, see step 7d on page 1155, step 7e on page 1156, and step 7g on page 1157 under "Steps for authorizing resources for NSS."

Preparing to provide network security services

Before network security services can be provided, authorization to several resources must be defined to the external security manager. This topic also includes NSS server certificate label naming considerations, an NSS client authorization example, information on configuring and controlling the NSS server, and recovery considerations.

Steps for authorizing resources for NSS

Before you begin: RACF is used as the external security manager in the following examples. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST dataset. In these examples, it is assumed that the NSS server is running under the user ID NSSD.

Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the NSSD user ID.

   The NSS server is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the NSS server, you must define the NSSD user ID to the external security manager

with UID 0. If you start the NSS server from an MVS started procedure, the NSSD user ID must also be authorized to the STARTED class.

Issue the following commands:

```
ADDUSER  NSSD     DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0)  HOME('/'))
RDEFINE  STARTED  NSSD.*            STDATA(USER(NSSD))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

2. Permit the NSSD user ID to SYS1.PARMLIB.

   The NSS server uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default NSS server component trace parmlib member is stored in SYS1.PARMLIB. The NSSD user ID must be permitted to access SYS1.PARMLIB.

   Issue the following command:

   ```
   PERMIT   SYS1.PARMLIB  ID(NSSD) ACCESS(READ)
   ```

3. Define key ring controls.

   Certificates used by NSS clients are stored on a SAF key ring. The RACDCERT command is used to manage a RACF key ring. The IRR.DIGTCERT FACILITY class resource is used to control access to the RACDCERT command. If these controls do not already exist, they must be defined as follows:

   ```
   RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
   ```

   For details about these controls, see *z/OS Security Server RACF Command Language Reference*.

4. Give the user ID of the administrator that will manage the NSS server's key ring appropriate access to manage the key ring.

   Issue the following commands:

   ```
   PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   ```

   If you will issue the RACDCERT command using the NSSD user ID, READ authority to the IRR.DIGTCERT.ADD, IRR.DIGTCERT.ADDRING, IRR.DIGTCERT.GENREQ, and IRR.DIGTCERT.LISTRING resources is sufficient. Authority requirements for the other resources remain the same. If you will issue the RACDCERT command using a user ID other than the NSSD user ID, you must provide appropriate access for the NSSD user ID to its own key ring as follows:

   ```
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(NSSD) ACC(READ)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(NSSD) ACC(READ)
   ```

   After you permit access to the various IRR.DIGTCERT resources, update the FACILITY class as follows:

   ```
   SETROPTS RACLIST(FACILITY) REFRESH
   ```

5. Optionally, permit the NSS server to the BPX.DAEMON FACILITY class profile.

   For information concerning the use of the BPX.DAEMON profile, see "BPX.DAEMON FACILITY class profile" on page 43.

If you decide to use this profile, permit the NSS server user ID to this profile using the following command, where the *userid* value is the user ID under which the NSS server runs:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(userid) ACCESS(READ)
```

6. Enable the secured signon function.

   The NSS server supports the use of PassTickets. To use this support, the secured signon function must be enabled, and at least one profile must be created for the NSS server.

   The secured signon function of RACF is enabled by activating the PTKTDATA class as follows:

   ```
   SETROPTS CLASSACT(PTKTDATA)
   SETROPTS RACLIST(PTKTDATA) REFRESH
   ```

   Profiles in the PTKTDATA class control the use of the secured signon function by an application. A secured signon application key is associated with each profile. This key is stored in the external security manager's database. When RACF is used as the external security manager, this key is stored in a masked or encrypted state.

   With RACF, you can use a secured signon application key that is controlled at the following levels:

   - All users who need access to the application
   - A specific RACF group of users who need access to the application
   - A specific RACF user, when connected to a specific RACF group
   - A specific RACF user

   The application name NSSD must be used when defining the secured signon keys for the NSS server. Following is an example of a RACF command that you can issue to assign a secured signon key that can be used by all NSS clients authenticating to the NSS server:

   ```
   RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E001193519561977)) UACC(NONE)
   ```

   For specific information about enabling the secured signon function and defining profiles to be used by the single signon function, see *z/OS Security Server RACF Security Administrator's Guide*.

7. Define SERVAUTH profiles to authorize NSS clients to network security services.

   These profiles reside on the same system as the NSS server. Many of these profiles are constructed using the name of an NSS client. NSS clients must authenticate to the NSS server using a valid user ID and password, or a valid user ID and PassTicket. This user ID must be given access to the SERVAUTH profiles created on behalf of the NSS client.

   For details about how to define the IKE daemon as an NSS client, see "Using network security services" on page 1102.

   Perform the following steps to authorize NSS clients:

   a. Define a SAF user ID representing an NSS client to the external security manager.

      An NSS client must present valid credentials to the NSS server before accessing any services. Valid credentials include a user ID and password, or a user ID and PassTicket if secured signon is enabled. A SAF user ID representing an NSS client must be defined to the external security manager.

      Issue the following command:

      ```
      ADDUSER  userid   DFLTGRP(OMVSGRP)  OMVS(UID(x))
      ```

Rules:

- Multiple NSS clients can use a single user ID. However, each NSS client must have a unique client name.
- A SAF user ID must have an OMVS segment with either AUTOID or a specific UID(*x*) defined for the NSSD to authenticate it as an NSS client.

Guideline: Because SAF user IDs are used to authorize a client to the NSS services, avoid sharing a single user ID across NSS disciplines.

b. If you choose to define an NSSD profile in the APPL class with UACC(NONE), issue the following command to authorize each SAF user ID to the NSSD application:

```
PERMIT NSSD CLASS(APPL) ID(userid) ACC(READ)
SETROPTS RACLIST(APPL) REFRESH
```

c. Authorize the user ID associated with an NSS client for each of the network security services it will use.

To authorize an NSS client to use a network security service, you must create a SERVAUTH resource profile for that service that represents the NSS client. The user ID associated with the NSS client must be permitted READ access to that profile. Table 50 shows the name of the SERVAUTH profile for each service, where *sysname* is the name of the z/OS system running the NSS server and *clientname* is the name by which the NSS server knows the NSS client.

Table 50. SERVAUTH profile names for NSS

Service	SERVAUTH profile name
IPSec certificate service	EZB.NSS.*sysname*.*clientname*.IPSEC.CERT
IPSec remote management service	EZB.NSS.*sysname*.*clientname*.IPSEC.NETMGMT
XMLAppliance certificate service	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.CERT
XMLAppliance private key service	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.PRIVKEY
XMLAppliance SAF access service	EZB.NSS.*sysname*.*clientname*.XMLAPPLIANCE.SAFACCESS

You can authorize the NSS client to a SERVAUTH profile using the following commands:

```
RDEFINE SERVAUTH profile_name  UACC(NONE)
PERMIT  profile_name (SERVAUTH) ID(nssclient) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Tip: You can use a wildcard in the profiles to reduce the number of profile entries that must be defined.

d. Create a SERVAUTH resource profile for each NSS IPSec client certificate added to the NSS server's key ring, and give each NSS IPSec client's user ID access to the profiles created for its own certificates.

The name of such a resource profile is EZB.NSSCERT.*sysname*.*mappedlabelname*.HOST, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see "NSS server certificate label naming considerations" on page 1158.

This can be accomplished with the following commands:

```
RDEFINE SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.HOST UACC(NONE)
PERMIT EZB.NSSCERT.sysname.mappedlabelname.HOST CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

e. Create a SERVAUTH resource profile for each certificate authority (CA) certificate that could be used by an NSS IPSec client, and give the NSS client's user ID access to the profiles.

When the digital signature mode of authentication is used, an NSS IPSec client can provide a remote security endpoint with information about certificate authorities that are trusted by the NSS client. The remote security endpoint should use this information as a hint to decide which of its certificates to use when creating its signature.

By default, an NSS IPSec client sends a remote security endpoint information about all the certificate authorities that the NSS IPSec client is authorized to advertise. This can result in an NSS IPSec client sending a large amount of data to a remote security endpoint. Use the CaLabel parameter on the RemoteSecurityEndpoint statement to reduce the amount of data sent to specific remote security endpoints. For details about the RemoteSecurityEndpoint statement, see *z/OS Communications Server: IP Configuration Reference*.

A SERVAUTH resource profile is used to authorize NSS IPSec clients to use a CA. A SERVAUTH resource profile must be created for each CA certificate that could be used by an NSS IPSec client. The name of such a resource profile is EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see "NSS server certificate label naming considerations" on page 1158. An NSS IPSec client's user ID must be given access to this profile before it can use the corresponding CA certificate.

This can be accomplished with the following commands:

```
RDEFINE  SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH UACC(NONE)
PERMIT   EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

f. Create a SERVAUTH resource profile for each certificate that an NSS XMLAppliance client could retrieve and give the user ID of the NSS XMLAppliance client access to the appropriate profiles.

In contrast to the IPSec discipline, the XMLAppliance discipline does not distinguish between host, site, or certificate authority certificates. For any given certificate request, the NSS server first checks the EZB.NSSCERT.*sysname.mappedlabelname*.HOST profile. If that check fails, the server then checks the EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH profile. If the NSS XMLAppliance client has read access to either profile, the server permits access to the certificate resource. It is up to the NSS server administrator to allow or deny access to each certificate, and it is up to the XML appliance administrator to determine how each certificate should be used. The user ID of an NSS XMLAppliance client must be given access to one of these profiles before it can use the corresponding certificate. For examples on how to define the required profiles and permit access, see step 7d on page 1155 and step 7e, under "Steps for authorizing resources for NSS" on page 1152. For details about determining the mapped name of a certificate label, see "NSS server certificate label naming considerations" on page 1158.

g. Create a SERVAUTH resource profile for the private key of each certificate to which an NSS XMLAppliance client requires access and give the user ID of the NSS XMLAppliance client access to the profiles.

   Use the SERVAUTH resource profile to authorize NSS XMLAppliance clients to retrieve the private key from a certificate, and to locally perform any RSA operations that are based on the private key or to make ICSF calls requesting RSA operations on System z for ICSF-protected keys. You must create a SERVAUTH resource profile for each private key against which the XMLAppliance client needs to perform operations. The name of such a resource profile is EZB.NSSCERT.*sysname*.*mappedlabelname*.PRIVKEY, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate label in the key ring. Ensure that the user ID of an NSS XMLAppliance client has appropriate access to this profile so that it can retrieve the private key or perform any RSA operations that are based on the private key. This can be accomplished with the following commands:

```
RDEFINE  SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY UACC(NONE)
PERMIT   EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

   For details about determining the mapped name of a certificate label, see "NSS server certificate label naming considerations" on page 1158.

h. Create the following SERVAUTH profiles to enable users to remotely monitor (IPSEC.DISPLAY) or manage (IPSEC.CONTROL) NSS clients:

   - EZB.NETMGMT.*sysname*.*clientname*.IPSEC.DISPLAY
   - EZB.NETMGMT.*sysname*.*clientname*.IPSEC.CONTROL

   For more information, see the information about the **-z** option of the **ipsec** command in "NSS client authorization example" on page 1159. For more details about managing network security, see *z/OS Communications Server: IP System Administrator's Commands*. For details about the network management interface, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

8. If you are using the NSS XMLAppliance private key service with ICSF-protected private keys, authorize the NSS server to the Integrated Cryptographic Service Facility (ICSF).

   ICSF is required when using the RSA operations in the XMLAppliance private key service. The XMLAppliance private key service uses ICSF in the following ways:

   - Encrypting signature data for the XMLAppliance private key service RSA signature generation message flow.
   - Decrypting data for the XMLAppliance private key service RSA decryption message flow.

   ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depend on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in *z/OS Cryptographic Services ICSF Overview*. For details about configuring ICSF, see *z/OS Cryptographic Services ICSF Administrator's Guide*.

   When using a cryptographic coprocessor, the callable ICSF service names that are used by the XMLAppliance certificate service are as follows:

   - CSNDDSG

- CSNDPKD

Requirement: If you plan to use the RSA operations within the XMLAppliance private key service, the NSS server must be permitted to access the ICSF cryptographic services (CSFSERV). Use the following commands to define the appropriate profiles in the CSFSERV class, give the NSS server access to the profiles, activate the CSFSERV class, and refresh the RACF profiles in storage:

```
RDEFINE service-name CLASS(CSFSERV) UACC(NONE)
PERMIT service-name CLASS(CSFSERV) ID(server-name) ACCESS(READ)
SETROPTS CLASSACT(CSFSERV)
SETROPTS RACLIST(CSFSERV) REFRESH
```

9. If XMLAppliance clients using the SAF access service are using certificates for access checks, enable RACF certificate name filtering.

   The NSS XMLAppliance SAF access service can use RACF certificate name filtering to map an X.500 distinguished name to a RACF ID when performing SAF access checks. The DIGTNMAP class must be active to perform certificate name filtering. Activate the DIGTNMAP class with the following commands:

   ```
   SETOPS CLASSACT(DIGTNMAP)
   SETROPTS RACLIST(DIGTNMAP) REFRESH
   ```

   Create a certificate name filter for each mapping of an X.500 distinguished name to a RACF ID using the following commands:

   ```
   RACDCERT ID(userid) MAP SDNFILTER('x500dn')
   SETROPTS RACLIST(DIGTNMAP) REFRESH
   ```

   For specific details on enabling RACF certificate name filtering, see *z/OS Security Server RACF Security Administrator's Guide*.

10. The NSSD uses ICSF callable services for ECDSA digital signature support. The services it uses are the PKCS11 private key sign service and the PKCS11 public key verify service. You can control access to these services with RACF, using the CSFSERV general resource class, and the CSF1PKS and CSF1PKV profiles. If the CSFSERV class is defined, and the CSF1PKS and CSF1PKV profiles are defined, grant the NSSD user ID read access to the defined profiles using the following commands:

    ```
    PERMIT CSF1PKS CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
    PERMIT CSF1PKV CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
    SETROPTS RACLIST(CSFSERV) REFRESH
    ```

    See *z/OS Cryptographic Services ICSF Administrator's Guide* for more information about the CSFSERV general resource.

NSS server certificate label naming considerations

During the processing of certificate operations, the NSS server validates that an NSS client is authorized to access the certificates required to complete the operation. The NSS server consults SERVAUTH profiles to perform this validation. The profile names consulted by the NSS server are dynamically constructed by the NSS server using the following information:

- The system name on which the NSS server is running
- The label of the certificate this is used during a certificate operation
- The certificate operation that is being performed:
  - When processing a request to create a signature, the format of the profile that is consulted is EZB.NSSCERT.*sysname*.*mappedlabelname*.HOST.
  - When processing a request to obtain a list of CA certificates, the format of the profile consulted is EZB.NSSCERT.*sysname*.*mappedlabelname*.CERTAUTH.

– When processing a request to retrieve a private key that is not protected by Integrated Cryptographic Service Facility (ICSF) or to use an ICSF-protected private key, the format of the profile consulted is EZB.NSSCERT.*sysname*.*mappedlabelname*.PRIVKEY.

The NSS server creates a mapped label name using the following algorithm:

- All lowercase alphabetic characters in a certificate's label are changed to uppercase. This is necessary because the class descriptor table for the SERVAUTH profile permits only uppercase profile names.
- The asterisk (*), percent sign (%), and ampersand (&) are replaced by a dollar sign ($). This is necessary because these characters have special meaning when generic profile processing is active.
- All embedded blanks are also replaced by a dollar sign ($). This is necessary because blanks are not allowed in SERVAUTH profile names.

Rules:

- The administrator of the NSS server must define profiles using the mapped label names generated by this algorithm. When the certificate's label name contains lowercase characters, the administrator must change each lowercase character to uppercase. When the certificate's label name contains the characters *, %, &, or a blank character, the administrator must replace each occurrence with a dollar sign ($) character.
- When a certificate label contains the period character (.), ensure that the corresponding SERVAUTH profile contains matching qualifiers. For example, if you request a certificate with the label CERTIFICATE.123.ABC for a private key operation, the NSS server checks a SERVAUTH profile named EZB.NSSCERT.*sysname*.CERTIFICATE.123.ABC.PRIVKEY; defining a SERVAUTH profile named EZB.NSSCERT.*sysname*.CERTIFICATE.*.PRIVKEY does not permit access to the private key of the certificate.

Using this algorithm, it is possible that multiple certificates can result in the same mapped name. This is shown in Table 51.

Table 51. Mapped label names

Label	Mapped label
CERTIFICATE_123	CERTIFICATE_123
Certificate_123	CERTIFICATE_123
CERTIFICATE 123	CERTIFICATE$123
CERTIFICATE%123	CERTIFICATE$123
CERTIFICATE*123	CERTIFICATE$123
CERTIFICATE&123	CERTIFICATE$123
CERTIFICATE$123	CERTIFICATE$123

Tip: When creating certificates for the NSS server's key ring, avoid using lowercase alphabetic characters, blanks, and the characters *, %, and & in the certificate's label.

NSS client authorization example

Consider the configuration shown in Figure 115 on page 1160.

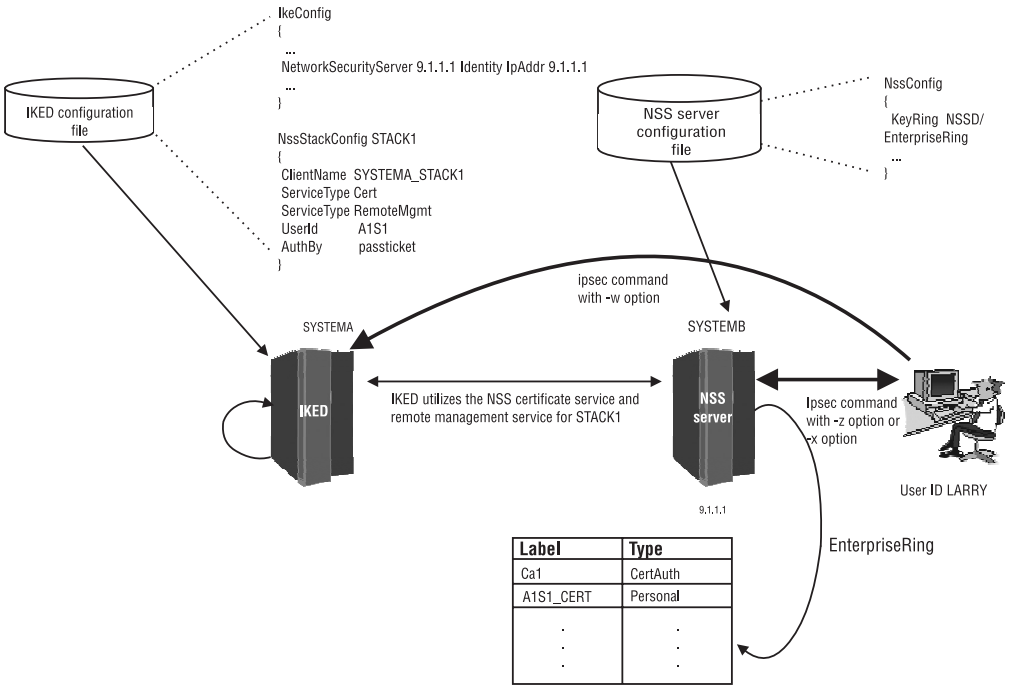

Figure 115. NSS client authorization example

In this example, note the following:

- Stack STACK1 is defined as an NSS IPSec client in the IKE daemon configuration file on system SYSTEMA. The client name for STACK1 is SYSTEMA_STACK1. The user ID associated with SYSTEMA_STACK1 is A1S1. The user ID A1S1 must be defined to the external security manager on system SYSTEMB.
- Client SYSTEMA_STACK1 is configured to use the NSS certificate service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

  `EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.CERT`
- Client SYSTEMA_STACK1 is configured to use the NSS remote management service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

  `EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.NETMGMT`
- The NSS server on system SYSTEMB is configured to use the key ring EnterpriseRing. This key ring is owned by the NSSD user ID. Certificates for all NSS IPSec clients are stored on this key ring.

  The NSS server's AT-TLS policy must also specify a key ring from which to obtain the NSS server's personal certificate for use during the TLS negotiation with an NSS client. The NSS server's AT-TLS policy can specify the same key ring as the NSS server's configuration file, or it can specify a different key ring. In either case, the AT-TLS policy should specify which personal certificate to use to represent the NSS server by using the CertificateLabel parameter on the TTLSConnectionAdvancedParms statement. If this parameter is not configured, AT-TLS attempts to use the default certificate, if one exists, on the configured key ring. If no default certificate exists on the configured key ring and the CertificateLabel parameter is not configured, the TLS negotiation between the NSS client and the NSS server will fail.

  The IKE daemon's AT-TLS policy also specifies a key ring. This key ring is used to locate the certificate that was used to sign the NSS server's personal

certificate. If the IKE deamon's AT-TLS key ring does not contain this signing certificate, TLS negotiation will fail to verify the NSS server's certificate and the TLS negotiation between the NSS client and the NSS server will fail.

In this example, there is one Personal certificate stored on the key ring for client SYSTEMA_STACK1. On system SYSYEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can use this certificate to create a signature for client SYSTEMA_STACK1:

```
EZB.NSSCERT.SYSTEMB.A1S1_CERT.HOST
```

In this example, there is also one CertAuth certificate stored on the key ring that should be advertised to IPSec peers by client SYSTEMA_STACK1. On system SYSYEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can inform client SYSTEMA_STACK1 that it can advertise this CERTAUTH certificate to its peers:

```
EZB.NSSCERT.SYSTEMB.CA.CERTAUTH
```

- The user LARRY will issue the **ipsec** command with the **-z** option to monitor and manage client SYSTEMA_STACK1. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profiles:

  ```
  EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.DISPLAY
  EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.CONTROL
  ```

  The user LARRY will also issue the **ipsec** command with the **-x** option to display information about the NSS server. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profile:

  ```
  EZB.NETMGMT.SYSTEMB.SYSTEMB.NSS.DISPLAY
  ```

  In addition, the user LARRY will issue the **ipsec** command with the **-w** option to display information from the IKE daemon about NSS IPSec clients. On system SYSTEMA, the user ID LARRY must be given read access to the following SERVAUTH profile:

  ```
  EZB.NETMGMT.SYSTEMA.SYSTEMA.IKED.DISPLAY
  ```

  Tip: A wildcard can be used in the profiles to reduce the number of profile entries that must be defined.

NSS server configuration considerations

This topic describes configuration issues specific to the NSS server.

Run-time environment

The NSS server is a z/OS UNIX application; it requires the z/OS UNIX file system. The NSS server can be started from an MVS started procedure, from the z/OS shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMND*xx* member of PARMLIB. The NSS server must be started by a RACF-authorized user ID, and it must reside in an APF-authorized library. For more information about how to start the NSS server, see “Starting the NSS server” on page 1170.

The NSS server uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of NSS requests. CTRACE is used for detailed tracing and debugging.

The NSS server uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The NSS server uses ICSF and System SSL for encryption and key management services to provide certificate services to NSS IPSec clients. If the NSS IPSec clients are configured in FIPS 140 mode, you must also configure the NSS server in FIPS 140 mode so that it invokes ICSF and System SSL in FIPS 140 mode. This configuration is required for the entire system to be in FIPS 140 mode.

Language Environment run-time considerations

When starting the NSS server from a started or cataloged procedure, you should typically start it directly from the SEZALOAD data set using PGM=EZANSSD. However, there is a situation in which you might want to start the NSS server using BPXBATCH.

When the NSS server is started using PGM=EZANSSD, the STDENV DD card, if used, is passed directly to the NSS server program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any NSS server options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus NSS server parameters that you want exceed 100 characters, consider using BPXBATCH to start the NSS server. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

Steps for configuring the NSS server

Perform the following steps to configure the NSS server:

1. Create the NSS server configuration file.

   Use the IBM Configuration Assistant for z/OS Communications Server to establish NSS server settings. Establish the settings using the NSS perspective of the Configuration Assistant, and then use the **Install Configuration File** button on the **Image Information** tab to store the generated NSS server configuration file on the z/OS system.

   Tip: A sample configuration file is provided in /usr/lpp/tcpip/samples/nssd.conf.

   The following search order is used by the NSS server to locate the configuration data set or file:

   a. If the environment variable NSSD_FILE has been defined, the NSS server uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
   b. /etc/security/nssd.conf

   You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the NSSD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

   The NSS server configuration file allows the URL of a certificate or certificate bundle that resides on an HTTP Web server to be associated with the label of a certificate on the key ring of the network security server. See "Using hash and URL certificate encoding types" on page 1166 for additional details.

2. Optionally, set the _BPX_JOBNAME environment variable.

   When starting the NSS server from the z/OS shell, you should set the environment variable _BPX_JOBNAME. This enables a specific job name to be used when reserving ports for the NSS server. This name can also be used

with the STOP or MODIFY console commands. For more information about _BPX_JOBNAME, see *z/OS UNIX System Services Planning*.

3. Authorize the NSS server to the external security manager, as described in "Steps for authorizing resources for NSS" on page 1152.

4. Configure and start syslogd.

   The NSS server uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use zSeries File System as its underlying file system. For more information about syslogd, see "Configuring the syslog daemon" on page 185.

5. Optionally, update the NSS server environment variables.

   The following environment variables are used by the NSS server and can be tailored to a particular installation.

   NSSD_CODEPAGE
   Use the NSSD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For more information about NSSD environment variables and the supported code pages, see *z/OS Communications Server: IP Configuration Reference*.

   NSSD_CTRACE_MEMBER
   Used by the NSS server to locate a parmlib member for NSS server CTRACE customization. For more information about the TCP/IP services component trace for the NSS server, see *z/OS Communications Server: IP Diagnosis Guide*.

   NSSD_FILE
   Used by the NSS server in the search order for the NSS server configuration file. For details about the search order used for locating this configuration file, see step 1 on page 1162.

   NSSD_PIDFILE
   Used by the NSS server in the search order for the NSS server PID file. The search order for the NSS server PID file is as follows:

   a. NSSD_PIDFILE environment variable
   b. /etc/nssd.pid

6. Set up the NSS server key ring.

   The NSS server's key ring serves a similar purpose as the IKE daemon's key ring. It contains certificates that are used in the process of creating and verifying signatures that are exchanged during digital signature authentication. A personal certificate or site certificate contained on the key ring of the NSS server represents the identity of an NSS IPSec client, whereas a certificate contained on the IKE daemon's key ring represents a local stack's identity. Certificates for all NSS IPSec clients must reside on this one key ring.

   If a personal certificate or site certificate that is contained on the key ring of the NSS server is signed by a certificate authority, then the certificate of that certificate authority must also be connected to the key ring of the NSS server. If the certificate authority is a subordinate certificate authority (such as one that was created by another certificate authority) you should ensure that all the certificate authority certificates that make up the trust chain are connected to the key ring of the NSS server.

   The same commands that are used to create and manage the IKE daemon's key ring also apply to the NSS server's key ring. For examples of how to create and manage the IKE daemon's key ring, see Appendix E, "Steps for preparing to run IP security," on page 1505.

You must create a SERVAUTH resource profile for each NSS IPSec client certificate that is added to the key ring of the NSS server. For details, see step 7d on page 1155.

7. Update the TCP/IP profile and policy files.

   You should update the TCP/IP profile to reserve the port on which the NSS server will listen. If IP security is enabled, consider updating the default IP filter rules in the TCP/IP profile to enable the NSS server to communicate with NSS clients. The IP security policy defined in Policy Agent configuration files must be updated to enable the NSS server to communicate with NSS clients. AT-TLS should be enabled and rules should be defined to protect NSS server communication with NSS clients.

   For additional details concerning these tasks, see "TCP/IP stack considerations."

8. Update the NSS server cataloged procedure (if starting as a started procedure).

   If the NSS server is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(NSSD) to your system. Specify NSS server parameters and change the data set names to suit your local configuration. For a copy of the sample, see *z/OS Communications Server: IP Configuration Reference*.

If these steps are completed successfully, you should be able to start the NSS server. For details, see "Starting the NSS server" on page 1170.

TCP/IP stack considerations: This topic describes TCP/IP stack considerations, including port reservation, IP filtering, and AT-TLS policy.

Port reservation: By default the NSS server uses TCP port 4159, but this value is configurable using the Port parameter of the NssConfig statement in the NSS server configuration file. For additional details about the NssConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

Tip: Update the PORT statement in the TCP/IP profile to reserve the port that the NSS server will use when listening for client connections.

```
PORT
     4159 TCP NSSD
```

IP filtering: The NSS server communicates with NSS clients using the TCP protocol. The NSS server binds to all stacks using either INADDR_ANY or in6addr_any as the IP address. IP filters rules must be defined for any IP security stacks that contain an interface to which the NSS client will connect (for details about configuring the IKE daemon as an NSS client, see Chapter 19, "IP security," on page 923). Remote IPSec clients use an ephemeral port when connecting to the NSS server. Ephemeral ports are generally in the range 1024–65355.

Two types of IP filter policy can be defined for a z/OS stack:

- You can define a default IP filter policy in the TCP/IP profile. Updating default IP filter policy to permit communications between the NSS server and NSS clients is optional. Default IP filter policy is in effect only when IP security filter policy cannot be loaded or when the **ipsec -f default** command has been issued.

  For details about defining default IP filter policy in the TCP/IP profile, see *z/OS Communications Server: IP Configuration Reference*.

  Following is a default policy containing IPSECRule definitions that allow IPv4 and IPv6 NSS server traffic with NSS clients:

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr   Logging Protocol   SrcPort    DestPort     Routing Secclass

; OSPF protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO OSPF

; IGMP protocol used by Omproute
  IPSECRule *       *         NOLOG   PROTO 2

; DNS queries to UDP port 53
  IPSECRule *       *         NOLOG   PROTO UDP  SRCPort *  DESTport 53

; Administrative access
  IPSECRule *       9.1.1.2   LOG                                                SECCLASS 100

; Network security services (NSS) server access to the NSS client
  IPSECRule *       *         LOG     TCP        SRCPort 4159 DESTport *

; Network security services (NSS) server access to the NSS client
  IPSEC6Rule *      *         LOG     TCP        SRCPort 4159 DESTport *

ENDIPSEC
```

Rule: The SRCport value in the filter rules must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

- You can define an IP security filter policy in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the NSS server and NSS clients.

  For details about defining IP security policy files, see the Policy Agent and policy applications topic in *z/OS Communications Server: IP Configuration Reference*.

  An example of an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement that allows NSS clients to communicate with the NSS server is as follows:

```
IpFilterRule             NssTrafficIPv4
  {
      IpSourceAddr             all4
      IpDestAddrSet            all4
      IpService
      {
         SourcePortRange        4159
         DestinationPortRange   1024 65535
         Protocol               tcp
         Direction              bidirectional InboundConnect
         Routing                local
      }
      IpGenericFilterActionRef  permit-nolog
  }

IpFilterRule             NssTrafficIPv6
  {
     IpSourceAddr             all6
     IpDestAddrSet            all6
     IpService
     {
        SourcePortRange        4159
        DestinationPortRange   1024 65535
        Protocol               tcp
        Direction              bidirectional InboundConnect
        Routing                local
     }
     IpGenericFilterActionRef  permit-nolog
  }

IpGenericFilterAction    permit-nolog
```

```
{
   IpFilterAction           permit
   IpFilterLogging          no
}
```

Rule: The DestinationPortRange value on the IpService statements must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

AT-TLS policy: Communications between the NSS server and NSS clients must be secured using Application Transparent Transport Layer Security (AT-TLS). You must define AT-TLS rules to secure this communication. Enable AT-TLS processing for a stack by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

Tip: Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with NSS clients. Failure to restrict the cipher suites to those requiring encryption can result in sensitive information flowing in the clear across an untrusted network.

Rule: You must define AT-TLS policy for each stack through which the NSS server will communicate with an NSS client.

Requirement: The NSS server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the NSS server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers using AT-TLS, see Appendix B, "TLS/SSL security," on page 1461.

A sample AT-TLS policy is located in /usr/lpp/tcpip/samples/pagent_TTLS.conf.

Rule: The LocalPortRange value on the TTLSRule statement must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

Using hash and URL certificate encoding types

During an IKE flow, security endpoints can authenticate each other by exchanging certificate information in certificate payloads and by performing digital signature operations on that certificate information. When the IKED negotiates an IKEv2 phase 1 Security Association on behalf of a network security client, the IKED uses the network security server for these digital signature operations. Encoded certificate information that is received from a remote security endpoint is forwarded to the network security server. Encoded certificate information that is sent to a remote security endpoint by the IKED is obtained from the network security server.

There are several encoding types defined for use in IKEv1, but the only encoding type that must be supported by an IKEv1 implementation is an X.509 certificate signature. Two additional certificate encoding types must be supported by an IKEv2 implementation:

- Hash and URL of an X.509 certificate
- Hash and URL of an X.509 bundle

Generally a hash and URL of a certificate or certificate bundle is considerably smaller than the certificate or the bundle that it represents. Less data is exchanged between IKE peers and between the IKED and the network security server. Although smaller message sizes might improve the efficiency of network resources, using hash and URL encoding requires more processing. The NSSD must communicate with an HTTP server to retrieve the certificate using the URL, and it must validate the certificate using the hash. This communication, when needed, increases the amount of time it takes to complete an IKEv2 phase 1 negotiation.

If you want the NSSD to create hash and URL certificates to send to peers, you must create files on an HTTP server that contain the certificates and the certificate bundles. You must also include the URLs of those files in the NSSD configuration file. See "Enabling the NSSD to generate hash and URL certificate encoding."

Rule: Even if you put a certificate or a certificate bundle on an HTTP server and add the URLs to the NSSD configuration file, you still need to store that certificate on the key ring of the NSSD.

The NSSD can accept hash and URL encoded certificates that it receives from its peers. In that case, the NSSD uses the URLs sent by the peers to locate the certificates. The NSSD caches data that it retrieves from an HTTP server using a URL. See "Enabling the NSSD to process received hash and URL certificate encoding" on page 1168.

Even when URL information is configured for the NSSD, it is ultimately the responsibility of the network security client to decide whether the network security server should use hash and URL encoding. See "Controlling the use of hash and URL certificate encoding" on page 1168.

Enabling the NSSD to generate hash and URL certificate encoding

To enable the NSSD to generate hash and URL certificate encoding, perform the following steps:

1. Export the certificates in CERTDER format from RACF.

   Use the RACDCERT EXPORT command with the CERTDER format option to create a data set that contains the binary DER encoding of a certificate on a key ring. If the HTTP server is running on the local system, copy the data set to the location specified by the CertificateURL parameter value. If the HTTP server is running on a remote system, transfer the data set to the appropriate location using a utility such as FTP. For more details about the RACDCERT command, see *z/OS Security Server RACF Command Language Reference*.

   Tip: Do not export the private key when you export the certificate from RACF.
2. Populate the HTTP server with exported certificates.
3. Identify the resources to the NSSD using the CertificateURL parameter.

   The CertificateURL parameter in the configuration file of the NSS server associates a certificate on the key ring of the NSS server with a URL that identifies an HTTP server and a file on that server that contains the binary DER encoding of the certificate. For more details about the CertificateURL parameter, see *z/OS Communications Server: IP Configuration Reference*.
4. Create the certificate bundles that you need by issuing the **certbundle** command.

   Use the **certbundle** command to create a file or data set that contains a certificate bundle. If the HTTP server is running on the local system, copy the file or data set to the location specified by the CertificateBundleURL parameter

value. If the HTTP server is running on a remote system, transfer the file or data set to the appropriate location using a utility such as FTP. For more details about the **certbundle** command, see *z/OS Communications Server: IP System Administrator's Commands*. For more details about creating certificate bundles, see "Creating certificate bundles."

5. Populate the HTTP server with the certificate bundle files.
6. Identify the resources to the NSSD using the CertificateBundleURL parameter.

   The CertificateBundleURL parameter in the configuration file of the network security server associates a certificate on the key ring of the network security server with a URL that identifies an HTTP server and a file on that server that contains the certificate in a certificate bundle. For more details about the CertificateBundleURL parameter, see *z/OS Communications Server: IP Configuration Reference*.

Enabling the NSSD to process received hash and URL certificate encoding

To enable the NSSD to process received hash and URL certificate encoding, perform the following steps:

1. Ensure that HTTP traffic is not impeded by IP filter rules.

   Tip: If IP filtering is enabled on the system where the network security server is running, ensure that the correct filter rules are in place to allow communication with the HTTP servers that are identified on a CertificateURL or CertificateBundleURL, as well as any HTTP servers used by the remote security endpoint of the network security client. This communication typically uses the TCP protocol with an ephemeral source port and a destination port of 80.
2. Use the URLCacheInterval parameter on the IPSecDisciplineConfig statement in the NSSD configuration file to determine the maximum amount of time that URL data is cached before being re-fetched from an HTTP server. For more details about the URLCacheInterval parameter, see *z/OS Communications Server: IP Configuration Reference*.

Controlling the use of hash and URL certificate encoding

To control the use of hash and URL certificate encoding, configure IP security policies to accept hash and URL encoded certificates by setting the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements in the IP security policy configuration file of network security clients. For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see *z/OS Communications Server: IP Configuration Reference*.

Creating certificate bundles

Certificate bundles are used to store a group of related certificate information. A certificate bundle contains zero or more certificates and zero or more certificate revocation lists (CRLs). When an IKEv2 negotiation uses a digital signature authentication method, this certificate information can be exchanged using a certificate bundle. When information is exchanged using a certificate bundle, a URL that identifies the certificate bundle and a hash of the data in the certificate bundle is sent to the remote security endpoint. The remote security endpoint then retrieves the certificate bundle from an HTTP server, and uses the bundle when it validates the digital signature.

A certificate bundle can hold in a single location all relevant information about an entire trust chain. The following types of information can be included in a certificate bundle:

- The certificate that was used to create a digital signature
- The certificates of certificate authorities in the trust chain
- Certificate revocation lists (CRLs)

Although consolidating this information in one place has advantages, consolidation might cause the remote security endpoint to retrieve unneeded information. Often the remote security endpoint already has knowledge of most of the certificates in the trust chain and is capable of retrieving CRL information using another method. In such cases, it might be more efficient to use individual certificates, rather than a certificate bundle.

You can use the **certbundle** command to create one or more files, each of which contains one certificate bundle. A certificate bundle options file is required as input to the **certbundle** command. The certificate bundle options file identifies how many certificate bundles are created, as well as the contents of each certificate bundle.

Guidelines:

- All certificate information in a certificate bundle file should be for the same trust chain.
- You should not include CRL information in a certificate bundle except when there is no other way for the remote security endpoint to retrieve the CRL information. Because certificate authorities periodically issue new CRLs, CRL information that is stored in a certificate bundle must be constantly updated to contain the most recent CRL information.

Rule: Do not put the certificate for the root certificate authority in a certificate bundle. An IKE implementation cannot accept a certificate for the root certificate authority from an untrusted source and, because certificate bundles are considered an untrusted source, any root certificates they contain are unusable. In addition, putting this certificate in the certificate bundle needlessly increases the size of the certificate bundle.

Steps for creating certificate bundles

Before you begin: Obtain from the certificate authority any certificate revocation lists (CRLs) that you want to put in a certificate bundle.

Perform the following steps to create certificate bundles:

1. Store the CRLs that you are going to include in a certificate bundle in a file or data set.
2. Create a certificate bundle options file. See The z/OS UNIX certbundle command options file in *z/OS Communications Server: IP System Administrator's Commands* for more information.
3. For each certificate bundle that you are creating, define a CertBundleOptions statement:
   a. Use the KeyRing parameter to identify the key ring containing any certificates that you want to include.
   b. Use the CertificateChain parameter to specify the label of the certificate that is lowest in any complete trust chain that you want to include (excluding the root CA). The CertificateChain parameter generates a certificate bundle file that contains an optimal set of certificates.

c. Use the CertificateLabel parameter to specify the label of any individual certificates that you want to include. Use the CertificateLabel parameter only when you need to include fewer certificates than the entire chain.
d. Use the CRLFile parameter to identify the files that contain any CRLs that you want to include.
e. Use the BundleFile parameter to identify the name of the certificate bundle file that you are creating.

4. Provide read access to the key rings that are specified in the certificate bundle options file to the user ID under which the **certbundle** command is issued. See *z/OS Security Server RACF Command Language Reference* for details concerning access to key rings.
5. Issue the **certbundle** command, specifying the certificate bundle options file that you just created.

Controlling the NSS server

This topic describes starting and stopping the NSS server, modifying the configuration file, and displaying configuration file parameters.

Starting the NSS server

The NSS server can be started in the following ways:

- Using an MVS procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(NSSD).
- From the z/OS shell, by starting OMVS and then issuing the **nssd** command.
- Using the COMMND*xx* member of PARMLIB. This allows the NSS server to be automatically started when the system is IPLed. For information about the use and configuration of the COMMND*xx* member of PARMLIB, see *z/OS MVS Initialization and Tuning Reference*.
- Using the AUTOLOG statement in the TCP/IP profile.

Tips:

- You should not start the NSS server using the AUTOLOG statement in a stack's profile. If the NSS server is listed in a stack's AUTOLOG statement, the server is cancelled if it is already running when that stack starts. This results in the NSS server losing any cached information that it has in place for NSS clients previously connected through all stacks, and could increase the overall recovery time when a TCP/IP stack recycles.
- If you start the NSS server from the z/OS shell and you stop the shell environment from scrolling, then when the **nssd** command needs to display data to the shell, the NSS server might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.
- When running from an MVS procedure, set the environment variables using the STDENV DD statement in the NSS server procedure.

Restriction: Only one instance of the NSS server can run on a z/OS image. If you attempt to start a second instance, the NSS server will fail.

Stopping the NSS server

Stop the NSS server from MVS by issuing the following command:

```
STOP procname
```

If the NSS server was started from a cataloged procedure, the *procname* value is the member name of that procedure. If the NSS server was started from the z/OS shell and the environment variable _BPX_JOBNAME was set, the *procname* value is the

same as the _BPX_JOBNAME value. If the NSS server was started from the z/OS shell and _BPX_JOBNAME was not set, the *procname* value is *useridX*, where *X* is the sequence number set by the system. To determine the sequence number, from the ISPF LOG window on TSO, issue the following:

```
/d omvs,u=userid
```

This command displays the programs running under the specified user ID. For more information about _BPX_JOBNAME, see *z/OS UNIX System Services Planning*.

To stop the NSS server from the z/OS shell, issue the **kill** command (from a superuser ID) to the process ID (PID) that is associated with the NSS server. By default, the NSS server PID is recorded in /etc/nssd.pid. You can change the default location using the NSSD_PIDFILE environment variable.

Using the NSS server MODIFY command

The NSS server provides a modify command to do the following:

- Reread the configuration file.

  Use the MODIFY *procname*,REFRESH command to flush all cached URLs and reread the NSS server configuration file. Not all NSS server configuration parameters can be updated using this command. For information about which parameters can be dynamically changed, see the parameter descriptions for the NssConfig and IPSecDisciplineConfig statements in *z/OS Communications Server: IP Configuration Reference*.
- Display the configuration file parameters.

  Use the MODIFY *procname*,DISPLAY command to display configuration values currently in use by the NSS server.
- Display the contents of the URL cache.

  Use the MODIFY *procname*,DISPLAY,URLCACHE command to display the current contents of the URL data cache maintained by the NSS server.

For more information on the MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

NSS server failover considerations

NSS IPSec clients can use the NSS certificate service when negotiating phase 1 Security Associations. Network monitoring applications can use the NSS remote management service to display information about NSS IPSec clients. The NSS server should be treated as an application that requires high availability, an application that is able to recover quickly from an outage that impacts the ability of the NSS server to respond to IPSec clients.

Recovery configurations for the NSS server include the following:

- For recovery of NSS server workload by another NSS server within a sysplex, configure NSS IPSec clients to connect to the NSS server on a non-distributed dynamic VIPA. TCP/IP stacks configured as backup for the dynamic VIPA must have the necessary external security manager definitions and certificates to support the NSS IPSec clients, and an NSS server must be running on the z/OS system hosting the TCP/IP stack configured as backup.

  Guideline: Do not configure NSS IPSec clients to connect to a distributed DVIPA address on the NSS server. If a distributed DVIPA is used, the **ipsec** command and IPSec NMI can manage only NSS IPSec clients that have been distributed to the system on which the **ipsec** command is being run or to the system on which the IPSec NMI is invoked.

- Alternatively, you can configure an IKE daemon running as an NSS IPSec client to connect to a backup NSS server with the NetworkSecurityServerBackup parameter on the IkeConfig statement in the IKE daemon configuration file. When the IKE daemon is unable to connect to the primary NSS server, or when it loses its connection with the primary server, the IKE daemon attempts to connect to the server configured as backup. This recovery configuration can be used regardless of sysplex configurations. The backup server must be configured with all necessary external security manager definitions and certificates to support the NSS IPSec clients. For additional details about the IkeConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

NSS server capacity considerations

A single NSS server instance can support a maximum of 500 concurrent NSS client connections, in addition to 10 concurrent NMI client connections.

NSS server certificate revocation support

The NSS server supports the checking of certificate revocation lists (CRLs) when verifying a signature. The NSS server obtains the CRL of a certificate from an HTTP repository, determining the location of the CRL using the CRLDistributionPoints extension of the certificate. The NSS server uses the first distribution point that contains an HTTP URL. If a certificate does not contain a CRLDistributionPoints extension or the CRLDistributionPoints extension does not contain at least one distribution point that contains an HTTP URL, then the NSS server is unable to retrieve the CRL.

The NSS server also supports the retrieval of certificate bundles, which can also contain a CRL. If a CRL cannot be retrieved using the CRLDistributionPoints extension of a certificate, the NSS server looks for a CRL in any certificate bundle that has hash and URL information provided by the network security client. The network security client obtains certificate bundle hash and URL information from certificate payloads sent by a remote security endpoint.

Managing network security services

Use the **ipsec** command to display information about NSS IPSec clients that are connected to the NSS server. You can also use this command to manage NSS IPSec clients that are enabled to use the NSS IPSec remote management service and that are currently connected to the NSS server.

Use the **-x** primary option on the **ipsec** command to display connection information about NSS IPSec clients connected to the NSS server.

```
ipsec -x display

CS V1R12 ipsec  NS Client Name: n/a  Mon Nov 27 12:40:02 2006

Use the **-z** option on the **ipsec** command to specify the name of an NSS client rather than a name of a local TCP/IP stack. When the **-z** option is specified, the **ipsec** command obtains information about the NSS client from the NSS server. The **-z** option is valid only on the system running the NSS server. The NSS client identified by the **-z** option must be connected to the NSS server. The NSS client must also be enabled to use the NSS remote management service. Following is an

example using the **-z** option to display phase 2 Security Association information about the NSS client client4, where the name client4 was obtained from the previous **ipsec -x display** command.

```
ipsec -y display -z client4
```

```

For details about the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Chapter 21. Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is an IP filter rule to discard packets, separate from IP security filters, and is typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. If traffic being blocked by a defensive filter should be blocked on a long-term basis, update your configured IP security policy to add an IP security deny rule.

A defensive filter uses a combination of the following characteristics to target traffic to be discarded:

- IP source or destination address
- IP protocol
- Source or destination port
- ICMP type or code
- Direction of flow
- Type of traffic: Routed or local

For example, a defensive filter might be installed to block all TCP traffic from IP address 10.1.1.1 that is destined for the Telnet server. The characteristics of this filter are the following:

- IP source address is 10.1.1.1.
- IP protocol is TCP.
- Destination port is 23.
- Direction of flow is inbound.
- Traffic is local.

Defensive filters are given higher priority than IP security filters. That is, IP filter processing first checks any installed defensive filters for a match against a packet, before checking the IP security filters. When a defensive filter is added to a TCP/IP stack, it is placed at the top of the filter search order.

Figure 116 on page 1178 provides an overview of defensive filtering.

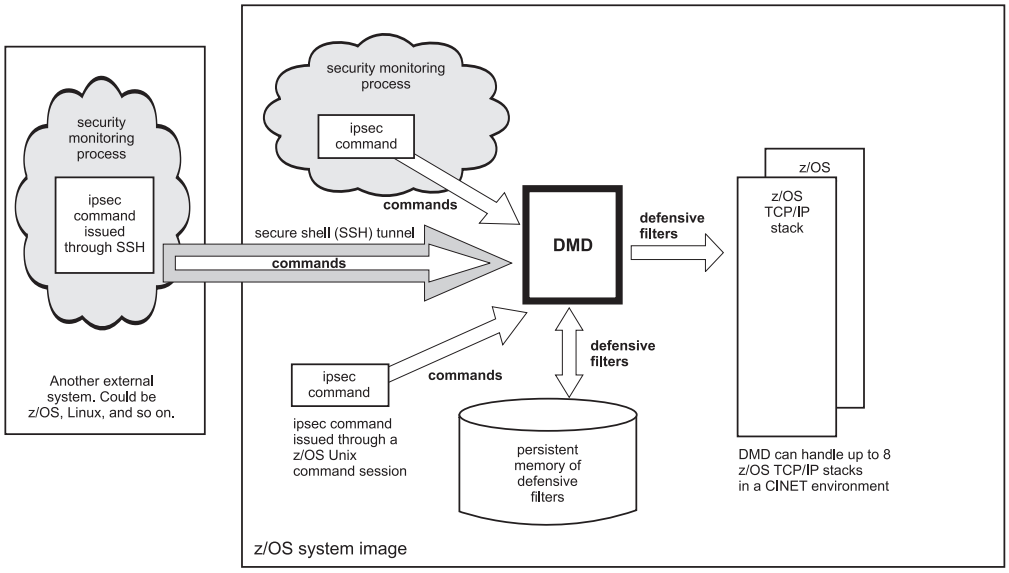

Figure 116. Defensive filtering overview

Defensive filters are added and managed using the z/OS UNIX **ipsec** command with the -F primary option.

- Defensive filters are typically added as an automated action resulting from an external security information and event manager's analysis. The manager issues the set of **ipsec** commands that install the required defensive filters.
- You can also add a defensive filter by manually issuing the **ipsec** command.
- After a defensive filter is created, you can use the **ipsec** command to update some attributes of the filter, such as its lifetime, and also to display and delete defensive filters.

For more information about the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Requirements:

- You must enable the IP security function for defensive filters to be installed in a stack. If you do not have the IP security function enabled, see "Enabling the IP security function" on page 1186.
- The Defense Manager daemon (DMD) plays an integral role in managing defensive filters, and must be active for defensive filters to be added, updated, or deleted. One instance of the DMD manages all eligible stacks on a z/OS image. An eligible stack is one that is enabled for IP security and that is included in the DMD configuration file with a mode of Active or Simulate. For information about configuring the DMD, see "Steps for configuring the DMD" on page 1187. You can refresh most of the DMD configuration parameters so that options can be changed without recycling the DMD.

Guideline: The DMD can support a maximum of 10 concurrent **ipsec** command connections.

Restriction: Remote management of defensive filters using a network security services (NSS) server is not supported. Management of defensive filters is provided only through the local **ipsec** command.

Global and stack-specific defensive filters

A defensive filter has either a global or stack-specific scope.

- A global defensive filter, identified by the -G option on the **ipsec** command, is installed in all eligible stacks on the z/OS image.
- A stack-specific defensive filter is installed in the stack specified by the -p *stackname* option on the **ipsec** command, if the stack is eligible.

When a defensive filter is created, the DMD installs the defensive filter in the eligible stacks and maintains a copy of the filter. The DMD maintains a persistent record of all active defensive filters, global and stack-specific, and the stacks into which those filters are installed.

This persistence enables the DMD to maintain the correct set of installed defensive filters across startup and shutdown activities for TCP/IP stacks, as well as across startup and shutdown of the DMD itself. If the DMD is already running when an eligible TCP/IP stack starts, the DMD installs all applicable defensive filters, global and stack-specific, to that stack. If, when the DMD starts up, it detects that eligible stacks are already running, it ensures that they have or receive the correct set of defensive filters.

After a global defensive filter is created and installed in one or more stacks, you can update it as a global filter, resulting in all copies of the filter being updated. You can also update it in an individual TCP/IP stack, resulting in only that stack's copy of the filter being updated. Similarly, you can delete a global defensive filter globally or only from an individual TCP/IP stack.

Defensive filter names

A defensive filter receives its name from the -N *DefensiveFilterName* option when the filter is created. All copies of a global defensive filter have the same name. Global filters and stack-specific filters share the same filter namespace, so a filter name cannot be used for both a global filter and a stack-specific filter. The creation of a stack-specific filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in the target stack. The creation of a global filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in any stack. This check includes filter names that are in the DMD's persistent memory, even if the corresponding stack is not active.

Tip: If you are manually creating defensive filters, avoid conflicts between global and stack-specific filter names by choosing a distinct naming convention for each, such as starting all global filter names with a G.

Defensive filter modes

Each defensive filter has a mode setting of block or simulate. The defensive filter's mode is set when the filter is created or updated by the **ipsec** command.

By default, defensive filters are in block mode, causing traffic to be discarded. A defensive filter in simulate mode simulates a block and lets you monitor the impact of enabling defensive filters without discarding traffic.

When a packet matches a defensive filter and the mode is simulate, a message is logged indicating that the packet would have been discarded, but the packet is not

discarded and IP filtering continues. The packet can subsequently match a defensive filter that is in block mode and be discarded, but the packet will not match another simulation filter.

The DMD configuration file also provides the mode settings Active, Simulate, or Inactive on the DmStackConfig statement.

- Active enables defensive filtering and honors the mode setting of the individual filters.
- Simulate enables defensive filtering and overrides the mode setting of the individual filters; simulate mode is used for all defensive filters installed in the stack.
- Inactive disables defensive filtering.

Table 52 summarizes the interaction between the mode setting on the DmStackConfig statement and the mode setting in individual filters set by the **ipsec** command.

Table 52. Interaction between the mode setting on the DmStackConfig statement and the mode setting in individual filters

		Mode setting on the DmStackConfig statement		
		Active	**Simulate**	**Inactive**
Individual filter mode set by the ipsec command	**Block**	Block the packet	Simulate blocking the packet	No defensive filters
	Simulate	Simulate blocking the packet	Simulate blocking the packet	No defensive filters

Tips:

- You might want to specify Mode Simulate on the DmStackConfig statement when you are first implementing defensive filtering. All defensive filters in the TCP/IP stack will be treated as if the mode was simulate. When a packet matches a defensive filter, syslog message EZD1722I is generated and IP filtering continues. Defensive filters added to this stack retain the mode setting with which they were added, block or simulate. In most cases, you should use the default mode, block, on the individual filter.
- After completing defensive filter testing in simulate mode, specify Mode Active on the DmStackConfig statement. If there are defensive filters installed in the stack when the mode is changed from simulate to active, the mode on the individual defensive filters is used.
- If defensive filtering is active (DmStackConfig statement with Mode Active) and you want to implement and test additional automation, you can revert to an overall mode of simulate for the whole stack. However, you might want only defensive filters added by the new automation to have a mode of simulate. The automation action can add individual defensive filters with a mode of simulate using the mode keyword on the **ipsec -F add** command. After testing, you can update the automation action to add defensive filters with a mode of block using the mode keyword on the **ipsec -F add** command.

For more information about the DmStackConfig statement, see *z/OS Communications Server: IP Configuration Reference*. For more information about adding or updating a defensive filter with the -F option of the **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*.

Allowing administrative access

Defensive filters are checked before IP security filters. To ensure that an administrator is not blocked by a defensive filter, you can exclude the administrator's IP address from defensive filter processing by specifying the administrator's address on the Exclude parameter of the DmStackConfig statement in the DMD configuration file. For more information about the DmStackConfig statement and its parameters, see *z/OS Communications Server: IP Configuration Reference*.

Filter-match logging

When a packet matches a defensive filter during IP filter processing, a message can be logged indicating that the packet was discarded based on this filter. When a defensive filter is added, filter-match logging can be enabled or disabled for the filter; it is enabled by default. The filter-match logging setting can be updated with the **ipsec** command for an existing defensive filter.

When a defensive filter is simulating a block, filter match logging is always performed to indicate that a packet would have been discarded based on the defensive filter.

TRMD

The Traffic Regulation Manager daemon (TRMD) is responsible for logging defensive filter events that are detected by the stack. These events include filter-match logging and the creation, deletion, and updating of defensive filters.

TRMD and syslogd provide the logging service for defensive filtering. In a Common INET environment, you must configure one instance of TRMD for each stack on a z/OS system. For information about configuring TRMD, see "TRMD" on page 919.

Disabling defensive filters for a single stack

To disable defensive filtering for a TCP/IP stack, while continuing to support defensive filtering for other stacks on the system, do the following:

1. Update the DMD configuration file and change the mode of the stack to Inactive on the DmStackConfig statement.
2. Issue the MODIFY REFRESH command for the DMD.

Results:

- All defensive filters are removed from the stack.
- The DMD's persistent memory of defensive filters for the stack is cleared.
- Additional defensive filters cannot be added to this stack.

Tips:

- If you cannot update your DMD configuration file, you can issue the MODIFY FORCE_INACTIVE command for the DMD to disable defensive filtering for the stack. However, a later MODIFY REFRESH command will use the DMD configuration file, so if you want defensive filtering to remain disabled, you should update the DMD configuration file as soon as possible.
- Removing the DmStackConfig statement from the DMD configuration file does not delete existing defensive filters from the stack. If you remove the

DmStackConfig statement, the defensive filters remain in the stack until they expire. To remove the defensive filters from the stack immediately, add the DmStackConfig statement back to the DMD configuration file and specify mode Inactive, or issue the MODIFY FORCE_INACTIVE command for the stack.

Relationship between Intrusion Detection Services and defensive filters

Communication Server's Intrusion Detection Services (IDS) support enables you to detect scans of your TCP/IP stack and possible attacks. It also provides traffic regulation for TCP connections and UDP sockets. One action that can be taken when a scan or attack is detected, or traffic regulation is enforced, is to generate a message to report the event.

An external security information and event manager that is configured to receive messages from the TCP/IP stack's IDS function can analyze the messages and correlate the information with other information that it has received. Communication Server's IDS messages can be one of a number of inputs that an external security information and event manager uses to make the decision to add a defensive filter to the stack. If the external security information and event manager detects an attack, it can add defensive filters to the stack to block the attack. Defensive filter support can be enabled without enabling Communication Server's IDS support.

For more information about IDS support, see Chapter 18, “Intrusion Detection Services,” on page 897.

Comparison of IP security filters and defensive filters

Table 53 compares IP security filters and defensive filters.

Table 53. Comparison of IP security filters and defensive filters

Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Configuring	Configured in a Policy Agent flat file.	Configured in the TCP/IP profile.	Not configured. The **ipsec** command is used to create defensive filters, either automatically or manually.
Installing in the TCP/IP stack	Installed by the Policy Agent.	Installed by TCP/IP profile processing.	Installed by the Defense Manager daemon (DMD).
Filter search order	The order in the configuration file.	The order in the configuration file.	Defensive filters are searched before IP security filters. When a defensive filter is created, it is installed at the top of the search order.

Table 53. Comparison of IP security filters and defensive filters (continued)

Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Displaying a filter	Use **pasearch** and **ipsec -f display**. The **ipsec -f display -c current** command displays all installed filters, both defensive filters and IP security filters.	Use **ipsec -f display -c profile**.	Use **ipsec -F display**.
Filter display order	The order in the configuration file. The **pasearch** command displays IP security filters as complex filter rules, not split filters as they are in the stack. The **ipsec -f display** command displays IP security filters as split filters, like they are in the stack. IPv4 IP security filters are shown first, followed by IPv6 IP security filters.	The order in the configuration file. The **ipsec -f display** command displays IP security filters as split filters, like they are in the stack. A single profile filter in the configuration file is split into an inbound and outbound filter in the stack. IPv4 IP security filters are shown first, followed by IPv6 IP security filters.	The **ipsec -F display** command displays defensive filters from the stack in four groups: • IPv4 inbound filters • IPv4 outbound filters • IPv6 inbound filters • IPv6 outbound filters Within each group, the filters are displayed from most recently installed to least recently installed. The **ipsec -F display -G** command displays global defensive filters from the DMD. The global filters are displayed from most recently installed to least recently installed.

Table 53. Comparison of IP security filters and defensive filters (continued)

Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Deleting a filter	Remove the filter rule from the configuration file. When Policy Agent detects the configuration file change, the filter rule is removed from the stack. Policy Agent detects the change in one of the following ways: • If Policy Agent was started with the **-i** startup option, an immediate refresh picks up the change. • You issue a MODIFY REFRESH command. • You issue a MODIFY UPDATE command. • Policy Agent checks for configuration changes using an update interval defined in the policy configuration file.	Use a VARY TCPIP,,OBEYFILE command with a data set that contains a new IPSEC statement with the filter rule removed.	Use **ipsec -F delete**. Defensive filters are also deleted when their lifetime expires.
Updating a filter	Update the filter rule in the configuration file. When the Policy Agent detects the configuration file change, the filter rule is updated in the stack.	Use a VARY TCPIP,,OBEYFILE command with a data set that contains a new IPSEC statement with the filter rule updated.	Use **ipsec -F update**. A defensive filter's lifetime, mode, and logging values can be updated.
Specifying time conditions	Specify time conditions in the policy. The Policy Agent installs an IP security filter when it becomes active, and deletes the filter when it becomes inactive due to time.	Not supported.	Not supported. Defensive filters have a lifetime that is minutes in length. A defensive filter is deleted when its lifetime expires.

Table 53. Comparison of IP security filters and defensive filters (continued)

Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Simulation mode	Not supported.	Not supported.	Controlled by the DMD configuration file and the **ipsec -F add** and **ipsec -F update** commands.
Global filters	IP security filters defined in a CommonIPSecConfig file are added to all eligible stacks.	Not supported.	Defensive filters added with the -G option of the **ipsec** command are added to all eligible stacks on the z/OS system.
Filter-match logging	Controlled by settings in the policy flat file.	Controlled by settings in the TCP/IP profile.	Set when the filter is added or updated with the **ipsec** command.

The DMD run-time environment

The DMD is a z/OS UNIX application; it requires the z/OS UNIX file system. You can start the DMD from an MVS started procedure, from the z/OS UNIX shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMND*xx* member of parmlib. The DMD must be started by a RACF-authorized user ID, and it must reside in an APF-authorized library. For more information about how to start the DMD, see "Starting the DMD" on page 1190.

The DMD uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of defensive filter requests. CTRACE is used for detailed tracing and debugging.

The DMD uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The DMD and Language Environment run-time options

When you start the DMD from a started or cataloged procedure, you typically start it directly from the SEZALOAD data set using PGM=EZADMD. However, you can also start the DMD using BPXBATCH.

When you start the DMD using PGM=EZADMD, the STDENV DD card, if used, is passed directly to the DMD. Language Environment does not have access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any DMD options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus the DMD parameters that you want to specify exceed 100 characters, consider using BPXBATCH to start the DMD. When you use PGM=BPXBATCH to start the DMD,

you can include the Language Environment variable _CEE_RUNOPTS on the STDENV DD card to specify run-time options in excess of 100 characters long.

For more information about how to start the DMD, see “Starting the DMD” on page 1190.

Enabling defensive filtering

To enable defensive filtering, first do both of the following:

- Enable the IP security function.

  See “Enabling the IP security function.”
- Configure the Defense Manager daemon (DMD).

  See “Steps for configuring the DMD” on page 1187.

After configuring the DMD and enabling IP security, start the DMD. For details, see “Starting the DMD” on page 1190.

Enabling the IP security function

The IP security function must be enabled for defensive filters to be installed in a stack. If you do not have the IP security function enabled and want to use defensive filters, perform the following steps.

1. Specify the IPSECURITY parameter on the IPCONFIG statement in the TCP/IP profile.
2. If you have IPv6 traffic in your network and want to use defensive filters for IPv6, specify the IPSECURITY parameter on the IPCONFIG6 statement in the TCP/IP profile.
3. Configure a default IP security filter policy in the TCP/IP profile using the IPSEC statement in the TCP/IP profile.

   Tip: To permit all IPv4 traffic, you can configure a single rule for the IPSEC statement that allows all traffic. The following example allows all IPv4 traffic, without logging filter matches.

   ```
   IPSEC
   ; Rule   SourceIp      DestIp    Logging   Prot       SrcPort    DestPort   Routing        Secclass
   ;
   ; Permit all local and routed IPv4 traffic, no logging.
     IPSECR *            *         NOLOG     PROTO *                          ROUTING EITHER
   ENDIPSEC
   ```

   For more information about the IPSEC statement, see *z/OS Communications Server: IP Configuration Reference*.
4. Optionally, configure a more comprehensive IP security policy in a flat file for the Policy Agent to install and manage.

   You can configure IPSec encryption and authentication only in a Policy Agent flat file.

   Tip: You can use the Configuration Assistant for z/OS Communications Server to create an IP security policy flat file.

   For more information about configuring an IP security policy, see Chapter 16, “Policy-based networking,” on page 829 and Chapter 19, “IP security,” on page 923.

Attention: You must configure an IP security policy if you enable the IP security function. If you specify IPSECURITY in your TCP/IP profile and do not configure an IP security policy, all inbound and outbound traffic will be discarded.

Steps for configuring the DMD

Perform the following steps to configure the DMD:

1. Authorize the DMD to the external security manager.

   See "Steps for authorizing resources for the DMD and the ipsec command" on page 1189.

2. Create the directories that the DMD needs.

   a. Create the directory /var/dm for use by the DMD. The DMD user ID must have permission to create, delete, read, and write files to this directory.

   b. If you set the PID file location with the DMD_PIDFILE environment variable, ensure that the path portion of the file name exists and that the DMD user ID has permission to create and write files to that directory. If you use the default PID file location, /var/dm/dmd.pid, you have already created the directory and given the DMD user ID the appropriate access in the previous step.

   c. Create the directory that will hold the persistent defensive filters for each stack, as well as the global defensive filters.

      The DMD configuration file parameter DefensiveFilterDirectory points to this directory. The default value is /var/dm/filters. Ensure that the DMD user ID is authorized to create, delete, read from, and write to files in this directory. The directory should have sufficient space to support at least 1 MB of data for each TCP/IP stack, plus another 1 MB for the global filter definitions. For more information about the DefensiveFilterDirectory parameter in the DMD configuration file, see *z/OS Communications Server: IP Configuration Reference*.

3. Create the DMD configuration file.

   Do one of the following:

   - Use the IBM Configuration Assistant for z/OS Communications Server.

     The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the DMD configuration file.

     The Configuration Assistant is available in either of the following forms:

     – As a task in IBM z/OS Management Facility (z/OSMF)

       z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.

     – As a standalone application that you can run on your workstation

       You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

     You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

     Through a series of wizards and online help panels, you can use the GUI to create DMD configuration files for any number of z/OS images with any number of TCP/IP stacks per image.

   - Configure the file manually.

A sample configuration file is in /usr/lpp/tcpip/samples/dmd.conf.

For a description of the DMD configuration file, see *z/OS Communications Server: IP Configuration Reference*.

If the DMD was defined to the external security manager with a nonzero UID, ensure that the DMD has permission to read the configuration file. The DMD user ID must have both read access to the configuration file and execute access to the directory containing the configuration file.

Tip: You can create the configuration file in the /var/dm directory and use the DMD_FILE environment variable to specify the configuration file. You set up the /var/dm directory in step 2 to allow DMD to create, delete, read, and write files to this directory.

The following search order is used by the DMD to locate the configuration data set or file:

a. If the environment variable DMD_FILE is defined, the DMD uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.

b. /etc/security/dmd.conf

You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the DMD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

4. Optionally, set the _BPX_JOBNAME environment variable.

   When you start the DMD from the z/OS UNIX shell, set the environment variable _BPX_JOBNAME. This enables a specific job name to be used with the STOP or MODIFY console commands. For information about _BPX_JOBNAME, see *z/OS UNIX System Services Planning*.

5. Configure and start syslogd.

   The DMD uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use zSeries File System as its underlying file system. For more information about syslogd, see "Configuring the syslog daemon" on page 185.

6. Optionally, update the DMD environment variables.

   The DMD uses the following environment variables. You can modify them for your installation.

   DMD_CODEPAGE
   Use the DMD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For details about the supported code pages, see *z/OS Communications Server: IP Configuration Reference*.

   DMD_CTRACE_MEMBER
   Used by the DMD to locate a parmlib member for DMD CTRACE customization. For more information about the TCP/IP services component trace for the DMD, see *z/OS Communications Server: IP Diagnosis Guide*.

   DMD_FILE
   Used by the DMD in the search order for the DMD configuration file. For details about the search order used for locating this configuration file, see step 3 on page 1187.

DMD_PIDFILE

Used by the DMD in the search order for the file that should contain the DMD process ID (PID). The search order for the DMD PID file is as follows:

a. DMD_PIDFILE environment variable

b. /var/dm/dmd.pid

7. If you are starting the DMD as a started procedure, update the DMD cataloged procedure.

   Create the cataloged procedure by copying the sample in SEZAINST(DMD) to your system. Specify the DMD parameters and change the data set names to suit your local configuration. A copy of the DMD cataloged procedure can also be found in *z/OS Communications Server: IP Configuration Reference*.

   If the DMD was defined to the external security manager with a nonzero UID and the cataloged procedure specifies an HFS file containing environment variables, ensure that the DMD has permission to read the HFS file.

You know you are done when you can start the DMD. For details, see "Starting the DMD" on page 1190.

Steps for authorizing resources for the DMD and the ipsec command

RACF is used as the external security manager in the following examples. However, you can use any SAF-compliant security product. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set. In these examples, it is assumed that the DMD is running under the user ID DMD.

Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the DMD user ID.

   The DMD is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the DMD, you must define the DMD user ID to the external security manager. If you start the DMD from an MVS started procedure, the DMD user ID must also be authorized to the STARTED class. In the following example, the DMD user ID is defined with UID 0:

   ```
   ADDUSER  DMD     DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0)  HOME('/'))
   RDEFINE  STARTED  DMD.*            STDATA(USER(DMD))
   SETROPTS RACLIST(STARTED) REFRESH
   SETROPTS GENERIC(STARTED) REFRESH
   ```

   You can define the DMD with a nonzero UID. For additional steps that you must take when the DMD UID is nonzero, see "Steps for configuring the DMD" on page 1187.

2. Permit the DMD user ID to SYS1.PARMLIB.

   The DMD uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default DMD component trace parmlib member is stored in SYS1.PARMLIB. The DMD user ID must be permitted to access SYS1.PARMLIB.

   Issue the following command:

   ```
   PERMIT   SYS1.PARMLIB  ID(DMD) ACCESS(READ)
   ```

3. Define SERVAUTH profiles to control the users that are allowed to manage defensive filters.

For information about defining the SERVAUTH profiles needed for a user to be able to add, update, delete, and display defensive filters, see "Step 3: Authorizing the ipsec command to the external security manager" on page 1506. Additional information about **ipsec** command security and the SERVAUTH profile is available in *z/OS Communications Server: IP System Administrator's Commands*.

Starting the DMD

You can start DMD in any of the following ways:

- By using an MVS procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(DMD).
- By issuing the **dmd** command from the z/OS UNIX shell.
- By using the COMMND*xx* member of parmlib. This member enables the DMD to be automatically started after an IPL of the system. For information about configuring and using the COMMNDxx member of parmlib, see *z/OS MVS Initialization and Tuning Reference*.
- By using the AUTOLOG statement in the TCP/IP profile. For information about the AUTOLOG statement, see *z/OS Communications Server: IP Configuration Reference*.

Tips:

- Do not start the DMD using the AUTOLOG statement in a stack's profile if you are running in a CINET environment with more than one stack configured. If a stack is configured using AUTOLOG to start and stop the DMD each time the stack starts and stops, it is difficult to maintain a stable running instance of the DMD in a multi-stack environment. In a multi-stack environment, you should use another method to automate starting the DMD when the system is started, such as using the COMMND*xx* member of parmlib.
- When you start the DMD from an MVS procedure, set the environment variables using the STDENV DD statement in the DMD procedure.
- If you start the DMD from the z/OS shell and you stop the shell environment from scrolling, when the daemon needs to display data to the shell, it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

Restriction: Only one instance of the DMD can run on a z/OS image. If you attempt to start a second instance, the second DMD will fail.

Stopping the DMD

Stop the DMD in one of the following ways:

- From MVS, stop the DMD by issuing the following command:

  ```
  STOP procname
  ```

  where *procname* is one of the following:

  – If the DMD was started from a cataloged procedure, the *procname* value is the member name of that procedure.

  – If the DMD was started from the z/OS UNIX shell and the environment variable _BPX_JOBNAME was set, the *procname* value is the same as the _BPX_JOBNAME value.

– If the DMD was started from the z/OS UNIX shell and _BPX_JOBNAME was not set, the *procname* value is *useridX*, where *X* is the sequence number set by the system. To determine the sequence number, from the ISPF LOG window on TSO, issue the following:

```
/d omvs,u=userid
```

This command displays the programs running under the specified user ID. For more information about _BPX_JOBNAME, see *z/OS UNIX System Services Planning*.

- From the z/OS shell, issue the **kill** command from a superuser ID for the process ID (PID) that is associated with the DMD. By default, the DMD PID is recorded in /var/dm/dmd.pid. You can change the default location using the DMD_PIDFILE environment variable.

Using the DMD MODIFY command

The DMD provides a MODIFY command to do the following:

- Reread the configuration file.

  Use the MODIFY *procname*,REFRESH command to reread the DMD configuration file. You can use this command to update some DMD configuration file parameters. For information about the DMD configuration file parameters that can be dynamically changed, see *z/OS Communications Server: IP Configuration Reference*.

- Display the configuration file parameters.

  Use the MODIFY *procname*,DISPLAY command to display configuration values currently in use by the DMD.

- Disable defensive filtering.

  Use the MODIFY *procname*,FORCE_INACTIVE,*stackname* command to disable defensive filtering for stack *stackname*. All defensive filters for the stack are removed from the DMD's persistent memory and from the stack. No additional defensive filters are added to the stack while the stack's mode is inactive. The change to the stack's mode persists until the next successful MODIFY *procname*,REFRESH command.

For more information about the MODIFY command for DMD, see *z/OS Communications Server: IP System Administrator's Commands*.

Chapter 22. Application Transparent Transport Layer Security data protection

The Transport Layer Security (TLS) protocol defined in RFC 2246 provides communications privacy over the Internet. The protocol enables client and server applications to communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery. To implement TLS protocols, typically, applications must be modified to incorporate a TLS toolkit. Modifying applications requires significant development overhead, ongoing maintenance for each application, and application-specific knowledge of the parameters needed to implement TLS for that application.

Application Transparent Transport Layer Security (AT-TLS) consolidates TLS implementation in one location, reducing or eliminating application development overhead, maintenance, and parameter specification. AT-TLS is based on z/OS System SSL, and transparently implements these protocols in the TCP layer of the stack. As shown in Figure 117, most applications do not need any awareness of the security negotiations and encryption done by TCP/IP on its behalf. However, you might want some applications to be aware of AT-TLS or have control over the security functions being performed by TCP/IP. For example, if the application is a server requesting client authentication, you might want the application to get the partner certificate or the user ID associated with the partner certificate, or the application might negotiate in cleartext with its partner to decide whether a secure session is necessary. If both agree to a secure session, the application needs to tell AT-TLS to set up a secure session. The SIOCTTLSCTL ioctl provides the interface for the application to query or control AT-TLS.

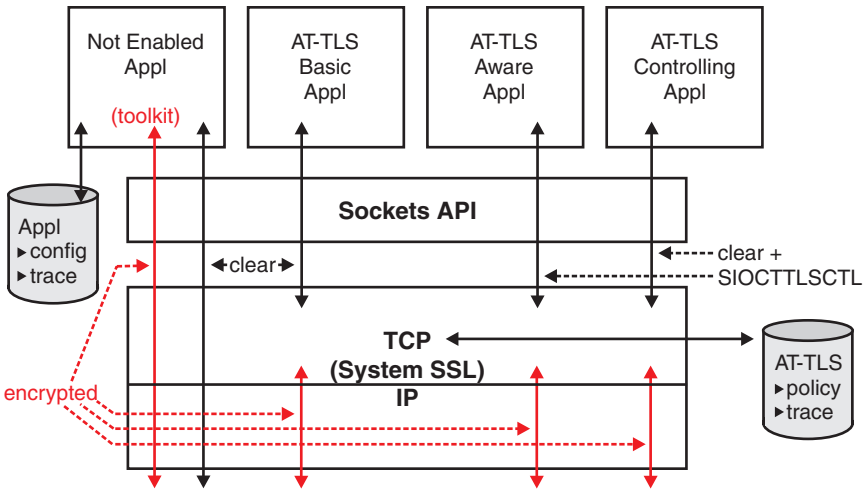

Figure 117. Application Transparent TLS

In all cases, an application using a socket enabled with AT-TLS continues to send and receive text data in the clear while encrypted data flows over the network. This allows the use of TLS with applications that cannot be modified or that cannot incorporate one of the available tool kits. The partner application must also support TLS protocols, either by using AT-TLS or an available TLS toolkit.

AT-TLS configuration in PROFILE.TCPIP

AT-TLS support is controlled by the TTLS or NOTTLS parameter on the TCPCONFIG statement in PROFILE.TCPIP. AT-TLS is enabled by specifying TTLS. The information required to negotiate secure connections is provided to the stack by AT-TLS policies configured in Policy Agent. When AT-TLS is enabled and a newly established connection is first used, the TCP layer of the stack searches for a matching AT-TLS policy installed from the Policy Agent. If no policy is found, the connection is made without AT-TLS involvement.

TCP/IP stack initialization access control

A TCP/IP stack initializes before Policy Agent installs configured policies into the stack. This leaves a window of time where connections that should be covered by AT-TLS are clear text connections. The RACF resource EZB.INITSTACK.*sysname.tcpname* in the SERVAUTH class is used to block stack access, except for the user IDs permitted to the resource. While in this initialization window, any socket request from an unauthorized application receives the same errno (EAGAIN with JrTcpNotActive) received prior to the stack coming up.

Checking is done only if the TCP/IP profile activates AT-TLS. If there is no profile in the SERVAUTH class covering this resource name, all socket requests fail, including those from Policy Agent. Checking ceases the first time that the Policy Agent indicates AT-TLS policy is complete, or if a TCP/IP profile change deactivates AT-TLS.

When the limited access window begins, non-scrollable message EZZ4248E is written to the system console stating that TCP/IP is waiting for Policy Agent to install AT-TLS policies. The message is released when the restriction ends. You can delay the start of AUTOLOG procedures during this window of time by specifying the optional DELAYSTART parameter with the TTLS subparameter on the AUTOLOG entry for that procedure; when specified, the procedure will start after the EZZ4248E message is deleted and message EZZ4250I is issued indicating that AT-TLS services are available.

You must permit a limited set of administrative applications to the profile to ensure full initialization of the stack. If Policy Agent is dependent on other applications in your environment, they must also be permitted. You can permit other applications that do not require AT-TLS and that you want to start prior to general applications. At a minimum, the following applications should be permitted to the profile:

- Policy Agent
- OMPROUTE
- SNMP agent and subagents
- NAMED

For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Options for configuring AT-TLS security

AT-TLS is configured using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the AT-TLS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Configuration Assistant to generate the Policy Agent files.

The Configuration Assistant is available in either of the following forms:

- As a task in IBM z/OS Management Facility (z/OSMF)

  z/OSMF provides a Web browser interface for a variety of z/OS system management functions. When you invoke the Configuration Assistant in z/OSMF, the Configuration Assistant runs natively in the z/OS system and you can access it through a Web browser. To use the Configuration Assistant in z/OSMF, your system must be z/OS V1R11 or later.
- As a standalone application that you can run on your workstation

  You can download the Configuration Assistant from the z/OS Communications Server product support Web page.

You can use the Configuration Assistant on your workstation and then later migrate your work to the z/OSMF environment. For information about transferring Configuation Assistant data to z/OSMF, see *IBM z/OS Management Facility Configuration Guide*.

Through a series of wizards and online help panels, you can use the Configuration Assistant to create AT-TLS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the Configuration Assistant, there are three types of reusable objects:

- Traffic descriptors that define the local application, by describing the TCP traffic with ports or identifying the application using its jobname.
- Security levels that define the different ways to protect data, such as the encryption level.
- Requirement maps that map traffic descriptors to security levels. A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The Configuration Assistant comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The Configuration Assistant can dramatically reduce the amount of time that is required to create AT-TLS policy files, contributing to ease of configuration and

maintenance. Because of the inherently complex nature of z/OS security, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing AT-TLS security.

This information primarily describes option 2, manual configuration. However, if you are using the Configuration Assistant, reading this information will help you understand security concepts and the relationship between Policy Agent and AT-TLS function.

Option 2: Manual configuration

You can manually create the AT-TLS policy configuration files by coding all the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by AT-TLS policy statements that permit advanced users to carefully fine-tune AT-TLS policy on a per-stack basis. This information describes the procedure for creating an AT-TLS policy by manually creating and editing the configuration files. For details about the AT-TLS policy statements, see *z/OS Communications Server: IP Configuration Reference*.

Specifying the AT-TLS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see "Policy types and infrastructure overview" on page 829. Regardless of which option is used to configure AT-TLS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves AT-TLS policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve AT-TLS policies from the policy server, specify the configuration files using the TTLSConfig statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the TTLSConfig statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

AT-TLS policy configuration

AT-TLS policy is provided to the stack by the Policy Agent. The Policy Agent main configuration file contains a TcpImage statement for each stack that is to receive policy, and can optionally contain a CommonTTLSConfig statement that identifies a local shared AT-TLS policy file.

The TcpImage statement identifies the z/OS UNIX file or MVS data set that contains policy for that stack. This policy file can contain a TTLSConfig statement to identify the z/OS UNIX file or MVS data set that contains the local AT-TLS policy. The TTLSConfig statement is required for each stack that is to receive AT-TLS policy. If both a TTLSConfig statement and a CommonTTLSConfig statement are defined, the specified CommonTTLSConfig file is processed before the TTLSConfig policy file specified for that stack.

On the policy server, use the DynamicConfigPolicyLoad statement to specify the remote AT-TLS policies. On the policy client, use the PolicyServer statement to retrieve the remote AT-TLS policies from the policy server.

Within the AT-TLS policy file, AT-TLS rules define a set of conditions that are compared to connections when policy is mapped during connect, or at the first select for readable or writable, poll for readable or writable, send, receive, or SIOCTTLSCTL ioctl. If a rule match is found, AT-TLS transparently provides TLS protocol control for the connection based on the security attributes specified in the actions associated with the rule.

AT-TLS rules

A TTLSRule statement consists of a set of conditions that are compared against the connection being checked. When a match is found, policy lookup stops and the connection is assigned the actions associated with the rule. The rule conditions are:

- LocalAddr - Local IP address or addresses
- RemoteAddr - Remote IP address or addresses
- LocalPortRange - Local port or ports
- RemotePortRange - Remote port or ports
- Jobname - Job name of the owning application or wildcard job name
- Userid - User ID of the owning process or wildcard user ID
- Direction - Inbound if applied to a passive socket (established by accept), Outbound if applied to an active socket (established by connect), or Both

Direction and at least one other condition must be specified. Other rule considerations include:

- If a condition is not specified, that condition is not considered when comparing the rule and the connection for a match.
- Multiple values can be specified for the IP address and port conditions, either directly in the condition or as a referenced group.
- IPv6 addresses are valid in all environments.

Each TTLSRule statement can also have a priority. Priority values can be integers in the range 1 to 2 000 000 000, with 2 000 000 000 being the highest priority. When assigning priorities, you should skip some values to allow for future rule insertion between existing rules. Policy Agent orders rules in alphabetical order within priority.

Tip: If connections can map to more than one rule, always use priority and leave priority space between rules.

AT-TLS actions

A TTLSRule statement can reference up to three actions:

- The TTLSGroupActionRef parameter includes the name of a globally defined TTLSGroupAction statement
- The TTLSEnvironmentActionRef parameter includes the name of a globally defined TTLSEnvironmentAction statement
- The TTLSConnectionActionRef parameter includes the name of a globally defined TTLSConnectionAction statement

The TTLSGroupActionRef parameter is required, and the TTLSGroupAction statement must specify TTLSEnabled ON or TTLSEnabled OFF. If TTLSEnabled

OFF is specified, no additional specifications are needed. Otherwise, the AT-TLS environment action is required and the AT-TLS connection action is optional. Each action represents a scope of control.

When an AT-TLS action statement is deleted or replaced, it is considered stale. New connections will not map to a stale action. Connections that mapped to an action that later becomes stale continue to use the resources associated with the stale action until the connection closes.

AT-TLS group action

This action defines whether AT-TLS is enabled, allows trace settings, and provides the ability to set unique Language Environment variables for the Language Environment process that will be started for the action. Many TTLSRule statements can reference the same TTLSGroupAction statement. In a simple implementation of AT-TLS, you need to specify only TTLSEnabled ON on the TTLSGroupAction statement.

The AT-TLS group action represents a single Language Environment process and enclave, and initializes one instance of the System SSL DLL. Global attributes are owned by this action. Each AT-TLS group has a main task, a logging task, and a dynamic pool of pthreads that handle System SSL secure environment and secure connection management. When a stale group has no remaining connections, the pthreads, tasks, and Language Environment process are removed.

Guideline: Use as few AT-TLS group actions as necessary.

AT-TLS environment action

This action requires a key ring name (either RACF or gskkyman format), and the handshake role (client or server) this half of the connection will assume. Cipher suites and trace settings can also be set. There are several advanced parameters available if needed, but in a simple implementation of AT-TLS, you need to specify only a key ring and the handshake role.

The AT-TLS environment action is used to create System SSL environments. A key ring and SSL Session ID (SID) cache are examples of attributes owned by a System SSL environment. The AT-TLS environment action initializes a System SSL environment within the Language Environment process that was created to represent an AT-TLS group action. Several System SSL environments can exist within a single AT-TLS group. The same TTLSEnvironmentAction statement can be used to create similar System SSL environments in the same or different groups. AT-TLS dynamically creates instances of System SSL environments as needed. AT-TLS deletes System SSL environments when they have had no connections using them for a period of ten to twenty minutes. If the TTLSEnvironmentAction statement used to create a System SSL environment becomes stale, AT-TLS deletes the environment when it has no remaining connections. Connections associated with the same server application or same client user ID can share a System SSL environment. Connections that share an existing System SSL environment avoid the processing required to initialize an environment, such as opening a key ring. Connections between the same partners can also reuse recent session information in the SID cache, allowing them to use the SSL short handshake that requires less processing. System SSL connection resources are released when the connection closes.

AT-TLS connection action

The AT-TLS connection action represents attributes at the connection level. This action is optional, and is needed only when a subset of connections within an

AT-TLS environment must have different parameters. Handshake role, security version, cipher suites, and tracing are examples of attributes that can be changed at the connection level. In a simple implementation of AT-TLS, you do not need to specify this action.

System SSL connections are initialized within a System SSL environment. Use the AT-TLS connection action to override attributes specified at the SSL environment layer. System SSL connection resources are released when the connection closes.

Getting started with AT-TLS

Assume you have a TCP client and server application pair running on z/OS platforms. This application handles sensitive data, and you want this application to be used only with the TLS protocol. The server application runs under the job name of XYZSRV, and creates a passive TCP socket bound to IP address INADDR_ANY and port 5000. The client application runs as a command, issued by TSO or z/OS UNIX interactive users, and connects to port 5000.

To complete AT-TLS security setup for this sample environment, you need to create both server and client key rings. The server key ring needs to contain a server certificate, and any certificates used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see Appendix B, "TLS/SSL security," on page 1461. For more information on managing key rings and certificates with RACF and the RACDCERT command, see *z/OS Security Server RACF Security Administrator's Guide*. For detailed information on managing key rings and certificates with gskkyman, see *z/OS Cryptographic Services System SSL Programming*.

Configuring the server system

On each z/OS system where you run the server application, see Table 54 for the tasks needed to configure the server.

Table 54. AT-TLS configuration for the server system

Task	Specification
Create key ring	Create server key ring with server certificate and necessary certificate authority certificates.
Create Policy Agent files	1. Create a Policy Agent main configuration file containing a TcpImage statement for the server stack. 2. Create a Policy Agent image configuration file for the server stack. 3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server.

Table 54. AT-TLS configuration for the server system (continued)

Task	Specification

Add AT-TLS configuration	1. For local AT-TLS policies, add a TTLSConfig statement to the Policy Agent image configuration file, identifying the TTLSConfig policy file location:
	`TTLSConfig serverpath`
	2. For remote AT-TLS policies, add a PolicyServer statement to the policy client image configuration file:
	`PolicyServer`
	`{`
	`ClientName name`
	`PolicyType TTLS`
	`{`
	`...`
	`}`
	`...`
	`}`
	
	Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:
	`DynamicConfigPolicyLoad clientname`
	`{`
	`PolicyType TTLS`
	`{`
	`PolicyLoad serverpath`
	`}`
	`...`
	`}`

Add statements to the AT-TLS policy file	Add the AT-TLS policy statements to the *serverpath* file:
	`TTLSRule XYZServerRule`
	`{`
	`LocalPortRange 5000`
	`JobName XYZSRV`
	`Direction Inbound`
	`TTLSGroupActionRef XYZGroup`
	`TTLSEnvironmentActionRef XYZServerEnvironment`
	`}`
	`TTLSGroupAction XYZGroup`
	`{`
	`TTLSEnabled On`
	`}`
	
	`TTLSEnvironmentAction XYZServerEnvironment`
	`{`
	`TTLSKeyRingParms`
	`{`
	`Keyring server_key_ring`
	`}`
	`HandshakeRole SERVER`
	`Trace 7`
	`}`

Table 54. AT-TLS configuration for the server system (continued)

Task	Specification
Set up InitStack access control	1. Define the EZB.INITSTACK.*sysname.tcpname* profile for each AT-TLS stack. 2. Permit administrative applications to use the stack before AT-TLS is initialized. For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.
Enable AT-TLS	Set TCPCONFIG TTLS in PROFILE.TCPIP.

Configuring the client systems

On each z/OS system where you run the client application, see Table 55 for the tasks needed to configure the client.

Table 55. AT-TLS configuration for the client system

Task	Specification
Create key ring	Create a client key ring for each client with necessary certificate authority certificates. If using client authentication, also attach each client's certificate to their key ring. **Tip:** To simplify AT-TLS policy, use the same RACF key ring name for every client. SystemSSL will qualify the key ring name with the current UserID when accessed.
Create Policy Agent files	1. Create a Policy Agent main configuration file containing a TcpImage statement for the client stack. 2. Create a Policy Agent image configuration file for the client stack. 3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server.

Table 55. AT-TLS configuration for the client system (continued)

Task	Specification

Add AT-TLS configuration	1. For local AT-TLS policies, add a TTLSConfig statement to the Policy Agent image configuration file, identifying the TTLSConfig policy file location:
	`TTLSConfig clientpath`
	2. For remote AT-TLS policies, add a PolicyServer statement to the policy client image configuration file:
	`PolicyServer`
	`{`
	`ClientName name`
	`PolicyType TTLS`
	`{`
	`...`
	`}`
	`...`
	`}`
	
	Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:
	`DynamicConfigPolicyLoad clientname`
	`{`
	`PolicyType TTLS`
	`{`
	`PolicyLoad clientpath`
	`}`
	`...`
	`}`

Add statements to the AT-TLS policy file	Add the AT-TLS policy statements to the *clientpath* file:
	`TTLSRule XYZClientRule`
	`{`
	`RemotePortRange 5000`
	`Direction Outbound`
	`TTLSGroupActionRef XYZGroup`
	`TTLSEnvironmentActionRef XYZClientEnvironment`
	`}`
	`TTLSGroupAction XYZGroup`
	`{`
	`TTLSEnabled On`
	`}`
	
	`TTLSEnvironmentAction XYZClientEnvironment`
	`{`
	`TTLSKeyRingParms`
	`{`
	`Keyring client_key_ring`
	`}`
	`HandshakeRole CLIENT`
	`Trace 7`
	`}`

Set up InitStack access control	1. Define the EZB.INITSTACK.*sysname*.*tcpname* profile for each AT-TLS stack. 2. Permit administrative applications to use the stack before AT-TLS is initialized. For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Table 55. AT-TLS configuration for the client system (continued)

Task	Specification
Enable AT-TLS	Set TCPCONFIG TTLS in PROFILE.TCPIP.

Steps for starting AT-TLS and verifying its operation

You are now ready to start the sample AT-TLS environment and verify its operation.

Before you begin:

1. Perform the tasks in Table 54 on page 1199 and Table 55 on page 1201.
2. Review your syslogd configuration to verify that messages written by Policy Agent and TCP/IP stacks are saved in the desired files. AT-TLS syslogd messages are written to the daemon facility by default.
3. Start syslogd.

Perform the following steps to start AT-TLS and verify its operation:

1. Start the TCP/IP stacks.
2. Start the administrative applications required for successful Policy Agent execution, such as OMPROUTE, LDAP, and the name server.
3. Start Policy Agent on all participating systems and verify that there were no policy errors in processing the policy files.
4. Verify that the participating TCP/IP stacks have received AT-TLS policy and released console message EZZ4248E.
5. Start server application and verify that it starts without errors.
6. Start client applications. Review the AT-TLS trace messages in the syslogd output on both the client and server systems. Verify that connections are mapping to the intended policy and no handshake errors occur. The info messages `EZD1281I TTLS Map` and `EZD1283I TTLS Initial Handshake` show the policy used and result of TLS handshake negotiation. The error message `EZD1286I TTLS Error` shows any failures.

For information on common AT-TLS startup errors, see *z/OS Communications Server: IP Diagnosis Guide*.

Application compatibility with AT-TLS

Most applications can use AT-TLS. However, some applications should not be configured to use AT-TLS. Any application that is already configured to use SSL or TLS protocols should not use AT-TLS. Use of AT-TLS would result in encrypting data that is already encrypted. The receiving partner would not be able to decipher the data that had been encrypted twice. If the application can be configured to use clear text or the application uses the SIOCTTLSCTL ioctl, AT-TLS can provide support.

TCP/IP applications that already support the TLS protocol include:

- TN3270E Telnet server

  Use the TTLSPort statement to configure the TN3270E Telnet server to support AT-TLS. See "Configuring Telnet security using AT-TLS" on page 585.
- FTP server

Code the TLSMECHANISM statement in FTP.DATA to configure the FTP server to support AT-TLS. See "Steps for migrating the FTP server and client to use AT-TLS" on page 700.

- FTP client

  Code the TLSMECHANISM statement in FTP.DATA to configure the FTP client to support AT-TLS. See "Steps for migrating the FTP server and client to use AT-TLS" on page 700.
- Sendmail
- DCAS (Express Logon server)
- Bind 9.*x*, which uses open SSL

AT-TLS does not support Web servers using the Fast Response Cache Accelerator (FRCA) support in TCP/IP. AT-TLS ignores policy for connections using FRCA. The sockets are treated as if they did not match any AT-TLS rules.

AT-TLS does not support applications that use the Pascal sockets API. AT-TLS ignores all Pascal sockets. The sockets are treated as if they did not match any AT-TLS rules. TCP/IP applications that use the Pascal API include:

- TSO TN3270E Telnet client
- SMTP server
- LPD server

Policy considerations

Policy is a powerful tool for configuring and managing your applications that use AT-TLS. Before configuring the AT-TLS policy, review the general syntax rules in the Policy Agent and policy applications topic in *z/OS Communications Server: IP Configuration Reference*.

Reusable objects

With several of the AT-TLS rule conditions and action parameters, you can reference named objects. If you are going to use the same definition in several rules or actions, it is easier to create a single named object and refer to it, rather than repeating the definition. This also makes changing these definitions easier and more accurate. For example, the IpAddrGroup statement can be used to identify groups of IP addresses that are used in several rules. You might find it useful to define TTLSRule statements that reference an IP address group with a name, such as LocalHost. In each stack's AT-TLS policy file, you would define that IP address group with all of the addresses local to that stack. That single reference can then be used throughout the policy to easily represent all local IP addresses, without re-coding the local addresses in each rule condition.

Common AT-TLS configuration file

The common AT-TLS configuration file should contain all of the policy that is common to multiple stacks. When the policy agent reads a policy file for a given stack, the contents of the common AT-TLS configuration file are logically added before the contents of the stack-specific file. Rules and actions in the common AT-TLS configuration file can reference objects, such as a local IpAddrGroup statement, that are defined in the stack-specific AT-TLS configuration file. Rules and actions in the stack-specific file can also reference objects that are defined in the common file.

If Policy Agent encounters multiple objects of the same type and name, the last occurrence is the one that is used. You can take advantage of this by defining an object that is used on many stacks in the common file, and then overriding it in the stack-specific file of a specific stack.

Exempting specific connections from AT-TLS

In some cases, you might want to have the majority of users of an application using AT-TLS, but then exempt a small group of users. You might find that it is simpler to define a broad AT-TLS policy for the application, and then define a higher priority rule for the exempt users. The simplest way to do this is to define a TTLSGroupAction statement with the TTLSEnabled parameter set to OFF. The exempt user rule would then reference this action. When the TTLSGroupAction statement specifies the TTLSEnabled parameter as OFF, the TTLSEnvironmentActionRef parameter on the corresponding rule is not required.

Action refresh

When Policy Agent is stopped and restarted, or when policy files are changed, policy objects that are currently in use might be deleted or replaced. When an AT-TLS action is deleted or replaced, connections using the old object continue processing without change. Connections that search AT-TLS policy after the change use the new action objects. A change to an AT-TLS group action causes a new Language Environment process to be created, along with new SSL environments for each user or application environment associated with that group. A change to an AT-TLS environment action causes new SSL environments to be initialized within each group with which that environment is associated. System SSL reopens key rings and certificates, and creates an empty session ID cache when it initializes an SSL environment.

There are cases when a change is made that is not reflected by a change in the action. For example, the default certificate in a key ring might change. The key ring name has not changed, but there is a need to open a new environment. Simply refreshing policy will not refresh the AT-TLS environment action in AT-TLS, because no values within the action have changed. To force a refresh in AT-TLS, some parameter must be changed. The EnvironmentUserInstance parameter can be used for this purpose. Incrementing the instance number forces a refresh of AT-TLS without changing any of the security parameters. Similarly, changes to the contents of the environment file named in a group action will not be applied until the group action is changed. The GroupUserInstance parameter can be used to force an AT-TLS refresh of the group, creating a new Language Environment process using the new environment file contents.

Sometimes after you have made a change to an AT-TLS policy, the changed policies are not automatically reinstalled by the Policy Agent; new connections might fail until the policies are reinstalled. If you see AT-TLS connection setup errors with message EZD1286I or EZD1287I after you made an AT-TLS configuration change, you can force all AT-TLS policies to be reinstalled by refreshing the Policy Agent. From the MVS console, issue the MODIFY *procname*,REFRESH command. For more information about controlling the refresh of polices using the TcpImage and PEPInstance statements, see *z/OS Communications Server: IP Configuration Reference*.

Achieving the basic level of security

To achieve the basic level of security, do the following:

1. Pick the handshake roles.
2. Specify the key ring.

Picking the handshake roles

Every secure connection must have one end using the HandshakeRole Client, and the other end using the HandShakeRole Server or HandShakeRole ServerWithClientAuth.

In the SSL and TLS protocols, the client side sends a ClientHello handshake record and the server side responds with a ServerHello handshake record. If both sides send ClientHello records, the handshake fails. If both sides wait for a ClientHello, the handshake times out.

The role played in the handshake is independent of whether the application is used as the client, server, or peer. It is also independent of which application does the listen() and accept() and which does the connect(). The primary consideration for deciding which role an application should play is certificate management.

- An application designated as HandshakeRole Server must have a user or site certificate on its key ring. It must have access to the private keys of its user or site certificate. It might also need other certificates on its key ring, required for authentication.

  The partner application designated as HandshakeRole Client must have a key ring that contains the root certificates required to authenticate the server's certificate. The client does not need access to the private keys of any certificate. Clients can share this key ring.
- An application designated as HandshakeRole ServerWithClientAuth might need additional root certificates on its key ring to authenticate client certificates. The server decides whether a client must present a user certificate and what constitutes an acceptable certificate.

  The partner application designated as HandshakeRole Client decides whether to present a user certificate when challenged. To present a user certificate, it must have a private key ring with that user certificate. It must have access to the private keys of the user certificate. The client key ring must also contain the root certificates required to authenticate the server's certificate.

When the HandshakeRole parameter is set to ServerWithClientAuth, a certificate request is sent to the client during the handshake. The client can send its certificate to the server, which can then validate the certificate. The level of validation done by the server is controlled by the setting of the ClientAuthType parameter. The following chart summarizes the differences between the parameter settings:

Table 56. ClientAuthType parameter settings

ClientAuthType	Client certificate required or optional	Certificate validation
PassThru	Optional	None
Full	Optional	Certificate is validated against keyring, if provided
Required	Required	Certificate is validated against keyring

Table 56. ClientAuthType parameter settings (continued)

ClientAuthType	Client certificate required or optional	Certificate validation
SAFCheck	Required	Certificate is validated against keyring and must be associated with a user ID in the security product

If the certificate fails validation, the secure connection does not initialize successfully. The default setting for ClientAuthType is Required. For applications that do not issue AT-TLS ioctl calls to obtain the certificate or user ID of the client, the Required setting ensures that any client that connects provides a valid client certificate. The ClientAuthType setting of PassThru should only be used for applications that will get the certificate from AT-TLS using the SIOCTTLSCTL ioctl call and implement their own security methods to validate the certificate. The ClientAuthType setting of Full can be used for applications that want to validate the client certificate if provided, but do not require a client certificate to establish a secure connection. The ClientAuthType setting of SAFCheck provides an additional level of security when using client authentication by requiring AT-TLS to derive a user ID associated with the certificate. An application can then get the user ID from AT-TLS using the SIOCTTLSCTL ioctl after the secure connection has been established. The user ID can be used to either verify the user ID presented by the client during the application's protocol flows or eliminate the need for a user ID to be sent by the client.

Specifying the key ring

AT-TLS configuration can be simplified by using key rings with a common name stored in RACF. The SAF key ring name is specified as *userid/keyring*. The current user ID is used if only the key ring name is specified. A value that begins with a forward slash is interpreted as the path name of a gskkyman key ring. A PKCS #11 token name is specified as *TOKEN*/*token-name*. *TOKEN* indicates that the specified key ring is actually a token name.

Configuring more sophisticated security

This topic describes decisions you can make to achieve more elaborate levels of security.

Protocol versions

SSLv3, TLSv1, and TLSv1.1 provide stronger security than SSLv2. Support for SSLv2 is off by default in AT-TLS policy. You should turn it on only if you must support older applications that do not support the newer protocols.

Cipher suite specification

The set of SSL protocol cipher specifications to be allowed for the secure session can be set. You should not include any that you do not want to allow. Order is important. System SSL selects ciphers according to the server's order of usage preference. The first cipher in the server's list that is also in the client's list is selected. Other implementations might work differently.

AT-TLS does not pass any cipher suites to System SSL by default. For the list of cipher suites supported and the default order used if none is specified, see *z/OS Cryptographic Services System SSL Programming*.

Certificate validation

You can specify that certificates should be validated using only the method described in RFC 2459, using only the method described in RFC 3280, or using either method.

FIPS 140-2 support

You can configure AT-TLS to support FIPS 140-2. Specify On for the FIPS140 statement of the TTLSGroupAction statement.

For information about configuring System SSL to run in FIPS140 mode, see *z/OS Cryptographic Services System SSL Programming*.

LDAP servers

Applications using HandshakeRole ServerWithClientAuth can optionally use a Certificate Revocation List (CRL) service. This service is provided by an LDAP server. The TTLSGskLdapParms statement is used to configure System SSL so that it can contact a CRL service. Connections used by System SSL to contact the CRL service should not fall under an enabled AT-TLS policy because these connections can be made before AT-TLS policy has been installed.

Encryption key refresh

The SSLv3, TLSv1, and TLSv1.1 protocols allow the encryption key to be renegotiated during a secure connection. This can provide a higher level of security for long running connections. The AT-TLS default is to not reset the cipher. You can specify a time interval to cause AT-TLS to request a reset of the cipher in the range 1 to 1440 seconds using the ResetCipherTimer statement. The cipher reset is requested when the timer expires and the next application read or write completes. The time interval is restarted when the cipher has been changed. Both ends of the secure connection must agree to perform another handshake to renegotiate the cipher. The HandshakeRole Client end must initiate this handshake. The HandshakeRole Server can send an alert to the client requesting another handshake. The client is free to ignore or postpone the request. The server is free to refuse a re-handshake request sent by the client.

Additional security customization considerations

This topic provides additional information that you might want to use to customize security for your environment.

Handshake timer

Certain configuration or application protocol mismatches can lead to stalled connections. The TLS handshake protocol always expects the end of the connection configured as HandshakeRole Client to send the first message. One connection stall scenario results when both ends of the connection are configured as HandshakeRole Server and wait for a ClientHello record from the other end. Another connection stall scenario results when the end of the connection that normally sends the first application data is configured as HandshakeRole Server, but the partner application is not configured to use a secure connection. The HandshakeRole Server end is waiting for a ClientHello, and the nonsecure end is waiting for application data.

You can use the HandshakeTimer action parameter to control the time that AT-TLS should wait during TLS handshake negotiation before resetting the connection.

AT-TLS times two different handshake intervals, handshake start and handshake completion. The handshake start interval is intended to detect configuration problems that result in neither partner sending data. The handshake completion interval is intended to detect problems that might stall a handshake in one of the TLS protocol implementations.

The handshake start interval begins when AT-TLS is ready to begin a TLS handshake, and ends when the hello handshake record is received from the partner. On the initiating or active side of the connection, the handshake start interval used is five times the specified HandshakeTimer value, because it includes:

- The network time for the ClientHello record to reach the partner if HandshakeRole is Client.
- The time a connection spends on the partner's listen backlog.
- The time before the partner causes the connection to be mapped.
- The time spent on the partner AT-TLS work queue.
- The time spent by the partner initializing a new System SSL environment, if necessary.
- The network time for the partner's ServerHello or ClientHello record to be returned.

On the listening or passive side of the connection, the handshake start interval used is the specified HandshakeTimer value, because it includes only the network time for one or both hello records. Handshake start interval timeouts result in AT-TLS return code 5004 and a connection reset.

The handshake completion interval begins when the hello handshake record is received from the partner, and ends when the System SSL gsk_secure_connection_init() service returns to AT-TLS. The handshake completion interval used is the specified HandshakeTimer value on either active or passive connections. Handshake completion interval timeouts result in AT-TLS return code 5005 and a connection reset.

The HandshakeTimer action parameter has a default value of 10 seconds. If you determine that you are getting handshake time-outs that are caused by network delays or application workload rather than configuration or application errors, you should increase the value. On the other hand, if you determine that handshakes normally complete much faster in your environment and you would like to detect the occasional incorrectly configured partner more quickly, you can decrease the value.

Diagnostic traces

In addition to the steps for diagnosing AT-TLS problems described in *z/OS Communications Server: IP Diagnosis Guide*, you might need to collect a System SSL trace when you are diagnosing an AT-TLS problem. The only method for collecting this trace is by using GSKSRVR CTRACE, as described in *z/OS Cryptographic Services System SSL Programming*. You cannot use the GSK_TRACE environment variable because it causes an abend if it is used with AT-TLS. When you use GSKSRVR CTRACE to diagnose AT-TLS problems, the job name that you specify on the JOBNAME parameter of the CTRACE command should be the TCP/IP job name rather than the application job name.

If you are not using any other features provided by the GSKSRVR started task, then you can use the sample procedure provided in the SGSKSAMP library without any changes.

Diagnosis considerations

Applications that implement SSL or TLS can control whether non-encrypted application data is included in diagnostic traces. Lower layers have access to only encrypted data. When using AT-TLS, the TCP, PFS, and SOCKAPI layers have access to non-encrypted data. The AT-TLS default is to suppress this data in CTRACE records generated by these layers to protect the application's users. If you need to see this data in these records to diagnose a problem, you can set CtraceClearText ON.

AT-TLS writes trace messages to syslogd. The AT-TLS default behavior is to write syslogd messages to the daemon facility. Other TCP/IP functions, such as the SNMP TCP/IP subagent, also specify the daemon facility name when writing records to syslogd. The job name and syslog facility name are the same. Filters cannot be used to direct the records to different output files. If you want AT-TLS records to go to a different output file, you can change the syslog facility name in the TTLSGroupAction statement to direct the messages from that group to the Auth facility instead. You can then set up filtering based on the job name and facility in the syslogd configuration file to direct AT-TLS records to a different output file.

The Trace value is interpreted by AT-TLS as a bit map. Each of the options is assigned a value that is a power of 2. You should add together the values of each option that you want to activate.

The default Trace value is 2, which provides error messages to syslogd. While you are deploying a new policy, you might find it beneficial to specify a Trace value of 6 or 7. This provides connection info messages, in addition to error messages in syslogd. The info messages provide positive feedback that connections are mapping to the intended policy.

Trace options event (8), flow (16), and data (32) are intended primarily for diagnosing problems. Trace values larger than 7 can cause a large number of trace records to be dropped instead of being sent to syslogd.

Tip: Use a TTLSConnectionAction with a higher Trace value to diagnose problems in a production environment. You can temporarily define a high priority TTLSRule with conditions that cover only a small number of problem connections. This temporary rule can reference the same TTLSGroupAction and TTLSEnvironmentAction that your production rule references, and a TTLSConnectionAction with the Trace level you want for diagnosis.

TLS function negotiation

TLS protocols enable the TLS client and TLS server to negotiate additional functionality for a connection. If either the TLS client or TLS server does not understand a function, the function is not used on the connection. However, the TLS client or TLS server might require that the function be supported by the remote partner. If the remote partner does not support the function, the connection can be closed. Each function can be configured as Required, Optional, or Off.

- Required

  The connection ends if the remote endpoint does not accept the TLS function.
- Optional

  The function is negotiated on the connection, but the connection does not end if the remote partner does not support the function.
- Off

The function is not supported on the connection. If the remote partner requires this function, the remote partner closes this connection.

Guideline: For TLS servers, configure the functions as Optional to prevent remote partners that require this extension from being unable to connect.

Wireless performance

AT-TLS supports the following negotiated functions:

- Maximum SSL fragment length

  This TLS function negotiates the maximum size of unencrypted data that can be sent in a single SSL fragment. Without this function, 16 K is the maximum fragment length. A TLS client can negotiate a size of 512, 1 K, 2 K or 4 K. Some clients need to use the smaller size because of memory or bandwidth limitations.
- Truncated HMAC

  TLS cipher suites use the MAC construction HMAC with either MD5 or SHA-1 (RFC 2104) to authenticate record layer communications. The truncated HMAC function saves bandwidth by truncating the HMAC to 80 bits.

Certificate selection

When AT-TLS supports a server, the certificate designated as the default for the key ring is used. Use the CertificateLabel parameter to explicitly identify a different certificate that you want to use.

If the SSL server needs to support multiple host names and multiple certificates, you can use the Server Name Indication function. The Server Name Indication function enables you to define pairs of certificate labels and host names. Use the HandshakeServerCertLabel parameter to specify these pairs.

The SSL client must support the Server Name Indication function as well. The SSL client includes a host name during the SSL handshake, which allows the matching certificate to be used.

When AT-TLS supports a client, you can use the HandshakeServerName parameter to specify the host name to be included in the SSL handshake.

For more information on configuring the HandshakeServerNameInd function, see "TLS function negotiation" on page 1210.

Session caching

SSL can cache session information based on the Session ID (SID). SSL connections can request that a previous session be resumed. When session information is found in the cache, connections can use the SSL short handshake, which requires less processing. The number of SIDs cached, the length of time that a SID is held in the cache, and whether the cache is available across the sysplex can be configured using the TTLSGskAdvancedParms statement.

AT-TLS access control considerations

Access to key rings and certificates is verified by System SSL when SSL environments are initialized. Access to certificate private keys is verified by ICSF when asymetric encryption services are requested that require the private keys. AT-TLS invokes System SSL services that cause these access control checks to occur on tasks created in the TCP/IP address space. TCP/IP replicates the security environment of the user running the application that owns the socket at the time AT-TLS policy is mapped, before invoking these System SSL services.

Several common application models were considered to determine the most appropriate time for replicating the security environment. Replication occurs when AT-TLS policy is mapped. Policy mapping occurs during processing of the first occurrence of connect, a SIOCTTLSCTL IOCTL, select for socket readable or writable, poll for socket readable or writable, or call that sends or receives data over the socket. This defers security environment replication for applications such as INETD until after the accept(), fork(), setuid(), and exec() sequence of services has established the server application process.

In the CICS socket environment, transaction security environments are not visible to AT-TLS support. The CICS job and all of its transactions appear to the stack as a single server application with a single z/OS UNIX process ID running in the security environment of the CICS job. All AT-TLS policy lookups, System SSL key ring authorization checks, and ICSF private key authorization checks are processed using the identity of the CICS job. Connections established, whether active or passive, can perform TLS handshake processing as either the client or server. All of the connections established by a single CICS job are able to share the session ID cache in the SSL environment. The CICS job should use a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate client certificates presented on its key ring.

Application model considerations

AT-TLS support provides for several typical socket application models. Socket applications with significantly different models might not benefit from AT-TLS.

Client application model

As shown in Figure 118 on page 1213, this type of application runs entirely within the security environment of a single user. Many users might use the application, but each usage is independent, runs in a separate process, and should not share System SSL information with other processes. All socket calls for each usage of the application are made from the same z/OS UNIX process. Most connections are active connections initiated with the connect() service by this application to a server. Some client applications, such as Web browsers, repeatedly connect to servers at the same or different IP addresses.

Some client applications, such as FTP or REXEC, support a second parallel connection with the server. This is often a passive connection, established by binding to an ephemeral port and listening for a single connection back from the server's IP address. For a description of an alternative method of mapping policy for these special cases, see “Secondary connection application model” on page 1217.

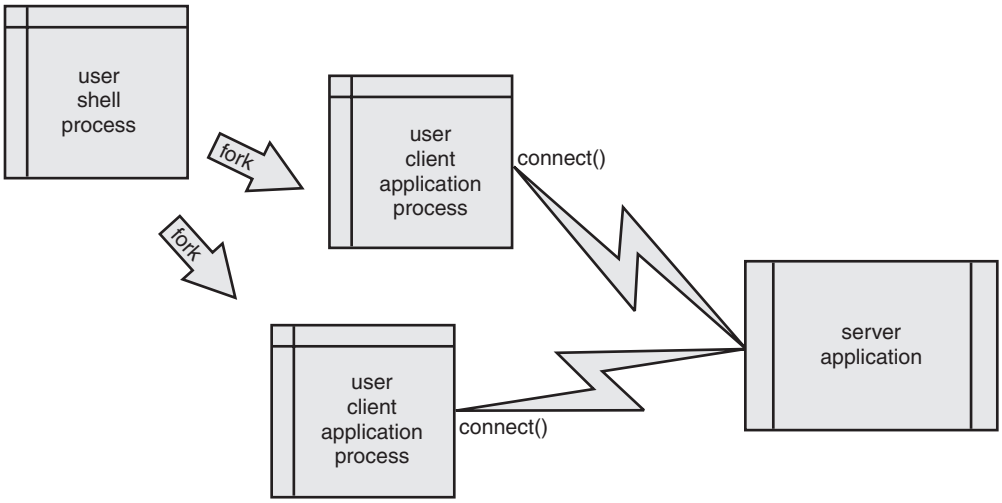

Figure 118. Client application model

All connections established by this application, whether active or passive, perform TLS handshake processing as a client. All of the connections established by a single process under the same user ID should be able to share the session ID cache in the SSL environment. If the server does not require client authentication, this client can use a shared key ring containing only the root certificates needed to validate the server's certificate. If the server does require client authentication, each user ID needs to own a key ring that contains that user's certificate, in addition to the necessary root certificates. RACF key ring names are qualified with the owning user IDand are specified as *userid/keyring*. If the user ID is not explicitly specified on the AT-TLS key ring parameter, the current user ID is used. Therefore, key ring names can be the same across different user IDs . If the same key ring name is used by all client user IDs, a single TTLSEnvironmentAction keyring parameter can represent all clients required to support client authentication. AT-TLS policy administration is simplified if the individual key rings all have the same key ring name.

Server application model

As shown in Figure 119 on page 1214, this type of application runs entirely within a single z/OS UNIX process. Connections can be either passive connections returned from a listening socket by the accept() service, or active connections initiated with the connect() service. Communication partners can be client applications or peer servers. Connections can be processed by subtasks or pthreads within the server process. The initial read or write of data on the connection is done under the primary security environment of the server process. Some server applications allow a client to log in with a user ID on the server system and can place this client-specified identity on the subtask or pthread used to access resources on behalf of the client. The user ID associated with the server is used for AT-TLS purposes, regardless of this ability to change to the client-specified identity.

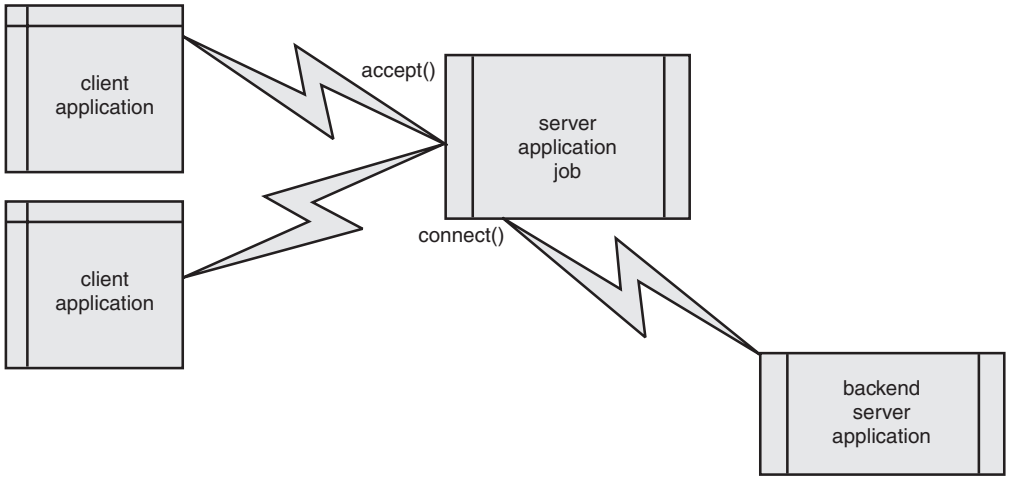

Figure 119. Server application model

Connections established by this application, whether active or passive, can perform TLS handshake processing as either a client or server. All of the connections established by a single process, under the same user ID and performing the handshake as a client or as a server, should be able to share a session ID cache in the SSL environment. The server process should use a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate the client certificates presented on its key ring.

Forked server application model

As shown in Figure 120 on page 1215, this type of application is forked by a daemon application, such as INETD, to handle a single passive connection to a socket that the daemon is listening on. The daemon invokes the bind(), listen(), and accept() services on the parent socket. It then forks a new process to handle each child connection, optionally changes the new process to a different identity, and optionally execs a configured server application. The server application reads and writes data on the child connection.

Some server applications support a second parallel connection with the client. This is often an active connection, established by connecting back to an ephemeral port opened by the client at the client's IP address. For a description of an alternative method of mapping policy for these special cases, see “Secondary connection application model” on page 1217.

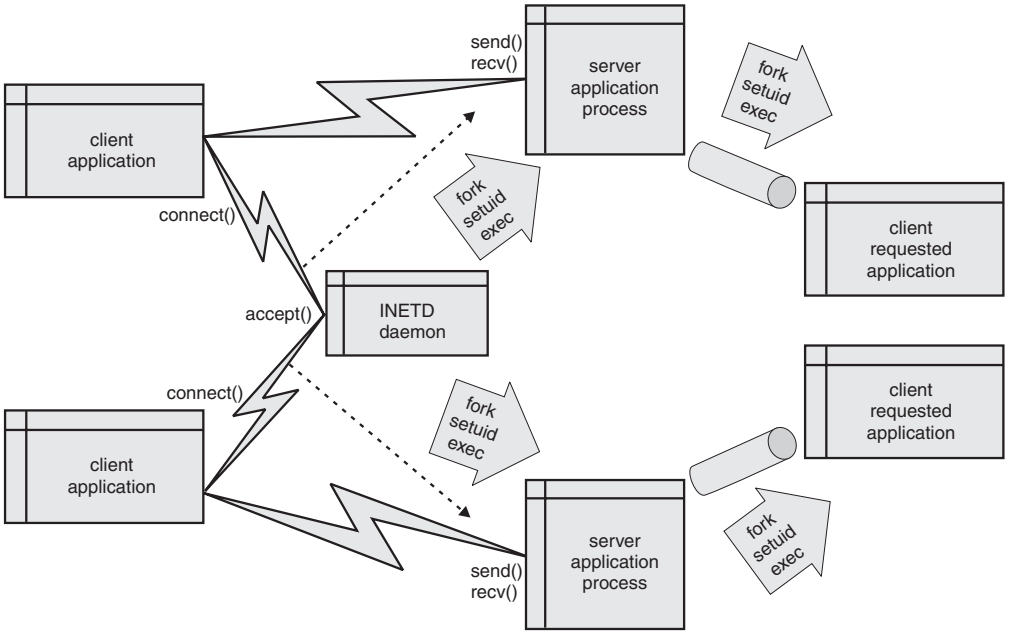

Figure 120. Forked server application model

Many server applications allow the client to log in with a user ID on the server system. Some server applications change the security environment of the server process to the client-specified identity prior to accessing resources on behalf of the client. Other server applications set up another communications path (pseudo terminal, named pipe, UNIX domain socket, and so on) and then fork an additional client process. The server changes the security environment in this client process to the client-specified identity, and then execs a client-specified program or login shell.

The initial child connection transferred by the daemon to the server process, and any additional connections established by the server process, perform TLS handshaking as the server, optionally requiring client authentication. Each forked server process runs under the same user ID. All of the server processes forked to handle child connections of the same parent connection should be able to share the session ID cache in the SSL environment. The server processes can use a shared key ring with a site certificate or a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the site or server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate client certificates presented on its key ring.

Any client process forked by the server process is treated as a new application by AT-TLS. New connections established will not share an SSL environment with the server process that created them.

CICS transaction model

TCP/IP CICS socket support provides a CICS resource manager that invokes z/OS UNIX socket services. It also provides a CICS Listener transaction that accepts passive connections from a listening socket. Each listening socket has a configured transaction that is launched to process a single established connection.

For more information on configuring TCP/IP CICS socket support, see *z/OS Communications Server: IP CICS Sockets Guide*.

Advanced application considerations

Some applications need to be aware of when a secure connection is being used or examine the certificate presented by the partner. Other applications need to control if and when the TLS handshake occurs. These applications typically support both TLS and non-TLS connections over the same port. They define an application protocol for negotiating whether to use TLS and when to begin. In both cases, these applications need to be aware that TLS is being used on the connection. However, you might not want to, or might not be able to, use any SSL toolkits in the application. AT-TLS support provides the SIOCTTLSCTL ioctl commands that can be used in these situations.

Some applications establish a second connection using ephemeral ports or after the server has changed to a client supplied identity. These secondary connections need to be associated with the policy and security environment used on the primary connection. AT-TLS provides special support for these applications.

AT-TLS aware application considerations

Applications that need to examine the partner's certificate can issue the SIOCTTLSCTL IOCTL with request type TTLS_RETURN_CERTIFICATE to get the certificate at any time during a secure connection. Applications that are running under a policy with the HandshakeRole parameter set to CLIENT receive the server's certificate. Applications that are running under a policy with the HandshakeRole parameter set to ServerWithClientAuth receive the client's certificate if provided.

Applications configured as HandshakeRole ServerWithClientAuth that need to examine or use the user ID associated with the certificate in SAF can issue the SIOCTTLSCTL ioctl with request type TTLS_QUERY_ONLY or TTLS_RETURN_CERTIFICATE. If a partner certificate is available on the secure connection, AT-TLS uses a RACF service to extract the associated user ID. If no client certificate is available, or no user ID has been associated, the ioctl returns zero as the associated user ID length.

AT-TLS controlling application considerations

Applications that need to control AT-TLS behavior, using the SIOCTTLSCTL IOCTL with the TTLS_INIT_CONNECTION, TTLS_RESET_SESSION, or TTLS_RESET_CIPHER request flags, must have the ApplicationControlled parameter set to ON in their TTLSEnvironmentAdvancedParms or TTLSConnectionAdvancedParms statement. This causes AT-TLS to postpone the TLS handshake. After the connection is established, the application can issue the SIOCTTLSCTL IOCTL to get the current AT-TLS connection status and determine whether or not AT-TLS support is available on this connection. When the application is ready for AT-TLS to perform the TLS handshake, it issues the SIOCTTLSCTL IOCTL with request type TTLS_INIT_CONNECTION. The SIOCTTLSCTL IOCTL initiates an AT-TLS policy lookup, if one has not yet been done, and assigns a rule and actions to the connection if a match is found. For more IOCTL information, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Some application protocols provide a way for the client and server programs to negotiate whether to use the TLS or SSL protocol to protect data on the connection. This cleartext negotiation typically occurs very early in the connection. When both partners agree to use TLS, they initiate the handshake. These applications can take advantage of AT-TLS. The policy must indicate ApplicationControlled ON. After

the connection is established, the application can use the SIOCTTLSCTL IOCTL to determine whether AT-TLS support is configured, policy covers the connection, and the policy specifies ApplicationControlled ON. The application can then send and receive cleartext data to negotiate the use of TLS. When both partners agree, they each must initiate a secure connection. The AT-TLS application can use the SIOCTTLSCTL ioctl with TTLS_INIT_CONNECTION to initialize the secure connection. AT-TLS performs the initial handshake and provides encryption and decryption services for the application. The application can simply send and receive cleartext over the socket as it would if it were not a secure connection.

The application can also use the SIOCTTLSCTL IOCTL to reset the cipher or the session. Resetting the cipher causes AT-TLS to initiate another handshake. If the session is reset first, the subsequent handshake is a full handshake. If the session has not been reset, a short handshake is attempted for the subsequent handshake. The partner application must agree to the short handshake.

Secondary connection application model

Some applications create two connections between the client and server programs. These applications typically have a single primary connection that is bound to a well-known port on the server side. After exchanging some information, a second connection is established. This second connection often uses dynamically assigned ports on both ends. Examples of this behavior include the stderr connection in the rsh, rexec, and rlogin family of applications, as well as the firewall-friendly FTP data connection. It is often not possible to define a set of policy rule conditions to correctly map these secondary connections on the client side or when the server forks a new process, with a dynamic job name, for each connected client.

In other cases, this second connection is established after the server has changed to a client-supplied identity. Mapping this second connection to AT-TLS policy as a new and independent connection would force the use of a different System SSL environment. The client-supplied identity would need to have access to the certificate private keys. Normal FTP data connections are an example of this behavior.

AT-TLS provides an alternate method of mapping policy for these secondary connections. This alternate method causes the secondary connection to share the System SSL environment and security environment of the associated primary connection.

To activate the alternate policy mapping method, define a policy rule using conditions that will map the primary connection. In this policy, specify the SecondaryMap parameter with a value of ON. When this policy is mapped to a primary connection, an entry is made in an internal table. Future connections do a normal policy lookup, and then look in the internal table for an entry with the same process ID and pair of IP addresses. If a matching entry is found and the new connection has no mapped policy, or has a mapped policy with a lower priority than the matching entry, the new connection is marked as a secondary connection and uses the same policy and user ID as the primary connection.

You should use this alternate policy mapping method only for client applications and server applications that have a single primary connection. Careful consideration should be given before using it for non-forking server applications that accept multiple primary connections, such as MVRSHD (TCP/IP's combined rsh and rexec server for the TSO environment). The alternative method of policy mapping always associates secondary connections with the most recent primary

connection mapped by this process. When the process establishes multiple primary connections, the alternate mapping method is not able to reliably associate secondary connections with the correct primary connection. You should not use this alternate policy mapping method when the primary connections can map to different policies based on client IP address or multiple server listening port numbers. You should use normal policy mapping with a job name condition for the secondary connections of non-forking servers.

Chapter 23. z/OS Load Balancing Advisor

The z/OS Load Balancing Advisor communicates with external load balancers and one or more Load Balancing Agents. The main function of the Load Balancing Advisor is to provide external TCP/IP load balancing solutions, such as the Cisco Content Switching Module (CSM), with recommendations on which TCP/IP applications and target z/OS systems within a z/OS sysplex are best equipped to handle new TCP/IP workload requests. These recommendations can then be used by the load balancer to determine how to route new requests to the target applications and systems (that is, how many requests should be routed to each target). The recommendations provided by the Advisor are dynamic, and can change as the conditions of the target systems and applications change. The recommendations include several key components:

- State of the target application and system

  This includes an indication of whether the target application and target system is currently active. This enables the load balancer to exclude systems that are not active or do not have the desired application running.
- z/OS Workload Management (WLM) system-wide recommendations

  WLM recommendations provide a relative measure of a target system's ability to handle new workload, as compared to other target systems in the sysplex. The WLM recommendations are derived using several measures, including each system's available general CPU capacity, which is used for both system members and application members. For application members, the amount of available System z Application Assist Processor (zAAP) capacity and System z9 Integrated Information Processor (zIIP) capacity can also be considered.

  If systems are 100% utilized, a WLM recommendation is a measurement of available displaceable capacity (capacity that can be displaced by higher importance workloads). The latter is important for scenarios where systems might be 100% utilized, but some might be running a larger portion of lower importance work (as defined by the WLM policy) that can therefore be displaced by higher importance workloads.
- z/OS WLM server-specific recommendations

  These recommendations are similar to the WLM system-wide recommendations, but are more specific as they are based on the following:
  - How well individual server applications are doing compared to the WLM policy goals that have been specified for that workload.
  - The amount of displaceable capacity of the general, zAAP, and zIIP CPU work on each system, based on the following:
    - The workload's importance (as defined by the WLM policy).
    - The proportion of each CPU type that is currently being consumed by the application's workload.

  These recommendations can be very useful in helping the load balancers avoid selecting application servers that are experiencing performance problems (that is, not meeting the specified WLM policy goals).
- Application server health from a TCP/IP perspective

  TCP/IP statistics for target applications are monitored to determine whether specific server applications are encountering problems keeping up with the current workload. For example, is a target TCP server application keeping up with TCP connection requests? Or are requests being rejected because the

backlog queue is full? In scenarios where this occurs, the recommendations passed back to the load balancers are adjusted appropriately, so that the load balancer can direct fewer connections to any application that is experiencing these problems. These recommendations are provided for both UDP and TCP server applications. These recommendations are referred to as Communication Server weights in this information.

z/OS Load Balancing Advisor system overview

Figure 121 illustrates the relationship between the load balancer, a z/OS Load Balancing Advisor, and Load Balancing Agents.

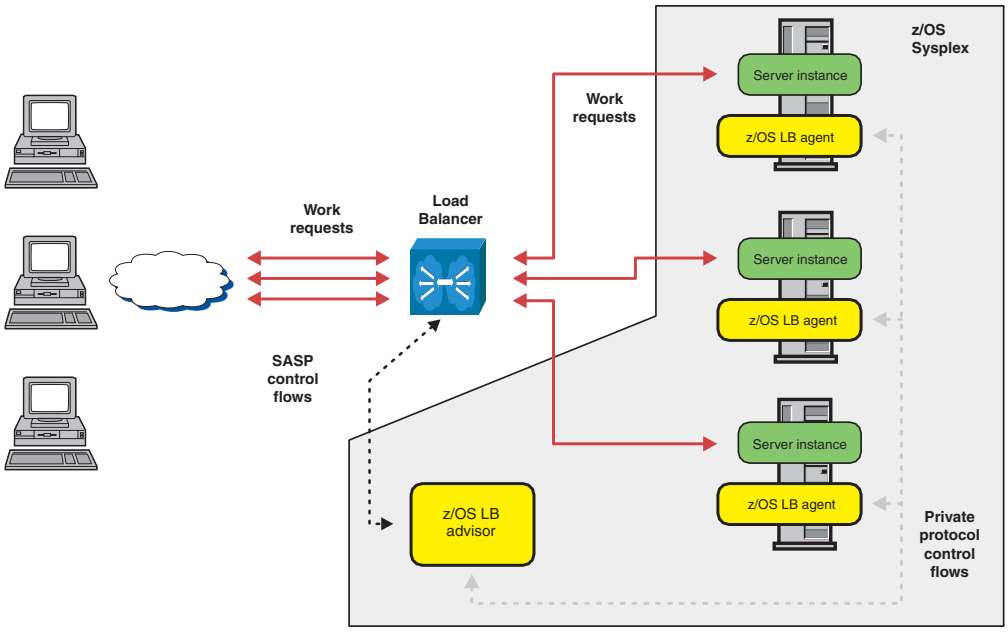

Figure 121. z/OS Load Balancing Advisor

The load balancer is configured with a list of systems and applications that it will balance. The load balancer tells the Load Balancing Advisor about the applications by specifying an IP address, port, and protocol, or about the systems by specifying an IP address. The Advisor is configured with a poll interval at which the Agents update the Advisor's data. You can configure the Advisor with a list of authorized load balancers and a list of authorized Load Balancing Agents with which it can gather data, or you can use AT-TLS support to provide the authorization for the load balancers and Load Balancing Agents. Each Agent gathers data on its own z/OS system about the TCP/IP stacks and applications running on that system.

The Agent is configured with the information it needs to contact the Advisor. The Advisor consolidates the data from all its Agents, and returns the data to the load balancer to advise the load balancer about the status of the systems and applications.

TLS/SSL enablement for the z/OS Load Balancing Advisor

As you plan to use the z/OS Load Balancing Advisor, consider whether you need to use TLS/SSL (using AT-TLS on z/OS). The z/OS Load Balancing Advisor acts as a TCP server application, listening on two distinct ports that allow both Load Balancing Agents and external load balancers [or automated domain name

registration (ADNR)] to connect to it. You need to restrict the ability to establish a connection to either of these ports, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. For the agent listening port, you need to ensure that only authorized agents are allowed to connect, because these agents are responsible for providing sensitive information that indicates server application availability, health, and performance. For the external load balancer Server/Application State Protocol (SASP) port, you need to ensure that only authorized load balancers and ADNR are allowed to connect, because this interface can be used to obtain sensitive information regarding TCP/IP applications in a sysplex, CPU utilization information for each system, and so on. You can use AT-TLS to encrypt data between the external load balancer and the Advisor's TCP/IP stack, and between the Agent's TCP/IP stack and the Advisor's TCP/IP stack.

You can use one or both of the following methods to authorize connections to the z/OS Load Balancing Advisor:

- You can explicitly configure the following lists:
  - The list of IP addresses of all the external load balancers (including ADNR) that are allowed to connect to the Load Balancing Advisor
  - The list of source IP addresses and source ports that each of the Load Balancing Agents use to connect to the Load Balancing Advisor
- You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS, and load balancers are required to use TLS/SSL.

Although the configuration parameters might be sufficient in certain environments in which the Load Balancing Advisor, Agents, and external load balancers all reside inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important.

With AT-TLS, the z/OS Load Balancing Advisor provides you with a more secure way to authorize access to critical Load Balancing Advisor resources using industry-standard network security standards like TLS/SSL. The AT-TLS approach also provides some additional benefits:

- Ease of use
  - Reduces the number of IP address and port lists that need to be maintained in the Load Balancing Advisor and coordinated with the external load balancers and Load Balancing Agents.
  - Eliminates the need for defining a source IP address and port for each Load Balancing Agent. This includes the Agent configuration file, the TCP ports that need to be reserved in the TCP/IP profile, and the DVIPAs that are recommended for the source IP address that is used for Agent connections.
- Outage avoidance

  If you do not use AT-TLS, adding an Agent instance into the sysplex requires updates to the Load Balancing Advisor configuration, which in turn requires a recycle of the Load Balancing Advisor so that it can process the configuration changes. With AT-TLS, you can add an Agent instance into the sysplex without recycling the Advisor.

For more information about using AT-TLS, see Chapter 22, “Application Transparent Transport Layer Security data protection,” on page 1193.

Steps for configuring the z/OS Load Balancing Advisor

Before you begin: You must meet the following requirements:

- You must have at least one external load balancer that supports the Server/Application State Protocol (SASP). This load balancer must have IP connectivity to each z/OS system in the sysplex that is to participate in load balancing. If you are using TLS/SSL (through AT-TLS on z/OS) for incoming connections to the Load Balancing Advisor, the load balancer must also be capable of using TLS/SSL on its SASP communication flows.
- Read Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193 and Chapter 16, "Policy-based networking," on page 829 to decide how you want the Advisor and Agents to use AT-TLS policies. To use AT-TLS, AT-TLS must be enabled and the Policy Agent must be configured and activated for each TCP/IP stack where the Load Balancing Advisors and Load Balancing Agents might run.

Perform the following steps to configure the z/OS Load Balancing Advisor and one or more Load Balancing Agents. References are included regarding special considerations for the following configurations:

- For configurations that include multiple TCP/IP stacks on a single system image, references are made to "Configuring the z/OS Load Balancing Advisor in a multiple TCP/IP stack environment" on page 1245.
- For configurations in which the z/OS Load Balancing Advisor is running in a sysplex subplexing environment, references are made to "Configuring the z/OS Load Balancing Advisor with subplexing" on page 1247.

1. Evaluate TCP/IP workloads to be load balanced and select a load balancing solution. (optional)
2. Decide who will have authority to start the Advisor. (optional)
3. Decide who will have authority to start the Agents. (optional)
4. Authorize the Agents to use WLM services
5. Optionally configure the Advisor and Agents to automatically restart in case of application or system failure. (optional)
   - For CINET considerations for this step, see "Step 5 (CINET): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)" on page 1245.
   - For information about the changes you need to make to this step to use subplexing, see "Step 5 (subplex): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)" on page 1248.
6. Configure and start syslogd.

   For information about the changes you need to make to this step to use subplexing, see "Step 6 (subplex): Configure and start syslogd" on page 1249.
7. Configure one Advisor per sysplex.
   - For CINET considerations with DVIPAs and regarding stack termination, see "Step 7 (CINET): Configure one Advisor per sysplex" on page 1245.
   - For information about the changes you need to make to this step to use subplexing, see "Step 7 (subplex): Configure one Advisor per sysplex" on page 1249.
8. Configure one Agent per z/OS system in the sysplex.

- For CINET considerations regarding the host_connection statement, see "Step 8 (CINET): Configure one Agent per z/OS system in the sysplex" on page 1246. Also see "Step 7 (CINET): Configure one Advisor per sysplex" on page 1245 for CINET considerations regarding unique application-instance DVIPAs and stack affinity.
- For information about the changes you need to make to this step to use subplexing, see "Step 8 (subplex): Configure one Agent per z/OS system in the sysplex" on page 1250.

9. Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on. (optional)
   - For CINET considerations regarding the lb_connection_v4 and lb_connection_v6 statements, see "Step 9 (CINET): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)" on page 1247.
   - For information about the changes you need to make to this step to use subplexing, see "Step 9 (subplex): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)" on page 1250.
10. Start the TCP/IP stacks that the Advisor and the Agents will use.

    For CINET considerations regarding Agent recovery after stack failure, see "Step 10 (CINET): Start the TCP/IP stacks that the Advisor and the Agents will use" on page 1247.
11. Start the target applications that will be the targets of load balancing.
12. Customize WLM policies for the Advisor and Agents. (optional)
13. Start one Agent on each sysplex system that you want to participate in this method of workload balancing.

    For information about the changes you need to make to this step to use subplexing, see "Step 13 (subplex): Start one Agent on each sysplex system you want to participate in this method of workload balancing" on page 1251.
14. Start the one instance of the Advisor in the sysplex.

    For information about the changes you need to make to this step to use subplexing, see "Step 14 (subplex): Start the one instance of the Advisor in the sysplex" on page 1251.
15. Configure the external load balancers.

    For information about the changes you need to make to this step to use subplexing, see "Step 15 (subplex): Configure the external load balancers" on page 1251.
16. Start the load balancers.
17. Verify that the Advisor system is functioning correctly. (optional)

Step 1: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution (optional)

The first steps involve identifying the TCP/IP applications that you want to load balance, the systems that these applications will be running on, and ensuring that these applications can exploit load balancing. When this is done, evaluate the load balancing techniques that best meet your requirements. You might want to use a combination of workload balancing solutions.

There are various technology choices for performing IP load balancing in a sysplex environment. For a discussion of some of these choices, see "Workload balancing" on page 462.

Step 2: Decide who will have authority to start the Advisor (optional)

Explicit authority should be granted to all users that can start the Advisor, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start the Advisor.

Tip: You might want to combine this step with the next two steps, "Step 3: Decide who will have authority to start the Agents (optional)," and "Step 4: Authorize the Agents to use WLM services" on page 1225, since these steps use similar commands.

Steps for granting authority to start the Advisor

Perform the following steps to grant authority to start the Advisor:

1. Ensure that the OPERCMDS class is active and RACLISTed, and RACLIST processing is enabled:

   ```
   SETROPTS CLASSACT(OPERCMDS)
   SETROPTS RACLIST (OPERCMDS)
   ```

2. Define the following OPERCMDS class profile using a security product like RACF:

   ```
   RDEFINE  OPERCMDS (MVS.SERVMGR.LBADV) UACC(NONE)
   ```

3. Grant the Advisor access to the OPERCMDS class:

   ```
   PERMIT   MVS.SERVMGR.LBADV CLASS(OPERCMDS) ACCESS(CONTROL) -
                    ID(userid)
   ```

4. Refresh the OPERCMDS class:

   ```
   SETROPTS RACLIST(OPERCMDS) REFRESH
   ```

5. See the EZARACF sample in SEZAINST for specific instructions.

   All commands that you can issue against the Advisor are MODIFY commands, with the exception of the STOP command used to stop the Advisor. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 3: Decide who will have authority to start the Agents (optional)

Explicit authority should be granted to all users that can start the Agents, to prevent unauthorized users from starting them. If you do not grant explicit authority, any user able to issue the START command can start the Agents.

Steps for granting authority to start the Agents

Perform the following steps to grant authority to start the Agents:

1. Ensure that the OPERCMDS class is active and RACLISTed, and RACLIST processing is enabled. If you have already done this for the Advisor, you can skip this step.

   ```
   SETROPTS CLASSACT(OPERCMDS)
   SETROPTS RACLIST (OPERCMDS)
   ```

2. Define the following OPERCMDS class profile using a security product like RACF:

```
RDEFINE  OPERCMDS (MVS.SERVMGR.LBAGENT) UACC(NONE)
```

3. Grant the Agents access to the OPERCMDS class:

```
PERMIT   MVS.SERVMGR.LBAGENT CLASS(OPERCMDS) ACCESS(CONTROL) -
                ID(userid)
```

4. Refresh the OPERCMDS class:

```
SETROPTS RACLIST(OPERCMDS) REFRESH
```

5. See the EZARACF sample in SEZAINST for specific instructions.

   All commands that you can issue against the Agents are MODIFY commands, with the exception of the STOP command used to stop the Agents. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 4: Authorize the Agents to use WLM services

You might want or need to define the BPX.WLMSERVER resource profile to your security product and grant the Agents access to it. If you are using RACF and already have the resource profile defined and the FACILITY class is enabled, permit the Agents to the resource profile. If you are using a security product other than RACF that by default denies access to the resource profile, grant the Agents access to the resource profile. If you do not already have the resource profile defined and you are using RACF, consult the documentation of other programs and products that require WLM services and coordinate any potential changes with these programs and products.

Steps for defining the resource profile with RACF

Perform the following steps for RACF if you choose to define the resource profile:

1. Ensure that the FACILITY class is active and RACLISTed, and RACLIST processing is enabled:

```
SETROPTS CLASSACT(FACILITY)
SETROPTS RACLIST (FACILITY)
```

2. Define the following FACILITY class profile:

```
RDEFINE  FACILITY (BPX.WLMSERVER) UACC(NONE)
```

3. Grant the Agent access to the FACILITY class:

```
PERMIT   BPX.WLMSERVER CLASS(FACILITY) ACCESS(READ) -
                       ID(userid)
```

4. Refresh the FACILITY class:

```
SETROPTS RACLIST(FACILITY) REFRESH
```

For more information, see the EZARACF sample in SEZAINST.

Step 5: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)

Although this step is optional, performing it will provide high availability to your target applications. In the event that an Agent fails, the Advisor would indicate that it has no information for any applications running on that system. As a result, target applications on the failing system would cease to receive new workload requests, in most cases, until the Agent is restarted. Automatically restarting the Agent on the same system would minimize this perceived outage. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information on defining ARM policies, see *z/OS MVS Setting Up a Sysplex*. In a sysplex subplexing environment, this step requires

additional actions. For information about the changes to this step, see “Step 5 (subplex): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1248.

The Agent registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBsysclone LBAGENT
TERMTYPE=ELEMTERM
```

where *sysclone* is a 1- or 2-character shorthand notation for the name of the MVS system. For example, if the *sysclone* value is 02, the resulting ELEMNAME value is EZB02LBAGENT. For a complete description of the SYSCLONE static system symbol, see *z/OS MVS Initialization and Tuning Reference*.

This indicates that if the Agent fails on this system, it should be restarted on this system only.

If the Advisor or its underlying system were to fail, the load balancer might continue to distribute workload requests according to the last set of information received from the Advisor, it might resort to preconfigured weights, or it might even stop distributing new work requests to the cluster. (The behavior depends upon the load balancer implementation; consult the load balancer documentation for details.) Therefore, it is important that the Advisor be restarted as soon as possible when a failure occurs, so that it can begin communicating with the load balancer and workload request distribution can resume normally. This restart capability should cover scenarios where the Advisor itself fails, and where the system that the Advisor is running on fails. The Advisor can run on any system in the sysplex and thus can be restarted on any system in the sysplex, as long as it is configured to use dynamic VIPAs and dynamic routing is in effect. The Advisor registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBLBADV
TERMTYPE=ALLTERM
```

This indicates that the Advisor should be restarted only on the same system in cases where the Advisor itself fails, and also restarted on a different system if the system fails. Using an ARM policy, you can indicate which systems are eligible for running the Advisor in the case of system failures. You also need to ensure that the specified backup systems have all the necessary configuration in place to enable the Advisor to be restarted there.

Some special considerations exist for scenarios where ARM is used and the TCP/IP stack address space terminates, as the result of a failure or of a planned operation. When the TCP/IP stack becomes unavailable, the Advisor also terminates, as it can no longer establish any TCP/IP communications. An ARM restart of the Advisor will likely fail, as the TCP/IP protocol stack will not be available when the restarts occur. You can handle these scenarios in the following ways:

- Planned outages of the TCP/IP stack

  Manually start the Advisor on another system, as soon as the Advisor terminates on the system where TCP/IP is stopped.
- Unplanned outages of the TCP/IP stack

  Ensure that an ARM policy (or other automation) is in place to quickly restart the TCP/IP stack on the same system. The Advisor also needs to be quickly restarted on the same system. This can be done by using an automation software package, or by using the TCP/IP profile AUTOLOG statement.

The AUTOLOG statement also has some important considerations:

- You should place the Advisor in the AUTOLOG statement list to ensure that it is started when TCP/IP is started on that system. However, you should specify the NOAUTOLOG parameter on the PORT reservation statements for the Advisor ports in the TCP/IP profile. This prevents TCP/IP from monitoring and attempting to restart the Advisor, as that could interfere with your automation logic or the ARM policy that you have put in place.
- The AUTOLOG function works best on systems where a single TCP/IP stack is active (INET environment). For CINET considerations, see "Step 5 (CINET): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)" on page 1245.

Guideline: Establish an ARM policy with TCP/IP at a lower level than the Advisor and Agent, so that TCP/IP is restarted before the Advisor and Agent are restarted. For more information, see *z/OS MVS Setting Up a Sysplex*.

Requirement: The Load Balancing Advisor and Agent do not run using a system key. Therefore, if you are using ARM registration, the started task IDs need to be permitted with UPDATE authority to the associated IXCARM.SYSTCPIP.EZBLBADV and IXCARM.SYSTCPIP.EZBLBAGENT profiles in the FACILITY class within the SAF product on your system. To enable the Advisor and Agent to register with ARM, use the following RACF commands to define the profiles and grant update access to the user IDs that are assigned to start the Advisor and Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBADV UACC(NONE)
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBAGENT UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBLBADV CLASS(FACILITY) ID(LBADV) ACCESS(UPDATE)
PERMIT IXCARM.SYSTCPIP.EZBLBAGENT CLASS(FACILITY) ID(LBAGENT) ACCESS(UPDATE)
SETROPTS RACLIST(FACILITY) REFRESH
```

Restrictions:

- If using AUTOLOG for the Agent, code the NOAUTOLOG parameter on the PORT reservation statement for the Agent port in the TCP/IP profile. This prevents the Agent from automatically being cancelled and restarted because the Agent does not listen on the port.
- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

Step 6: Configure and start syslogd

The Advisor and Agent write most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For the Advisor and Agent to be able to write their log messages and trace data to syslogd, syslogd must be properly configured and started before the Advisor and Agent are started.

Because it is likely that you will be running an Agent on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and Agent log output in separate files. For further information, see "Configuring the syslog daemon" on page 185. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see "Step 6 (subplex): Configure and start syslogd" on page 1249.

Tip: As more data is logged by the Advisor and Agent, performance of the Advisor and Agent can be adversely affected. The amount of data that is logged by the Advisor and Agent is determined by the debug_level statement. Backing the syslogd output file with a zSeries File System instead of an HFS file system can minimize performance impacts caused by logging.

Step 7: Configure one Advisor per sysplex

There can be only one Advisor active in the sysplex at any given time, unless you are using sysplex subplexing. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see "Step 7 (subplex): Configure one Advisor per sysplex" on page 1249.

The Advisor reads configuration data from one file, which might exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan on allowing the Advisor to move within the sysplex in the case of failure, you probably want the Advisor configuration file or data set to exist on shared DASD, to make it accessible to all systems in the sysplex if necessary. The Advisor configuration file is specified on the CONFIG DD statement in the Advisor start procedure. A sample start procedure is provided in EZBLBADV in SEZAINST.

The Advisor configuration file serves three basic purposes:

- Defines the listening sockets for the load balancers and Agents
- Provides an access control list for specifying which load balancers and Agents can connect to the Advisor
- Customizes some optional parameters

A sample Advisor configuration file is provided in EZBLBADC in SEZAINST.

Define listening sockets/ports (required)

The Advisor maintains at least two, and up to three, listening sockets/ports, one for Agents to connect to and up to two for load balancers to connect to. There are separate IPv4 and IPv6 listening sockets for load balancers. If your TCP/IP stack is not IPv6 enabled, you will not be able to use the IPv6 listening socket.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

Tip: Any statement containing the word *connection* refers to a local socket, and any statement containing the word *id* refers to a remote address and possibly a port.

Specify the local IPv4 address and port that the Advisor listens on for IPv4 load balancer connections with the lb_connection_v4 configuration statement. The default port for communications with load balancers is 3860.

The lb_connection_v6 statement does the equivalent for IPv6 that lb_connection_v4 does for IPv4. You can specify either or both of these statements. For CINET considerations regarding stack termination, see "Step 7 (CINET): Configure one Advisor per sysplex" on page 1245.

Guideline: To enable movement of the Advisor to another system in the sysplex or to another TCP/IP stack on the same system in the event of failure of the Advisor or its underlying system, use a dynamic VIPA (DVIPA) for the address specified on the lb_connection_v4 and lb_connection_v6 statements. Furthermore, make this DVIPA a unique application-instance DVIPA (defined through VIPARANGE) rather

than a multiple application-instance DVIPA (defined through VIPADEFINE), to enable movement of the Advisor if the Advisor itself failed. For CINET considerations with DVIPAs, see "Step 7 (CINET): Configure one Advisor per sysplex" on page 1245.

Restriction: If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

Specify the local port that the Advisor listens on for Agent connections with the agent_connection_port statement. If the Advisor's TCP/IP stack is IPv6 enabled, the Advisor opens a listening socket for Agents on the IPv6 unspecified address (::) on the port specified by this statement. This enables Agents to connect to the Advisor using either IPv4 or IPv6, and by using any address on the Advisor's system. If the TCP/IP stack is not IPv6 enabled, the Advisor opens a listening socket on the IPv4 unspecified address, 0.0.0.0. This enables Agents to connect to the Advisor using any IPv4 address on the Advisor's system.

Guideline: The port number used on the agent_connection_port statement should not be the same as the port used on the lb_connection_v4 statement or the lb_connection_v6 statement.

Rules:

- The port number specified on the agent_connection_port statement must match the port number specified on the Agents' advisor_id statement.
- If at least one IPv4 address is specified in the lb_id_list statement, the lb_connection_v4 statement must be specified. Similarly, if at least one IPv6 address is specified in the lb_id_list statement, the lb_connection_v6 statement must be specified.

Define the access control list

You can use one or both of the following methods for z/OS Load Balancing Advisor security:

- Access control list configuration statements

  The Advisor can control which load balancers and which Agents are allowed to connect to it by maintaining an access control list. The access control list specifies the remote IP address of the connecting load balancers and the remote IP address and port of the Agents that are allowed to connect.

  Specify the list of load balancers that are allowed to connect to the Advisor in the lb_id_list statement. Specify the list of Agents that are allowed to connect in the agent_id_list statement.

  Rules:

  – Specify only complete IP addresses in access control lists; subnetworks, IP prefixes, or other types of wildcards are not allowed.

  – The addresses in the agent_id_list statement must match the addresses in the host_connection statement of the Agents. For the purposes of high availability, the addresses specified in the agent_id_list statement of the Advisor and the host_connection statement of the Agents should be static or dynamic VIPAs, to tolerate individual link outages on the hosts.

  Restriction: There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

- Policies

You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS for connections to the Advisor, and load balancers are required to use TLS/SSL.

When you are using AT-TLS for all connections to the Advisor, the Advisor's lb_id_list and agent_id_list statements and the Agents' host_connection statements are optional. If you use these statements, the rules for access control list configuration statements still apply. AT-TLS is an alternative to using these statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the agent_id_list statement does not list that Agent.

Customizing optional statements

Customize the optional statements in the Advisor's configuration file.

The update_interval statement controls how often each Agent updates the Advisor with data, and depending upon load balancer implementation and configuration, can control how often load balancers are updated with information from the Advisor. The default value is 60 seconds. At each update interval, each Agent refreshes the Advisor with the status of each registered member for which the Agent is responsible. This information includes the status of the target application (active or not), whether it is an application member, the operator quiesce state of the member, and various weights that measure the target system and application's ability to handle additional workload requests. The lower the update interval, the more up-to-date the load balancer's data will be with respect to the target's availability and capability to handle additional workload requests. Of course, the lower the update interval, the higher the network traffic and CPU overhead is.

Depending upon load balancer implementation and configuration, the update_interval statement might also determine how often the load balancer is updated with data from the Advisor. If the load balancer supports the SASP push flag, and it has been specified in the load balancer, the Advisor sends data to the load balancer at least every update interval. Regardless of what the update interval is set to, if this push flag is supported and configured in the load balancer, certain events might cause the Advisor to update the load balancer with information before the update interval timer expires. These events include the starting or stopping of a target application, or the addition or deletion of a member's IP address on the Agent host.

Therefore, the update interval is a key factor in determining the latency period between when changes occur on the target application system, and when the load balancer is informed of them. Each Agent updates the Advisor with new information every update interval. The Advisor, in turn, updates the load balancer with changes in weights every update interval, if the load balancer supports the push flag. In addition, if the push flag is supported and configured by the load balancer, the Advisor updates the load balancer with any change in the target's availability status as soon as it discovers such a change from the Agent, instead of waiting for the update interval to expire. Therefore, when the load balancer supports and configures the push flag, the maximum amount of latency expected between a change in a member's weight and when the load balancer is informed of it is twice the update interval (that is, one update interval for the Agent to report it to the Advisor and one update interval for the Advisor to report it to the load balancer). However, on the average, it should take one update interval for a change in the target application weight to reach the load balancer.

Use the optional wlm statement to specify the default type of WLM recommendation to be used for all groups. There are two choices for this, the basewlm and serverwlm values. If you do not specify this statement, the default is basewlm. If you want a specific group of applications to use a type of WLM recommendation other than the default, you can override the default WLM recommendation type for that group on a port number basis using the port_list statement. The WLM recommendation is a key component used in determining the net weight assigned to a member.

The type of WLM recommendation represented by the basewlm value indicates the overall displaceable capacity (general, zAAP, and zIIP) of the system where the application represented by the member resides, relative to the other systems in the sysplex. This is referred to as a WLM system weight recommendation. Use the optional proctype parameter with basewlm to specify the proportion of general, zAAP, and zIIP CPU that is consumed by an application's workload.

The serverwlm value represents a different type of WLM recommendation, in that it reflects how well an individual server application is performing from a WLM perspective (based on the WLM policy). This type of recommendation is a server-specific recommendation and is referred to as a server-specific WLM recommendation. Server-specific WLM recommendations are composed of two key elements:

- The amount of displaceable capacity (general, zAAP, and zIIP) available on the target system based on the importance level of the application, and the proportion of general, zAAP, and zIIP CPU that is currently being consumed by the application's workload. For example, if the application is utilizing only general and zAAP CPU, the displaceable zIIP capacity is not considered.
- How well the application is performing compared to the WLM goals for that application workload.

In addition, WLM provides an interface that enables applications to report the following additional information:

- Abnormal transaction completion rate, or the rate of abnormal completions per 1000 total transactions
- Application health, a value in the range 0–100% (100% being optimal), representing the overall health of the application

Using this additional information, WLM might reduce the server-specific recommendation. For more information, see “Sysplex distributor” on page 469.

Evaluate whether you can use WLM server-specific distribution as an alternative to WLM system weight distribution for an application. In addition to the above reasons, server-specific distribution has the added advantage that processor proportions are automatically determined and dynamically updated by WLM, based on the actual CPU usage by the application. If you need to use system weight distribution, to determine the processor proportions to configure, study the workload usage of assist processors by analyzing SMF records, using performance monitors reports such as RMF, and so on.

System members (port and protocol are zero) always use WLM system weight recommendations and cannot be configured to consider zAAP and zIIP CPU, because the type of workload is unknown. This is true even if proctype is coded on the wlm statement.

Application members can use either type.

It is important that you choose the type of WLM recommendation that is best suited to each group of applications. Some types of applications are better suited to using WLM system weight recommendations rather than server-specific WLM recommendations. For most applications, server-specific WLM recommendations provide a more accurate way to distribute workload to their servers. However, when a server acts as an access point to applications that run in other address spaces (and therefore in a different service class), WLM system weight recommendations might be the preferred distribution method; if expected usage of general, zAAP, and zIIP processors is known, this recommendation can be further refined by using the proctype parameter. The sysplex distributor function can also use server-specific WLM recommendations or WLM system weight recommendations. For examples of some applications that might be better represented by WLM system weight recommendations, see "Sysplex distributor" on page 469.

The optional port_list statement enables you to override or specify parameters for members on a port number basis. The wlm parameter of the port_list statement enables you to override the value defined (or specified by default) on the wlm statement, for all members that use the port number specified. The actual WLM recommendation type used is still dependent upon the value specified and the z/OS level of the Agents owning the members of the group.

When selecting the type of WLM recommendation to use for a given group, it is important to consider the following requirements:

- All members in a group must specify the same type of WLM recommendation (using the wlm or port_list statement).
- To use server-specific recommendations, no Agent reporting on behalf of a member of a group can be at a release level prior to z/OS V1R7.

For any groups where these requirements are not met, the Advisor uses WLM system weight recommendations, and a warning message is written to syslogd. The main rationale behind this is that WLM system weight recommendations and server-specific WLM recommendations cannot be directly compared to one another.

The Advisor can detect dynamically whether or not these requirements are being met. For example, if all owning Agents of a group, except one, support server-specific WLM recommendations, and the application on that one system is brought down, the WLM recommendation type would change dynamically from WLM system weight recommendations to server-specific WLM recommendations, provided the Advisor was configured to request server-specific WLM recommendations for that group. Similarly, if that same application is brought back up, the WLM recommendation type would dynamically switch back to WLM system weight recommendations. A similar circumstance would arise if the member owned by the Agent that does not support server-specific WLM recommendations was quiesced by the z/OS operator or the load balancer administrator.

The optional debug_level statement determines how much trace data is captured in the Advisor's log file.

Restriction: In most cases, you should not customize the debug_level statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the Advisor configuration file statements, see *z/OS Communications Server: IP Configuration Reference*.

Step 8: Configure one Agent per z/OS system in the sysplex

There can be only one Agent active per z/OS system in the sysplex at any point in time, unless sysplex subplexing is used. When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see "Step 8 (subplex): Configure one Agent per z/OS system in the sysplex" on page 1250.

The Agent reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. The Agent configuration file is specified on the CONFIG DD statement in the Agent start procedure. A sample start procedure is provided in EZBLBAGE in SEZAINST.

The Agent configuration file serves three basic purposes:

- Defines the IP address and port that the Agent binds to for communication with the Advisor
- Identifies the location (IP address and port) of the Advisor
- Customizes optional parameters

A sample Agent configuration file is provided in EZBLBAGC in SEZAINST.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

Tip: Any statement containing the word *connection* refers to a local socket, and any statement containing the word *id* refers to a remote address and possibly port.

Defining the IP address and port to bind to for communications with the Advisor

Specify the local IP address and port that the Agent binds to for communications with the Advisor on the host_connection statement. This is used as part of the Advisor's access control enforcement.

Rules:

- The IP address on the host_connection statement can be an IPv6 address, if the Agent's system is running an IPv6-enabled TCP/IP stack and the Advisor has an IPv6-enabled TCP/IP stack available.
- If an IPv4 address is specified on the host_connection statement, an IPv4 address must be specified on the advisor_id statement. Similarly, if an IPv6 address is specified on the host_connection statement, an IPv6 address must be specified on the advisor_id statement.

Guidelines:

- For simplicity and consistency, you might want to specify the same port on the host_connection statement for each Agent, and reserve the same port for the Agent on each TCP/IP stack that an Agent will run on. For more information about port reservation, see "Step 9: Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)" on page 1235.
- The address in the host_connection statement (and therefore, also in the Advisor's agent_id_list statement) should be a static VIPA. For CINET

considerations regarding the host_connection statement, see “Step 8 (CINET): Configure one Agent per z/OS system in the sysplex” on page 1246.

The Agent host_connection statement and the Advisor agent_id_list statement are optional if AT-TLS is used for all Agent-Advisor connections. If you specify these statements, the rules and guidelines previously stated still apply. AT-TLS is an alternative to using these statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the agent_id_list statement does not list that Agent.

Also see “Step 7 (CINET): Configure one Advisor per sysplex” on page 1245 for CINET considerations regarding unique application-instance DVIPAs and stack affinity.

Restriction: If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.

Identifying the location of the Advisor (required)

Specify the location of the Advisor on the advisor_id statement. This statement contains an IP address and port that the Advisor uses to listen for connections from Agents in the sysplex.

Guideline: Use a dynamic VIPA for this address, to enable the Advisor to be moved within the sysplex in the event of a failure of the Advisor or the Advisor's underlying system.

Rules:

- The port specified on the advisor_id statement must match the port specified on the Advisor's agent_connection_port statement.
- If an IPv4 address is specified on the advisor_id statement, an IPv4 address must be specified on the host_connection statement. Similarly, if an IPv6 address is specified on the advisor_id statement, an IPv6 address must be specified on the host_connection statement.

Customizing optional statements

Similar to the Advisor, the optional debug_level statement determines how much trace data is captured in the Agent's log file.

Restriction: In most cases, you should not customize this statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the Agent configuration file statements, see *z/OS Communications Server: IP Configuration Reference*.

Step 9: Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)

When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see "Step 9 (subplex): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)" on page 1250.

There are several things to do to customize the TCP/IP profile to accommodate the Advisor and Agents.

- In the appropriate TCP/IP profiles that they will use, including the TCP/IP stacks that they could potentially move to, reserve the ports that the Advisor and Agents will use. All ports for the Advisor and Agent utilize the TCP protocol, and thus should be reserved for TCP. The Advisor has at least two ports, and potentially three ports, to reserve, including the ports specified on the following statements:
  - lb_connection_v4
  - lb_connection_v6
  - agent_connection_port

  For CINET considerations regarding the lb_connection_v4 and lb_connection_v6 statements, see "Step 9 (CINET): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)" on page 1247.
- If you use dynamic VIPAs for the Advisor as recommended, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions would include VIPADEFINE with MOVEABLE IMMEDIATE, or VIPARANGE with MOVEABLE NONDISRUPTIVE. For more specific information, see "Using dynamic VIPAs" on page 359.

  Restriction: Do not mix sysplex distributor functions with these DVIPAs.
- If you are currently using the SHAREPORT or SHAREPORTWLM parameters on the TCP/IP profile PORT statement to enable multiple TCP applications to share the same port, some additional considerations might apply to your configuration. For example, if the TCP applications sharing the same port are also members of groups that are being reported to external load balancers with SASP, it is important to ensure that consistent criteria are used by the various load balancing components.

  When using the z/OS Load Balancing Advisor, all instances of a TCP application sharing the same port on a target system are reported to external load balancers using a single member entry, and therefore, a single recommendation. This recommendation reflects the average net weight calculated for all the servers sharing the same port on a target system, and is based on the type of WLM recommendation configured on the Advisor. When the TCP connection requests reach a target TCP/IP stack and multiple applications are sharing the same port, the connections are then load balanced by TCP/IP across the multiple application server instances. How this load balancing is performed depends on whether the SHAREPORT or SHAREPORTWLM parameter is specified on the PORT statement. For more details on the PORT statement, see *z/OS Communications Server: IP Configuration Reference*.

  Guideline: If server-specific WLM recommendations are configured within the Advisor for a given group that contains servers that share the same port on a given system or TCP/IP stack, the SHAREPORTWLM parameter should also be specified on the PORT statement in the TCP/IP profile for these servers. This enables both the external load balancers and the internal TCP/IP load balancer to operate with the same type of recommendations when load balancing work

requests to these servers. Similarly, if WLM system weight recommendations were configured in the Advisor for a group, the SHAREPORT parameter would probably be more appropriate.

Enabling TLS/SSL for z/OS Load Balancing Advisor (optional)

For AT-TLS, the following customization tasks are required before starting the TCP/IP stacks and the Advisor and Agent applications:

- Enable AT-TLS in the TCP/IP stack.

  Specify the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. For additional information about AT-TLS, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193. For information about the TCPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.

- Set up authorization for the **pasearch** command, if the command will not be issued from a superuser.

  Create a SERVAUTH profile of EZB.PAGENT.*sysname*.*image*.*ptype*, where the *ptype* value is set to TTLS or to a wildcard value. For more information, see "Steps for configuring the Policy Agent" on page 848 and *z/OS Security Server RACF Security Administrator's Guide*.

- Enable AT-TLS configuration for the Policy Agent.

  Specify the CommonTTLSConfig and TTLSConfig statements in the Policy Agent configuration file for each stack. On the TTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for the server. For additional information about the CommonTTLSConfig and TTLSConfig statements, see *z/OS Communications Server: IP Configuration Reference*.

- Define AT-TLS policies in new or existing Policy Agent configuration files.

  Specify the AT-TLS policies in the configuration files that are identified with the CommonTTLSConfig and TTLSConfig statements. Ensure that the Load Balancing Advisor policy definitions are defined on all systems in the sysplex on which the Advisor can run.

  The Load Balancing Advisor is a server application. For general information about setting up AT-TLS for a server, see Table 54 on page 1199.

  Following is an example of the TTLSConfig policy file statements in the path file for the load balancer connections to the Advisor. Port 3860 is the default port.

```
TTLSRule                LBAdvisorLBRule
{
   LocalPortRange            3860
   Direction                 Inbound
   TTLSGroupActionRef        LBAdvisorLBGroup
   TTLSEnvironmentActionRef  LBAdvisorLBEnvironment
}
TTLSGroupAction          LBAdvisorLBGroup
{
   TTLSEnabled               On
}
TTLSEnvironmentAction    LBAdvisorLBEnvironment
{
   TTLSKeyRingParms
   {
      Keyring                server_key_ring
   }
   TTLSEnvironmentAdvancedParms
   {
      # TTLS will verify a user ID is associated with certificate
      ClientAuthType         SAFCheck
      ApplicationControlled  On
   }
```

```
   HandshakeRole             ServerWithClientAuth
   TTLSCipherParmsRef        RequireEncryption
   Trace                     7
}
```

In this example, all external load balancers must use TLS/SSL and supply a client certificate that will be validated in the key ring and must be associated with a user ID on the SAF-compliant security product on the local z/OS system. This type of policy allows additional finer-grain SAF checks using optional SERVAUTH profiles. You can use other, less restrictive, policies; however, if you use less restrictive policies, the Advisor, Agent, and ADNR require that you specify the configuration parameters for those connections (lb_id_list or agent_id_list statements in the Advisor configuration file, host_connection statement in the Agent configuration file, and host_connection_addr statement in the ADNR configuration file).

Following is an example of the TTLSConfig policy file statements in the path file for the Agent connections to the Advisor. Port 8100 is the port used in the sample Advisor configuration file:

```
TTLSRule                  LBAdvisorAgentRule
{
   LocalPortRange             8100
   Direction                  Inbound
   TTLSGroupActionRef         LBAdvisorAgentGroup
   TTLSEnvironmentActionRef   LBAdvisorAgentEnvironment
}
TTLSGroupAction           LBAdvisorAgentGroup
{
   TTLSEnabled                On
}
TTLSEnvironmentAction     LBAdvisorAgentEnvironment
   {
   TTLSKeyRingParms
   {
      Keyring                 server_key_ring
   }
   TTLSEnvironmentAdvancedParms
   {
      # TTLS will verify a user ID is associated with certificate
      ClientAuthType          SAFCheck
      ApplicationControlled   On
   }
   HandshakeRole              ServerWithClientAuth
   TTLSCipherParmsRef         RequireEncryption
   Trace                      7
}

# Set of TLS Ciphers with Encryption
TTLSCipherParms RequireEncryption
{
   V3CipherSuites         TLS_RSA_WITH_RC4_128_MD5
   V3CipherSuites         TLS_RSA_WITH_RC4_128_SHA
   V3CipherSuites         TLS_RSA_WITH_DES_CBC_SHA
   V3CipherSuites         TLS_RSA_WITH_3DES_EDE_CBC_SHA
}
```

The Load Balancing Agent is a client application. For general information about setting up AT-TLS for a client, see Table 55 on page 1201.

You must configure the policy on the TCP/IP stack where the Agents will run with the same SSL protocol, key ring, and cipher suite (if encrypting data) for which the Advisor is configured.

Following is an example of the TTLSConfig policy file statements for a Load Balancing Agent. On the TTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for the client. For additional

information about the TTLSConfig statement, see *z/OS Communications Server: IP Configuration Reference*. Port 8100 is the port used in the sample Agent configuration file.

```
TTLSRule                      LBAgentRule
{
   RemotePortRange               8100
   Direction                     Outbound
   TTLSGroupActionRef            LBAGroup
   TTLSEnvironmentActionRef      LBAgentEnvironment
}
TTLSGroupAction               LBAGroup
{
   TTLSEnabled                   On
}
TTLSEnvironmentAction         LBAgentEnvironment
{
   TTLSKeyRingParms
   {
      Keyring                   client_key_ring
   }
   HandshakeRole                 CLIENT
   TTLSCipherParmsRef            RequireEncryption
   Trace                         7
}

# Set of TLS Ciphers with Encryption
TTLSCipherParms RequireEncryption
{
   V3CipherSuites         TLS_RSA_WITH_RC4_128_MD5
   V3CipherSuites         TLS_RSA_WITH_RC4_128_SHA
   V3CipherSuites         TLS_RSA_WITH_DES_CBC_SHA
   V3CipherSuites         TLS_RSA_WITH_3DES_EDE_CBC_SHA
}
```

For additional information, see:

- Chapter 16, "Policy-based networking," on page 829.
- Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193. Table 54 on page 1199 is for the Advisor, and Table 55 on page 1201 is for the Agent and for load balancers.
- AT-TLS policy statements in *z/OS Communications Server: IP Configuration Reference*
- CommonTTLSConfig and TTLSConfig statements in *z/OS Communications Server: IP Configuration Reference*.
- Online help for the IBM Configuration Assistant for z/OS Communications Server

- Create z/OS server (Advisor) and client (Agent, ADNR, external load balancer) key rings and necessary certificate authority certificates.

  The server key ring needs to contain a server certificate, and any certificates that are used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate that is used to sign the server certificates.

  For a TLS/SSL primer and some step-by step examples, see Appendix B, "TLS/SSL security," on page 1461. For more information about managing key rings and certificates with RACF and the RACDCERT command, see *z/OS Security Server RACF Security Administrator's Guide*. For detailed information about managing key rings and certificates with gskkyman, see *z/OS Cryptographic Services System SSL Programming*.
- Send the external load balancer's certificate to the z/OS host.

- Associate each user ID (for the Advisor, Agents, ADNRs, and external load balancers) with a certificate.

  Use the RACDCERT ADDRING command to define a key ring in RACF and to associate it with your application's user ID. Use the RACDCERT CONNECT command to connect certificates to the key ring. For detailed information about setting up your certificate environment, see *z/OS Security Server RACF Security Administrator's Guide*.
- Create client side certificates for the external load balancers. See the load balancer documentation for instructions.
- Define client user IDs on the TCP/IP stacks on which the Advisor will run by issuing security product commands to establish authorization for the user IDs.

  You can configure the Advisor's clients (Agents, ADNR, and external load balancers) to present security credentials, including a user ID. If you configure this, you must set up the security manager on the Advisor system to accept these credentials.

  Using a security product like RACF, perform the following steps to control access to the Load Balancing Advisor, Agents, and ADNR.

  1. Use the following commands to ensure that the SERVAUTH class is active and RACLISTed, and that RACLIST processing is enabled:

     ```
     SETROPTS CLASSACT(SERVAUTH)
     SETROPTS RACLIST (SERVAUTH)
     ```

  2. Use the following commands to define the following SERVAUTH class profiles on each system on which the Advisor might run.

     ```
     RDEFINE SERVAUTH EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname UACC(NONE)
     RDEFINE SERVAUTH EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname UACC(NONE)
     ```

     where *sysname* is the MVS system name or a wildcard (*) and *tcpsysplexgroupname* is the TCP/IP sysplex group name. If you are not using subplexing, use the default subplex identifier EZBTCPCS or a wildcard (*). For example, on system MVSSYS using the default subplex, the profile name is EZB.LBA.LBACCESS.MVSSYS.EZBTCPCS.
  3. Use the following commands to grant access to the SERVAUTH class for the user IDs associated with the Agents, ADNR, and the external load balancers on each system on which the Advisor might run:

     ```
     PERMIT   EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname -
        CLASS(SERVAUTH) ACCESS(READ) ID(userid)
     PERMIT   EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname -
        CLASS(SERVAUTH) ACCESS(READ) ID(userid)
     ```

  4. Use the following command to refresh the SERVAUTH class:

     ```
     SETROPTS RACLIST(SERVAUTH) REFRESH
     ```

  For specific instructions, see the EZARACF sample in SEZAINST.

  Requirements:

  – The AT-TLS policies and SERVAUTH profiles must be coordinated to provide the appropriate level of security. For example:

    - If a connection is presented to the Advisor and the AT-TLS check indicates that this is not a secure connection, then no subsequent SAF check is performed but an IP address ACL check (using the statements in the Load Balancer Advisor configuration files) is performed. If the IP address ACL check is successful, the connection is accepted.
    - If you always want a SAF level check to be performed, then ensure that the AT-TLS policy requires client certificates that are associated with user IDs defined on the local SAF-compliant security product. Also ensure that the SAF profile is defined and the correct user IDs are permitted READ access

to the profile. If a secure connection is presented to the Advisor, and the SAF profile exists but the user ID is not authorized to the profile, then the connection will fail and no ACL check will be performed.

- If the SERVAUTH profile is not defined, then the Load Balancer Advisor performs the IP Address (and port where appropriate) access control list checks before permitting a connection to the Load Balancer Advisor.

– If the Advisor might run on more than one system, perform set up on all those systems or use a wildcard (*).

For additional information, see *z/OS Security Server RACF Security Administrator's Guide*.

Step 10: Start the TCP/IP stacks that the Advisor and the Agents will use

The TCP/IP stacks that the Advisor will use must be started prior to starting the Advisor. An Agent can be started before the TCP/IP stack it uses is started. If the TCP/IP stack that an Agent uses terminates, the Agent remains active and reestablishes communication with the TCP/IP stack once it becomes active again. For CINET considerations regarding Agent recovery after stack failure, see "Step 10 (CINET): Start the TCP/IP stacks that the Advisor and the Agents will use" on page 1247.

Step 11: Start the target applications that will be the targets of load balancing

No modifications are necessary to these applications, their configurations, or start procedures, unless the load balancer is using dispatch mode for packet forwarding. For more information on dispatch mode, see "Step 15: Configure the external load balancers" on page 1241.

Step 12: Customize WLM policies for the Advisor and Agents (optional)

It is important that the Advisor and Agents receive an adequate amount of system resources to properly balance workloads. Part of this task involves making the Advisor and Agent run non-swappable. In addition, WLM can control the amount of system resources allocated to the Advisor and Agents.

Guideline: The Advisor and Agents should be assigned to the WLM SYSSTC service class to receive the proper dispatching priority. For more information on categorizing work into service classes, see *z/OS MVS Planning: Workload Management*.

Step 13: Start one Agent on each sysplex system you want to participate in this method of workload balancing

It does not matter whether the Agents are started before the Advisor, or whether the Advisor is started before the Agents. If the Advisor is started after the Agents are started, the Agent periodically attempts to connect to the Advisor. Only one Agent can be started per z/OS system. Agents must be started from a start procedure as a started program (EXEC PGM=). They cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Agents run non-swappable. You should not override this entry to make the Agents run swappable.

When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Step 13 (subplex): Start one Agent on each sysplex system you want to participate in this method of workload balancing” on page 1251.

Step 14: Start the one instance of the Advisor in the sysplex

As Agents connect to the Advisor, MVS console messages appear on the Advisor's MVS console and on the Agents' MVS consoles. Verify that each Agent you expect to connect to the Advisor has connected. You can also use the NETSTAT,CONN command on the Advisor's TCP/IP stack to see which Agents are currently connected. The Advisor must be started from a start procedure as a started program (EXEC PGM=). It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Advisor run non-swappable. You should not override this entry to make the Advisor run swappable.

When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Step 14 (subplex): Start the one instance of the Advisor in the sysplex” on page 1251.

Step 15: Configure the external load balancers

Configure the load balancers with the location (IP address and port) of the Advisor. For maximum availability, this address should be defined as a DVIPA.

In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see “Step 15 (subplex): Configure the external load balancers” on page 1251.

If you are using TLS/SSL, the load balancers are client applications in a z/OS Load Balancing Advisor environment. You must configure the load balancers with the same TLS/SSL protocol and cipher suite (if encrypting data) with which the Advisor is configured. Client certificates should be configured on the load balancer, and also defined in the z/OS SAF-compliant security product if that level of authentication is required. See the load balancer documentation for instructions.

Restrictions:

- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6–enabled TCP/IP stacks.
- There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

You might be able to customize features of the load balancer's communication with the Advisor. The SASP protocol defines two features that the load balancer implementation might or might not allow to be configured. One determines whether the load balancer polls the Advisor for updated data, or whether updated data is pushed to the load balancer. The other determines whether only members that have updated data should be sent to the load balancer, or whether all members should be sent to the load balancer regardless of whether their data has changed or not. To determine whether these features can be customized, and how to perform the customization if available, consult your load balancer's documentation. If the load balancer is capable and configured to request that the Advisor push updated information to the load balancer, the Advisor will update the load balancer at least every update interval. If the load balancer is capable and configured to poll the Advisor for updated information, the Advisor will

recommend to the load balancer that it poll every update interval. However, the load balancer can choose to disregard this guideline. Consult the load balancer documentation for the expected behavior in these circumstances.

You might want to consider having redundant load balancers configured alike for availability reasons. If so, you need to be aware of the load balancer's unique load balancer identifier (LB UID), sometimes referred to as the UID or UUID, which uniquely identifies a load balancer. Duplicate LB UIDs are not allowed and connection attempts to the Advisor from a load balancer using the same LB UID as an existing connection will force the existing connection to be broken and replaced by the new connection. Redundantly configured load balancers either need to have unique LB UIDs, if you want them to serve as hot standbys that are connected simultaneously along with the load balancer they are backing up, or if they are configured with the same LB UID, they must remain unconnected from the Advisor until the original load balancer fails.

Some load balancers might be capable of using either dispatch or directed mode when forwarding packets to their destinations. External load balancers typically use a cluster IP address to represent the set of applications being load balanced. Client applications use this cluster IP address as the destination IP address for their requests. When a load balancer uses dispatch mode, the destination IP addresses for incoming IP packets is not changed. Instead, the load balancer forwards the packet to a target z/OS system by using the MAC address of a network adapter on that system. The receiving z/OS system inspects the destination IP address of the packet, and if it matches one of the IP addresses in its HOME list, accepts the packet. As a result, with dispatch mode, all target z/OS systems must have the load balancer's cluster IP address defined in their HOME list. However, it is important that these addresses are not advertised externally through dynamic routing protocols. One way to accomplish this is by defining these IP addresses as loopback addresses on z/OS.

With directed mode, the load balancer converts the destination IP address (that is, the cluster IP address) to an IP address owned by the target z/OS system, using technologies such as network address translation (NAT). When IP packets for these connections are sent back to clients, the load balancer converts the source IP address (that is, the target z/OS system's IP address) back to the cluster IP address that the application had used on its request.

While dispatch mode eliminates the need for performing NAT, it does have some special considerations. For example, in Figure 125 on page 1267, both SYSA and SYSB have the same server, FTPD, bound to the same port number using INADDR_ANY. The packet will have the cluster IP address (both SYSA and SYSB are in the same cluster), so the load balancer will use the MAC address to decide to send the packet to SYSA or SYSB, and TCP/IP will then route the packet to the server.

Restrictions: When using dispatch mode, for the load balancer to function correctly, there are the following limitations:

- An OSA can be shared among LPARs only if Virtual MAC (VMAC) addressing is configured for each TCP/IP target stack sharing the OSA.
- All target applications must bind to the IP address specified by INADDR_ANY or in6addr_any, and the cluster IP address must be defined to the stack; however, this must be done so that the address is not advertised (as in a loopback address).

If these restrictions are not met, load balancing will not be optimal because some servers will not get work routed to them.

With directed mode, either the destination IP address (server NAT) is modified in the packet itself, or both the destination and source IP addresses (server NAT and client NAT) are modified in the packet. The packet must return through the same load balancer that will recognize the changes and do the reverse mapping, so a packet can flow from the original destination to the original source.

Configure each load balancer with the members that represent the individual target application instances, or system members that generically represent a system in the sysplex, or both. Members that can share the same type of workload are defined under the same group. For example, TN3270E Telnet servers are defined under one group, and HTTP servers in another. Application members are defined by specifying an IP address, a nonzero port, and a nonzero protocol. System members are defined by specifying an IP address, and specifying the port and protocol to be zero. Members that have only a port of zero or only a protocol of zero (that is, one but not both are zero) are not considered valid members and will not receive any data from the Advisor. The IP addresses of the members must represent valid, reachable addresses within the sysplex that are unique to a specific sysplex system. This excludes such addresses as the loopback addresses, and other non-advertised addresses.

Tip: The Advisor does not check for improperly configured members. After the entire z/OS Load Balancing Advisor system is operational, display all members registered by each load balancer and verify each member you expect to be available is flagged as available. Screen any unavailable members for coding errors in the member, such as incorrect IP addresses, ports, or protocols.

Guideline: For availability reasons, the IP addresses configured for each member should be VIPA addresses (static or dynamic). If the IP address of a physical interface fails and a member specifies that IP address, the Advisor still indicates that the member is available, as alternate routing paths to that member might exist. However, if no alternate routing paths exist, workload requests cannot be delivered to the target system. By using static or dynamic VIPAs in members, the chance of an alternate route being available when a physical interface fails is greatly increased, as long as at least one physical interface is still available.

Restrictions:

- All IP addresses configured in members belonging to the same group must exist within the same sysplex.
- All members belonging to the same group must be of the same type. That is, all members must be application members or all must be system members.
- Certain classes of IP addresses must not be coded for members in the load balancer. This includes the following classes of addresses:
  - Distributed DVIPAs (the address specified on a VIPADISTRIBUTE statement). Defining members with these addresses would combine two load balancing methodologies for the same workload, wasting system resources.
  - Deprecated IPv6 addresses. These are flagged as such in a NETSTAT HOME display. It is probably safest to not code any autoconfigured IPv6 addresses within members.
  - Addresses that are not unique within the sysplex.
  - Addresses that are not reachable from the load balancer, including:
    - Loopback addresses.

- Unavailable IPv6 addresses. These might be marked as unavailable if duplicate address detection is in progress, has failed, or the interface ID is unknown. These addresses are displayed in a NETSTAT HOME display, including the reason they are marked unavailable.

Step 16: Start the load balancers

When a load balancer has connected, messages appear on the Advisor's MVS console. You can also use the Advisor's MODIFY *procname*,DISPLAY,LB command to see which load balancers are connected to the Advisor. For details on the Advisor's MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

Restriction: There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

Step 17: Verify that the Advisor system is functioning correctly (optional)

View the MVS console of the Advisor and Agent systems after they are started to verify that the applications started correctly and are still running. If there are any failure messages, see the appropriate message description for the proper corrective action. View the syslogd files of the Advisor and Agent systems to see whether any error or warning messages were issued.

Use the following commands to verify that the Advisor system is functioning correctly:

- Verify that the Advisor is started and connected to the expected load balancers by issuing the Advisor's MODIFY *procname*,DISPLAY,LB command. Verify that each load balancer is displayed. Take note of the LB INDEX displayed for each load balancer. This identifier is needed to display details of the load balancer, including its registered groups and members.

  Tip: Individual load balancers are identified in displays by their load balancer index (LB Index), which is generated by the Advisor when the load balancer first connects. To display the details of a particular load balancer, first obtain the LB Index by displaying the list of all load balancers using the Advisor's MODIFY *procname*,DISPLAY,LB command. When you have the LB Index, display the details of a particular load balancer using the appropriate LB Index on the INDEX parameter as follows:

  ```
  MODIFY procname,DISPLAY,LB,INDEX=lb_index
  ```

- Verify that each load balancer configured and registered the proper groups and members with the Advisor by issuing the following command:

  ```
  MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
  ```

  This display should show all groups and members defined to the load balancer.

- Verify that each Agent has started properly and is communicating with the Advisor. On each Agent, issue the following command:

  ```
  MODIFY procname,DISPLAY,MEMBERS
  ```

  Each member that has an IP address owned by this Agent should appear in the display.

- Verify that the target applications that you want to load balance to are actually available for load balancing. On the Advisor, for each load balancer connected to the Advisor, issue the following command:

  ```
  MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
  ```

Check for the AVAIL flag for each member in the display. The flag is either YES, meaning the member is available for load balancing, or NO, meaning it is not available for load balancing. To be available for load balancing, all of the following must be true:

- The Agent owning the member's IP address must be active and communicating with the Advisor.
- The application must be active, if the member represents an application member, and must be on a TCP/IP stack that has not had eventual action message EZD1973E issued by sysplex problem detection and recovery. For more information, see "Problem detection" on page 450.
- The member must not be quiesced by the Agent operator or the load balancer. The z/OS Agent operator is able to quiesce any member that is owned by that Agent. Also, depending upon load balancer implementation, it might be possible for the load balancer administrator to quiesce individual members.

If one of the above conditions is false, correct the situation and repeat the display command until you are satisfied that all members that you intend to have available for load balancing are displayed as being available.

- Verify that the Advisor system is functioning correctly when using AT-TLS:
  - Use the **pasearch** command from the z/OS UNIX shell to query information from the Policy Agent. For example, **pasearch -t -r** displays active AT-TLS rule details. For more information about displaying policy based networking information, see *z/OS Communications Server: IP System Administrator's Commands*.
  - Use the Netstat TTLS/-x command to display z/OS Load Balancing Advisor, Agent, and ADNR AT-TLS policies. For more information about the Netstat TTLS/-x report, see *z/OS Communications Server: IP System Administrator's Commands*.

Configuring the z/OS Load Balancing Advisor in a multiple TCP/IP stack environment

To configure the z/OS Load Balancing Advisor in a multiple TCP/IP stack (CINET) environment, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222. This topic provides special CINET considerations that are referenced from those steps. Subtopics are provided only for steps that have special CINET considerations.

Step 5 (CINET): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)

If you are considering using the AUTOLOG statement to restart the Advisor in a CINET environment, and you placed the Advisor in the AUTOLOG statement list of each TCP/IP stack, each stack attempts to start the Advisor during initialization. Only the first one will succeed, as only a single instance can be active at any time within a system or within a sysplex.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 7 (CINET): Configure one Advisor per sysplex

You must define listening sockets and ports, as described in "Define listening sockets/ports (required)" on page 1228.

Rule: If you use a unique application-instance DVIPA for the Advisor in a CINET environment, all TCP/IP stacks on that system must code the VIPARANGE statement for that DVIPA. Alternatively, and less desirably, you can establish stack affinity to one of the TCP/IP stacks that are coded with the VIPARANGE statement for that DVIPA, if you do not have VIPARANGE coded for that DVIPA on all of the TCP/IP stacks on that system. This alternative, of course, does not enable the Advisor to be moved to another TCP/IP stack in the event of failure, unless you are able to restart the Advisor with a different start procedure that can establish stack affinity to another TCP/IP stack that has the DVIPA defined in a VIPARANGE statement. For information on the use of the _BPXK_SETIBMOPT_TRANSPORT environment variable that can be used to establish stack affinity, see "Generic server versus server with affinity for a specific transport provider" on page 51.

The lb_connection_v6 statement does for IPv6 what the lb_connection_v4 statement does for IPv4. You can specify either or both of these statements. If you run the Advisor on a CINET system, be aware that the address or addresses you choose for these statements tie the Advisor to the stack owning those addresses. Consequently, termination of that stack results in termination of the Advisor.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 8 (CINET): Configure one Agent per z/OS system in the sysplex

If the system where the Agent is running is a CINET system, the address in the host_connection statement (and therefore, also in the Advisor's agent_id_list statement) should be a dynamic VIPA (DVIPA) to facilitate movement of the Agent to another TCP/IP stack on that system.

Rule: If you use a unique application-instance DVIPA (coded with VIPARANGE) for the Agent in a CINET environment, all TCP/IP stacks on that system must code the VIPARANGE statement for that DVIPA. When configured in this manner, if the TCP/IP stack that currently owns the DVIPA fails, the Agent remains up and automatically attempts to bind again to the DVIPA. The next available default TCP/IP stack becomes the new owner of the DVIPA. (If this is a sysplex subplexing environment, all TCP/IP stacks on that system that are within the same subplex as the Agent must code the same VIPARANGE statement for that DVIPA. This allows the Agent to reestablish connectivity with the Advisor through another stack in the same subplex on that system.) Alternatively, and less desirably (see following restriction), you can establish stack affinity to one of the TCP/IP stacks that are coded with the VIPARANGE statement for that DVIPA, if you do not have VIPARANGE coded for that DVIPA on all of the TCP/IP stacks on that system. Of course, this does not enable the Agent to be automatically moved to another TCP/IP stack in the event of failure. To recover the Agent in this type of configuration, manual intervention (or automation) is required. Because the Agent remains active if its TCP/IP stack fails, you must manually terminate the Agent. Then you must restart the Agent with a different start procedure that can establish stack affinity to another available TCP/IP stack. For information on the use of the _BPXK_SETIBMOPT_TRANSPORT environment variable that can be used to establish stack affinity, see "Generic server versus server with affinity for a specific transport provider" on page 51.

Restriction: When running in a CINET environment, establishing stack affinity between the Agent and one of the TCP/IP stacks on that system enables only

resources on that TCP/IP stack to participate in workload balancing. The Agent running on that system is not aware of resources on the other TCP/IP stacks on that system. If you want to enable resources on all TCP/IP stacks in a CINET environment to participate in workload balancing, do not establish stack affinity with the Agent.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 9 (CINET): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)

The Advisor can use multiple TCP/IP stacks in a CINET environment. The addresses specified in the lb_connection_v4 and lb_connection_v6 statements can belong to different TCP/IP stacks. Moreover, because the socket that listens for Agent connections uses the IPv4 or IPv6 unspecified address, the TCP/IP stack or stacks that incoming Agent connections utilize depends upon the IP addresses specified in the Agents' agent_id_list statements. To simplify your configuration and to make Advisor outages that are the result of a TCP/IP stack failure or termination more predictable and recoverable, all incoming connections to the Advisor should use a single TCP/IP stack. Therefore, the addresses you specify in the lb_connection_v4 and lb_connection_v6 statements should belong to the same TCP/IP stack, and you should configure all load balancers and Agents to use these same IP addresses when connecting to the Advisor. The addresses you specify should be dynamic VIPAs to enable the movement of the Advisor in case of failure. This implies that these dynamic VIPAs should be defined in the TCP/IP profiles of all the stacks using a VIPARANGE statement. If the Advisor is restarted as a result of failure in a given TCP/IP stack, the dynamic VIPAs are then activated on another TCP/IP stack in that system. If you decide to use the IPv4 or IPv6 unspecified addresses for the lb_connection_v4 and lb_connection_v6 statements, you should use the BIND parameter on the PORT reservation statement to bind these sockets to the dynamic VIPA on the one TCP/IP stack you have decided to use.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 10 (CINET): Start the TCP/IP stacks that the Advisor and the Agents will use

In a CINET environment, certain configurations might necessitate manual intervention for recovery if the Agent's TCP/IP stack fails. For more information, see the rule in "Step 8 (CINET): Configure one Agent per z/OS system in the sysplex" on page 1246.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Configuring the z/OS Load Balancing Advisor with subplexing

Before you begin: Read the following:

- Chapter 24, "Automated domain name registration," on page 1275, if you are also using Automated Domain Name Registration (ADNR), for some additional considerations for configuring ADNR in a subplexing environment.
- "Sysplex subplexing" on page 430, to decide how you want the Advisor and Agents to interact in a subplexing environment:

– You need to determine what set of subplexes will exist in your sysplex, both how many VTAM subplexes and how many TCP/IP subplexes within a VTAM subplex.
– You need to decide which subplexes will need Load Balancing Agents and a Load Balancing Advisor.

To configure the z/OS Load Balancing Advisor in a subplexing environment, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222. This topic provides special subplexing considerations that are referenced from those steps. Subtopics are provided only for steps that have special subplexing considerations.

Step 5 (subplex): Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)

When running the Load Balancing Advisor in a subplexing environment, there is one Load Balancing Advisor for each subplex that participates in load balancing. The subplex is determined by both the VTAM and TCP/IP subplex group IDs, which are denoted by *vv* for VTAM and *tt* for TCP/IP. These subplex group IDs are reflected in the TCP/IP sysplex group name, which is of the format EZBT*vvtt*. Each Load Balancing Advisor registers with ARM with the following parameters:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBTvvttLBADV
TERMTYPE=ALLTERM
```

You must define an ARM policy. For the EZBT*vvtt*LBADV element name, you must specify the TARGET_SYSTEM keyword to indicate the systems on which the Advisor can be restarted. This ensures that the Load Balancing Advisor for a subplex is restarted only on a system that is in the same subplex. That is, it is restarted on a system that has a VTAM that was started with the same XCFGRPID (*vv*) and that has an available TCP/IP stack with the same XCFGRPID (*tt*).

In a subplexing environment, there must be one Load Balancing Agent per subplex that participates in load balancing on each z/OS system. Each Load Balancing Agent registers with ARM with the following parameters:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBsysclonevvttLBAGENT
TERMTYPE=ELEMTERM
```

where:

- *sysclone* is a 1- or 2-character shorthand notation for the name of the MVS system. For a complete description of the SYSCLONE static system symbol, see *z/OS MVS Initialization and Tuning Reference*.
- *vvtt* is the last 4 characters of the sysplex_group_name parameter in the Agent configuration file. If this parameter is not specified, *vvtt* is omitted.

For example, if the *sysclone* value is 02 and the sysplex_group_name is EZBTCPCS, the resulting ELEMNAME value is EZB02CPCSLBAGENT.

Requirement: When ARM registration is used, the started task IDs for each Agent and each Advisor must be permitted with UPDATE authority to the IXCARM.SYSTCPIP.*elemname* profiles in the FACILITY class in the SAF-compliant security product on your system. The *elemname* value is the EZBT*vvtt*LBADV value or the EZB*sysclonevvtt*LBAGENT value previously described. You can use the

following RACF commands to define the profiles and grant update access to the user IDs that are assigned to the Advisors and Agents. For each Advisor:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBTvvttLBADV UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBTvvttLBADV CLASS(FACILITY) ID(advisor_userid) ACCESS(UPDATE)
SETROPTS CLASSACT(FACILITY)
```

For each Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT CLASS(FACILITY) ID(agent_userid) ACCESS(UPDATE)
SETROPTS CLASSACT(FACILITY)
```

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 6 (subplex): Configure and start syslogd

When you are using subplexing, if you will be starting more than one instance of an Advisor or Agent on the same system, you can configure the syslog daemon (syslogd) to place the output from the different instances of the Advisor and Agent into separate files based on job name, or you can use the syslogd **-u** start option to cause the user ID and job name to be displayed on each line of the syslog. For more information, see "Configuring the syslog daemon" on page 185.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 7 (subplex): Configure one Advisor per sysplex

When you are using subplexing, there can be more than one Advisor active in the sysplex at any given time. In fact, there should be one Advisor active for each subplex in the sysplex that you want to participate in load balancing through the Load Balancing Advisor. Each Advisor reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Advisor, the sysplex_group_name statement specifies the TCP/IP sysplex group name, in the form EZBT*vvtt*, where *vv* is the VTAM subplex group ID specified on the VTAM XCFGRPID start option, and *tt* is the TCP/IP subplex group ID specified by the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then *vv* is CP. If no TCP/IP subplex ID is specified in the TCP/IP profile, then *tt* is CS. If you have a default subplex in your sysplex (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Advisor for that subplex with a sysplex group name of EZBTCPCS.

Requirement: In a subplexing environment, the IP address of the Advisor's listening socket must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Advisor's configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a VIPARANGE statement on each of the stacks in the subplex. This enables the Advisor to connect regardless of the order that the TCP/IP stacks in the subplex are started.

Tip: In a subplexing environment, if you will have more than one Advisor started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, S LBADV.ADV0105 or S LBADV,JOBNAME=ADV0105).

To return to the configuration steps, see “Steps for configuring the z/OS Load Balancing Advisor” on page 1222

Step 8 (subplex): Configure one Agent per z/OS system in the sysplex

When you are using subplexing, there can be more than one Agent per z/OS system in the sysplex. In fact, there should be one Agent active for each subplex with a TCP/IP stack on a system that you want to participate in load balancing through the Load Balancing Advisor. Each Agent reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Agent, the sysplex_group_name statement specifies the TCP/IP sysplex group name, in the form EZBT*vvtt*, where *vv* is the VTAM subplex group ID specified with the VTAM XCFGRPID start option, and *tt* is the TCP/IP subplex group ID specified with the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then *vv* is CP. If no TCP/IP subplex ID is specified in the TCP/IP profile, then *tt* is CS. If you have a default subplex in your system (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Agent for that subplex with a sysplex group name of EZBTCPCS.

Tip: In a subplexing environment, if you will have more than one Agent started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, S LBAGENT.AGE0105 or S LBAGENT,JOBNAME=AGE0105).

Requirements:

- In a subplexing environment, the IP address used by the Agent to connect to the Advisor must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Agent's configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a VIPARANGE statement on each of the stacks in the subplex. This enables the Agent to connect regardless of the order that the TCP/IP stacks in the subplex are started.
- If you have more than one stack on a system, those stacks are not all in the same subplex, and you will be starting Load Balancing Agents on that system, the system must not be at a level prior to V1R10.

To return to the configuration steps, see “Steps for configuring the z/OS Load Balancing Advisor” on page 1222

Step 9 (subplex): Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)

In a subplexing environment, each Advisor and Agent must use a TCP/IP stack that is in its associated subplex. That stack should specify the TCP/IP subplex group ID that corresponds to the TCP/IP part (*tt*) of the sysplex_group_name (EZBT*vvtt*) for which the Advisor or Agent has been configured. The DVIPA for the Advisor must be defined in all the stacks that are associated with the subplex, where a restart of the Advisor can occur.

To return to the configuration steps, see “Steps for configuring the z/OS Load Balancing Advisor” on page 1222

Step 13 (subplex): Start one Agent on each sysplex system you want to participate in this method of workload balancing

You can start more than one Agent on a z/OS system, if there are TCP/IP stacks for more than one subplex on that system.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 14 (subplex): Start the one instance of the Advisor in the sysplex

You can start more than one Advisor in the sysplex, one for each subplex in the sysplex.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Step 15 (subplex): Configure the external load balancers

You might configure separate load balancers for each subplex, if the subplexes represent connectivity to networks with different security domains. When configuring a load balancer with the IP address of a Load Balancing Advisor, ensure that you have connectivity from the load balancer to the subplex that the Load Balancing Advisor is handling. In addition, groups and target applications that the external load balancer requests information on should belong to the same subplex that the Load Balancing Advisor is handling.

To return to the configuration steps, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222

Operating the z/OS Load Balancing Advisor

When the Advisor and Agent are operational, you can monitor and customize the following:

- Change the logging level of the Advisor and Agents to suit your needs (optional)
- Interpret Agent and Advisor display information
- Stop distributing new workload requests (QUIESCE) to particular members or resume distribution (ENABLE) to those members (optional)

Changing the logging level of the Advisor and Agents

Optionally, you can change the logging level of the Advisor and Agents to suit your needs. The amount of information that is logged by the Advisor and Agents can be modified dynamically using the following command:

```
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level is not a step that should be taken lightly. The IBM default of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see "Customizing optional statements" on page 1230.

Interpreting Agent and Advisor display information

Successfully interpreting the various flags and indicators that appear in Advisor and Agent displays can help you identify configuration problems, or might help

explain why workloads are not being distributed as expected. For information on each field in the Advisor and Agent displays, see *z/OS Communications Server: IP System Administrator's Commands*. Some portions of the displays are described in more depth in Table 57, Table 58 on page 1255, and the subtopics that follow.

Table 57. Summary of selected Advisor display output fields and flags

Flag or field name	Location	Description
ABNORM	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=nn command output	The rate of abnormal transaction completions per 1000 total transaction completions for this application. This value is optionally provided to WLM by the application. WLM provides this value along with the server-specific recommendation on the system where the member resides. For 1000 total transactions completed, it displays the number of those transactions that could not successfully complete. If the value is nonzero, WLM uses it to reduce the server-specific recommendation (WLM weight).
AVAIL	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=nn command output	Indicates whether the member is available for workload balancing requests.
BASEWLM	GROUP FLAGS field of the group area of the MODIFY *procname*,DISPLAY,LB,INDEX=nn command output	WLM system weight recommendations were configured or specified by default for the members of this group, and are being used as a component of the net weight.
BASEWLM*	GROUP FLAGS field of the group area of the MODIFY *procname*,DISPLAY,LB,INDEX=nn command output	Server-specific WLM recommendations were configured or specified by default for the members of this group. However, WLM system weight recommendations are actually being used as a component of the net weight.
CP	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	When shown on the next line after ProcType, indicates the proportion that is applied against the CP weight. When shown on the line starting with RAW, indicates the raw CP weight that was returned by WLM. When shown on the line starting with Proportional, indicates the proportionally adjusted raw CP weight that was used to determine the BASEWLM or SERVERWLM composite weight.

Table 57. Summary of selected Advisor display output fields and flags (continued)

Flag or field name	Location	Description
CS WEIGHT	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	Communications Server weight. A value calculated by the Agent that owns the member, representing the health of the application with respect to its ability to process the work that has recently been received.
HEALTH	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The general health of the application. This value is optionally provided to WLM by the application. WLM provides this value along with the server-specific recommendation on the system where the member resides. If the value is less than 100, WLM uses it to reduce the server-specific recommendation (WLM weight).
LB INDEX	For the MODIFY *procname*,DISPLAY,LB and MODIFY *procname*,DISPLAY,LB,INDEX=*nn* commands, an output field of the load balancer area	A unique identifier assigned to a load balancer for the purpose of referencing the load balancer in subsequent operator commands
LBQ	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The load balancer has quiesced the member.
NET WEIGHT	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The weight the Advisor passes to the load balancer, representing the desirability of the member to receive additional workload requests relative to the other members of the same group. The net weight is calculated using the WLM weight and Communications Server weight.
NOCHANGE	For the MODIFY *procname*,DISPLAY,LB and MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output, the FLAGS field of the load balancer area	The load balancer has requested that it be sent only information about members that have changed their status or weights since the last time the load balancer received information on its members.
NODATA	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	A transient flag indicating that the responsible Agent has not had enough time to calculate a Communications Server weight.
NOTARGETAPP	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The target application of this application member is not active.

Table 57. Summary of selected Advisor display output fields and flags (continued)

Flag or field name	Location	Description
NOTARGETIP	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	This is an unusable system member.
NOTARGETSYS	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The Advisor is not aware of the system that owns the IP address of the member.
OPQ	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	The z/OS operator has quiesced the member.
ProcType	A field of the group area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	Indicates that CP, zAAP, and zIIP proportions were configured. These proportions are applied against the processor weights to determine the composite BASEWLM weight.
PUSH	For the MODIFY *procname*,DISPLAY,LB and MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output, the FLAGS field of the load balancer area	The load balancer has requested to receive information from the Advisor on a scheduled basis, rather than having to poll the Advisor for the information.
SERVERWLM	GROUP FLAGS field of the group area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	Server-specific WLM recommendations are being used for the members of this group as a component of the net weight.
TRUST	For the MODIFY *procname*,DISPLAY,LB and MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output, the FLAGS field of the load balancer area	The load balancer will allow other system components besides itself to register members with the load balancer. The z/OS Load Balancing Advisor does not currently exploit this feature.
WLM WEIGHT	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	WorkLoad Manager weight. The value received from WLM on the system where the member resides, representing the displaceable capacity of that system relative to other systems in the sysplex (system weight), or the value received from WLM representing how well the server is performing relative to its WLM policies (server-specific weight). This weight is a composite weight determined from the displayed CP, zAAP, and zIIP weights.

Table 57. Summary of selected Advisor display output fields and flags (continued)

Flag or field name	Location	Description
zAAP	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	When shown on the next line after ProcType, indicates the proportion that is applied against the zAAP weight. When shown on the line starting with RAW, indicates the raw zAAP weight that was returned by WLM. When shown on the line starting with Proportional, indicates the proportionally adjusted raw zAAP weight that was used to determine the BASEWLM or SERVERWLM composite weight.
zIIP	A field of the member area of the MODIFY *procname*,DISPLAY,LB,INDEX=*nn* command output	When shown on the next line after ProcType, indicates the proportion that is applied against the zIIP weight. When shown on the line starting with RAW, indicates the raw zIIP weight that was returned by WLM. When shown on the line starting with Proportional, indicates the proportionally adjusted raw zIIP weight that was used to determine the BASEWLM or SERVERWLM composite weight.

Table 58. Summary of selected Agent display output flags

Flag or field name	Location	Description
ANY	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,MEMBERS command output	The target application is bound to the unspecified address, 0.0.0.0 for IPv4 or :: for IPv6.
V6	FLAGS field of the member area of the MODIFY *procname*,DISPLAY,MEMBERS command output	The target application was bound using the IPV6_V6ONLY socket option.

MODIFY *procname*,DISPLAY,LB

This command displays all load balancers that are currently connected to the Advisor. In Figure 122 on page 1256, the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure.

```
1  MODIFY LBADV,DISPLAY,LB
2  EZD1242I LOAD BALANCER SUMMARY
3  LB INDEX      : 00        UUID      : 637FFF175C
4   IPADDR..PORT : 10.42.154.105..50005
5   HEALTH       : 20        FLAGS     : NOCHANGE PUSH TRUST
6  LB INDEX      : 01        UUID      : 207FFF175C

8   HEALTH       : 7F        FLAGS     : PUSH TRUST
9  2 OF 2 RECORDS DISPLAYED
```

Figure 122. Sample output for the MODIFY procname,DISPLAY,LB command

LB INDEX: The LB index is generated by the Advisor to uniquely identify a load balancer, and is used in other MODIFY commands to display details of a particular load balancer. The LB index that is assigned to the next load balancer that connects can be difficult to predict at times, in case your automation attempts to predict them. Each time a load balancer connects, it is assigned a different LB index. At first, the numbers are assigned in order from 0 to 99, and then the numbers are reused. The next number assigned after 99 is based on a least-recently-used algorithm. Thus, of the load balancer connections that used the numbers 0-99, the index of the load balancer connection that ended first would be the next number assigned as the next LB index. This is done to prevent the confusion that could result if new load balancer connections obtained the lowest available index. If that were the case, it might be difficult to ascertain whether different load balancer displays referred to the same or different load balancer connection instances. If the Advisor is brought down and back up, the indexes start from zero again. Lines 3 and 6 in Figure 122 show two LB indexes. For more information on the LB INDEX field, see *z/OS Communications Server: IP System Administrator's Commands*.

NOCHANGE, PUSH, TRUST: All of these flags are set only by the load balancer. Whether they appear or not depends upon whether the particular load balancer implementation supports them, and if they are configured in the load balancer. The z/OS administrator has no control over the settings of these flags.

The NOCHANGE flag can affect the amount of data transferred between the load balancer and the Advisor. If this flag is set, only data that has changed since the last time data was sent to the load balancer is included. Consult the load balancer documentation to determine whether this setting is supported.

The PUSH flag can have an effect on how soon the load balancer is informed of certain events. If the PUSH flag is not on, the load balancer must poll the Advisor periodically for updates. If this flag is on, certain events can be communicated to the load balancer earlier than would be possible if polling were in effect. Those events include quicker notification of a target application being taken out of service, and quicker notification of when the member's IP address has been moved to another system in the sysplex (VIPA takeover) or removed entirely. When the PUSH flag is on, the Advisor also sends the load balancer updated information about weights and status at least every update interval, if new information is available. Consult the load balancer documentation to determine whether this setting is supported.

The TRUST flag indicates that the load balancer allows other system components besides itself to register members with the load balancer. The z/OS Load Balancing Advisor does not currently exploit this feature.

Line 5 of Figure 122 shows all of these flags. For more information on the NOCHANGE, PUSH, and TRUST flags, see *z/OS Communications Server: IP System Administrator's Commands*.

MODIFY *procname*,DISPLAY,LB,INDEX=*lbindex*

This command displays details about a particular load balancer, including its registered groups and members. In Figure 123 on page 1258, the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure.

```
1 MODIFY LBADV,DISP,LB,INDEX=0

Figure 123. Sample output for the MODIFY procname,DISPLAY,LB,INDEX=lbindex command

Group flags - BASEWLM, BASEWLM*, and SERVERWLM: The BASEWLM flag indicates that WLM system weight recommendations were configured or specified by default for this group, and are being used to calculate the net weight. The BASEWLM* flag indicates that server-specific WLM recommendations were configured for this group, but WLM system weight recommendations are being used instead. This occurs when at least one of the Agents owning members within the group does not support server-specific WLM recommendations. The SERVERWLM flag indicates that server-specific WLM recommendations are being used to calculate the net weight for each member in the group. Line 7 in Figure 123 shows the BASEWLM flag, line 39 shows the BASEWLM* flag, and line 25 shows the SERVERWLM flag. For more information on the BASEWLM, BASEWLM*, and SERVERWLM flags, see *z/OS Communications Server: IP System Administrator's Commands*.

Member flags - LBQ and OPQ: The LBQ flag indicates that the load balancer has quiesced the member. For details on what this entails, see "Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE)" on page 1264. Do not confuse this with the OPQ flag, which indicates that the z/OS

operator has quiesced the member at the z/OS Agent. In both cases, the member is ineligible for future workloads through the external load balancer. Line 43 in Figure 123 on page 1258 shows the LBQ flag and the OPQ flag. For more information on the LBQ and OPQ flags, see *z/OS Communications Server: IP System Administrator's Commands*.

Member flags - NOTARGETSYS, NOTARGETIP, and NOTARGETAPP: These flags indicate that the Advisor will advise the load balancer that the member should not currently receive new workload requests because a resource is unavailable. If the IP address in the member is not present on any TCP/IP stack within the sysplex or subplex, NOTARGETSYS is displayed for that member. This flag can also appear if the Agent owning the IP address in the member has lost contact with the Advisor or has yet to be started. There might be rare instances where the load balancer might decide to go ahead and route workload requests to members that have the NOTARGETSYS flag displayed, if it has no better candidates within the group to route workload requests to. If the member represents an application member and the application is not active, NOTARGETAPP is displayed for that member. If the member is a system member and the IP address is unusable, NOTARGETIP is displayed. This includes distributed VIPAs (DVIPAs), deprecated IPv6 addresses, and unavailable IPv6 addresses. If you ever see the NOTARGETIP flag, you should update the IP address in the member at the load balancer. If application members are coded with any of these addresses, you will always see NOTARGETAPP displayed for these members. Line 19 in Figure 123 on page 1258 shows the NOTARGETSYS flag, line 23 shows the NOTARGETIP flag, and line 47 shows the NOTARGETAPP flag. For more information on the NOTARGETSYS, NOTARGETIP, and NOTARGETAPP flags, see *z/OS Communications Server: IP System Administrator's Commands*.

Member flag - NODATA: This flag is transient and indicates that not enough time has elapsed for the reporting Agent to calculate a Communications Server weight for the member. Therefore, only the WLM weight is used to calculate the net weight, until such time that the Agent can report a Communications Server weight. Until that time, the CS WEIGHT is displayed as 100. When a Communications Server weight has been calculated and transmitted to the Advisor, the NODATA flag is turned off. This flag appears when new members are registered by the load balancer, when the target application that the member represents first becomes active, or shortly after a target application has been moved within the sysplex or subplex. Line 51 in Figure 123 on page 1258 shows the NODATA flag. For more information on the NODATA flag, see *z/OS Communications Server: IP System Administrator's Commands*.

Member field - AVAIL: This field is always displayed for each registered member, and has a value of YES or NO. YES indicates that the member is available for workload request distribution. NO indicates that the member is not available for workload request distribution. For the member to be available for workload request distribution, the target application must be active (if the member represents an application member) on a TCP/IP stack that has not had eventual action message EZD1973E issued by sysplex problem detection and recovery, an Agent must be active on the target system and connected to the Advisor, and the member must not be quiesced by the z/OS operator or by the load balancer. Line 9 in Figure 123 on page 1258 shows an example of the AVAIL field set to YES, and line 17 shows an example of the AVAIL field set to NO. For more information on the AVAIL field, see *z/OS Communications Server: IP System Administrator's Commands*.

Member field - NET WEIGHT: This field is always present for each registered member, and is the only weight that the load balancer actually receives. It is

calculated by applying the Communications Server weight as a percentage of the WLM weight, and then the weight is normalized within its group. Normalization involves reducing the weight values while largely preserving the ratios between the weights. Normalization is performed within a group only if there is more than one available member within the group. Net weights can be in the range 0 – 64. A higher net weight means that member is capable of receiving more work than a member within the same group that has a lower weight. There are certain situations where the net weight can be 0 when neither the WLM weight or the Communications Server weight is 0. This can happen if the member has been quiesced by the z/OS operator or the load balancer. Conversely, there is one case where the WLM weight or the Communications Server weight can be zero, but the net weight is nonzero. This can happen if the net weight of every member in the group calculates to zero, and at least one member of the group is available. In this case, the net weights of all of the available members in the group are changed to 1 to force round-robin distribution among the members in the group, rather than to stop sending new workloads to the group entirely. Line 10 in Figure 123 on page 1258 shows an example of the NET WEIGHT field set to a nonzero value, while line 18 shows an example of the field set to zero. For more information on the NET WEIGHT field, see *z/OS Communications Server: IP System Administrator's Commands*.

Member field - WLM WEIGHT: This field is always present for each registered member, and represents the desirability of the system owning the member, relative to the other systems in the sysplex or subplex (system weight), or a measure of how well the individual application is meeting its WLM policies (server-specific weight). Like the Communications Server weight and net weight, a higher value means it is more desirable. WLM weights can be in the range 0 – 64. The WLM weight is used as a key component of the net weight. The WLM weight is the composite weight, and is the sum of the modified CP, zAAP, and zIIP weights displayed on the next line. Line 10 in Figure 123 on page 1258 is one of many lines that contain the WLM WEIGHT field, and Lines 10a and 10b are some of the many lines that contain the modified CP, zAAP, and zIIP weights described in Table 59.

Table 59. WLM WEIGHT - CP, zAAP, and zIIP fields

Processor	DISTMETHOD BASEWLM	DISTMETHOD SERVERWLM
CP	The first value is the WLM system general CP weight recommendation. It is based on the amount of displaceable general CPU capacity on this system, as compared to the other target systems. The second value is the first value modified by the expected general CP utilization proportion configured on the PORTLIST and WLM statement for this application.	The first value is the WLM server-specific general CP recommendation. This is the amount of displaceable general CPU capacity, based on the application workload's importance (as defined by the WLM policy) as compared to the other target systems. The second value is the first value modified by the proportion of general CP capacity that is currently being consumed by the application's workload, as compared to the other processors (zAAP and zIIP).

Table 59. WLM WEIGHT - CP, zAAP, and zIIP fields (continued)

Processor	DISTMETHOD BASEWLM	DISTMETHOD SERVERWLM
zAAP	The first value is the WLM system zAAP weight recommendation. It is based on the amount of displaceable zAAP capacity on this system, as compared to the other target systems. The second value is the first value modified by the expected zAAP utilization proportion configured on the PORTLIST and WLM statement for this application.	The first value is the WLM server-specific zAAP recommendation. This is the amount of displaceable zAAP capacity, based on the importance (as defined by the WLM policy) of the application's workload, as compared to the other target systems. The second value is the first value modified by the proportion of zAAP capacity that is currently being consumed by the application's workload, as compared to the other processors (general CPU and zIIP).
zIIP	The first value is the WLM system zIIP weight recommendation. It is based on the amount of displaceable zIIP capacity on this system, as compared to the other target systems. The second value is the first value modified by the expected zIIP utilization proportion configured on the PORTLIST and WLM statement for this application.	The first value is the WLM server-specific zIIP recommendation. This is the amount of displaceable zIIP capacity, based on the importance (as defined by the WLM policy) of the application's workload, as compared to the other target systems. The second value is the first value modified by the proportion of zIIP capacity that is currently being consumed by the application's workload, as compared to the other processors (general CPU and zAAP).
Restriction: This information is available to be displayed only if no systems in the sysplex are prior to z/OS V1R9. If any systems in the sysplex are not at this release level, only CP weights are considered when determining a composite weight recommendation.		

For more information on the WLM WEIGHT field, see *z/OS Communications Server: IP System Administrator's Commands*.

Member field - CS WEIGHT: This CS WEIGHT field is always present for each registered member, and represents the health of the server with respect to its ability to satisfy recent requests. As with the WLM weight and the net weight, the higher the value the better the health. The Communications Server weight can range from 0 to 100, and is used as a component of the net weight. Line 10 in

Figure 123 on page 1258 is one of many lines that contains the CS WEIGHT field. For more information on the CS WEIGHT field, see *z/OS Communications Server: IP System Administrator's Commands*.

Member field - ABNORM: This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. The ABNORM value is a nonzero value if the server application is experiencing conditions in which transactions are completing abnormally, and represents a rate of abnormal transaction completions per 1000 total transaction completions. It is applicable only for target applications that act as Subsystem Work Managers, reporting transaction status using Workload Management Services, such as IWMRPT. For example, the value of 200 in this example (see Line 28c in Figure 123 on page 1258) indicates that 20% of all transactions processed by the server application are completing abnormally. Under normal conditions or if the server is not providing this information to WLM, this value is 0.

A nonzero value indicates that the server application has reported abnormal transaction completions to WLM and that WLM has reduced the server-specific recommendation for this server instance. The higher the value of this field, the greater the reduction in the recommendation provided by WLM. For more information regarding the conditions leading to abnormal transaction completions for a given server application, see the documentation provided by the server application.

Restriction: Although WLM uses the abnormal transaction completion rate provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal abnormal transaction completion rate of 0, even if WLM is reducing the server-specific recommendation because of a nonzero abnormal transaction completion rate reported from the application.

Member field - HEALTH: This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. This health indicator is available only for applications that provide this information to WLM using the IWM4HLTH or IWMSRSRG services, and it indicates the general health for an application or subsystem. Under normal circumstances, or if the server is not providing this information to WLM, the value of this field is 100, meaning the server is 100% healthy.

Any value less than 100 indicates that the server is experiencing problem conditions that are preventing it from processing new work requests successfully, which causes WLM to reduce the server-specific recommendation for this server instance. The lower the value of this field, the greater the reduction in the recommendation provided by WLM.

Restriction: Although WLM uses the health indicator provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal health indicator of 100, even if WLM is reducing the server-specific recommendation because of an abnormal health indication from the application.

Member field - ProcType: Indicates that CP, zAAP, and zIIP proportions were configured. These proportions are applied against the processor weights to determine the composite BASEWLM weight. For a description of the CP, zAAP, and zIIP fields for ProcType, see Table 57 on page 1252. Lines 54 and 54a in Figure 123 on page 1258 contain these fields.

MODIFY *procname*,DISPLAY,MEMBERS,DETAIL

This command displays details about members that are owned by the Agent. In Figure 124, the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure. For information about every field displayed by the Agent MODIFY command, see *z/OS Communications Server: IP System Administrator's Commands*.

Figure 124. Sample output for the MODIFY procname,DISPLAY,MEMBERS,DETAIL command

Member flag - ANY: The ANY flag means that the application represented by the port in the member is bound to INADDR_ANY or the IPv6 unspecified address (in6addr_any). This means that in an INET (one TCP/IP stack) environment, any externally available IP address owned by that TCP/IP stack might be used to reach the target application, not just the IP address coded in this member. Therefore, there is the potential that multiple members might exist in the load balancer or other load balancers that actually represent the same application, if members were coded with the same port, protocol, and an IP address owned by the same TCP/IP stack. You need to be aware of this if you want to issue operator commands to quiesce that application. If this were the case, quiescing the application at the port level, but specifying the individual IP address of the member, might not quiesce all new workload requests to that application. Quiescing the application at the port level without specifying an IP address would be required to accomplish that task. If the application is running in a CINET (multiple TCP/IP stack) environment, any externally available IP address on the z/OS system can be used to reach the target application, unless the application has stack affinity. If the application has stack affinity, the Advisor only indicates the member is available if the IP address coded in the member belongs to the TCP/IP stack that the application has affinity to. Line 18 in Figure 124 shows an example of this flag. For more information on the ANY flag, see *z/OS Communications Server: IP System Administrator's Commands*.

Member flag - V6: The V6 flag indicates that the application that the member refers to has set the IPV6_V6ONLY socket option. This socket option disallows connections to the server application using an IPv4 address as the destination IP address when the server application has bound to the IPv6 unspecified address (in6addr_any). If a member is coded with an IPv4 address and intends to represent an application that has the IPV6_V6ONLY socket option set, the member will not be available for workload balancing and the V6 flag is displayed for this member. Conversely, for any member that represents this target application and is coded with an IPv6 address that can be used to reach the target application, the member will be available for workload balancing and the V6 flag is displayed. Line 22 in Figure 124 on page 1263 shows an example of this flag. For more information on the V6 flag, see *z/OS Communications Server: IP System Administrator's Commands*.

Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE)

At least one and possibly two methods exist to stop sending new workload requests to particular members, referred to as quiescing. Quiescing does not disrupt existing connections with the target applications, but does prevent new workload requests from being distributed to those members from load balancers. Requests sent directly to applications that do not go through the load balancer are unaffected by quiescing. Quiescing certain members can be useful for a planned outage of a particular system in the sysplex, a particular TCP/IP stack, a particular application, or a homogeneous group of applications, such as all HTTP servers. The first method of quiescing is done using the MODIFY *procname*,QUIESCE operator command available at each Agent. The second potential method is through the load balancer administrator, if the load balancer implementation supports this function. Only the MODIFY *procname*,QUIESCE command is described in detail in this topic.

The MODIFY *procname*,QUIESCE command is available only on the Agents, because they own the IP addresses that belong to TCP/IP stacks on that z/OS system. Therefore, the scope of the quiesce operation cannot affect members that are not owned by the Agent that is issuing the command.

There are three major scopes or target options for the MODIFY *procname*,QUIESCE command:

- SYSTEM

  Every member owned on that z/OS system can be quiesced
- TCPNAME=*tcpname*

  Every member on one of the Agent's TCP/IP stacks can be quiesced
- PORT=*portnum*

  All members using a particular port can be quiesced

The last target option, quiescing by port, enables you to refine the quiesce to an individual member instead of quiescing all members using the port. For more information on how to specify individual members using the Agent's MODIFY *procname*,QUIESCE command, see *z/OS Communications Server: IP System Administrator's Commands*.

When ready for new workloads, use the MODIFY *procname*,ENABLE command to make the quiesced members available again. Like the quiesce command, this command is only an Agent command, and also has the same target options as the quiesce command.

The quiesce and enable commands are hierarchical. The system level (SYSTEM target option) is at the top of the hierarchy, the stack level (TCPNAME=*tcpname* target option) is the next highest, and the member level (PORT=*portnum* target option) is the lowest.

Rules:

- In the quiesce and enable hierarchy, a member quiesced at one level of the hierarchy cannot be enabled at a lower or higher level of the hierarchy. For example, if the MODIFY *procname*,QUIESCE,TCPNAME=*tcpname* command has been issued, a MODIFY *procname*,ENABLE,SYSTEM command or a MODIFY *procname*,ENABLE,PORT=*portnum* command will not be accepted.
- An enable command must be issued at the same level of the hierarchy as the last quiesce command that affected the member.
- When a member has been quiesced at one level of the hierarchy, it can be quiesced at a higher level of the hierarchy. This promotes the quiesce level of the member from the lower hierarchy level to the higher hierarchy level, and any history of it being quiesced at the lower level of the hierarchy is erased. When subsequently issuing an enable command in these circumstances, the enable command must be issued at the higher, promoted level of the hierarchy. For example, if member A was quiesced at the port level, a subsequent command to quiesce all members of the TCP/IP stack would be accepted. Furthermore, only a subsequent enable command at the TCP/IP stack level would be accepted to re-enable the member.

Table 60 shows which quiesce and enable commands are valid for a member after a previous quiesce command has affected that same member. A dot at the intersection of the prior command column and the current command row indicates that the current command would be valid for that member. Absence of a dot indicates that the current command would not be valid after the prior command had affected that member.

Table 60. Allowed quiesce and enable command sequences for members

		Prior command		
		QUIESCE,SYSTEM	QUIESCE,TCPNAME=	QUIESCE,PORT=
Current command	QUIESCE,SYSTEM		●	●
	QUIESCE,TCPNAME=			●
	QUIESCE,PORT=			
	ENABLE,SYSTEM	●		
	ENABLE,TCPNAME=		●	
	ENABLE,PORT=			●

Rules:

- A quiesce command is rejected if any member it applies to has already been quiesced by a command at a higher level of the hierarchy. For example, if you are running in a CINET configuration and you quiesce all members under stack A, which includes a member on stack A that used port 80, you cannot subsequently issue a quiesce command at the port level hoping to quiesce members using port 80 on stacks B and C, because the member on stack A that used that port was already quiesced at the stack level. Because the command would fail for one member, the entire command fails for all members.
- Quiesce commands at the system and stack level apply to currently registered members and also members that are registered in the future, provided that the

IP addresses of those future members are owned by the Agent that issued the command. For quiesce commands issued at the stack level, the specified stack must exist at the time the command is issued.

- Quiesce commands at the port level can apply to members registered in the future, if a member currently exists at that port number. For example, if a member is registered by one load balancer at port 80 and the Agent operator quiesces all members at port 80, and then another load balancer registers that same member (same IP address, port, and protocol), the newly registered member would inherit the quiesce performed at the port level.

When a member represents a shareport group (that is, multiple server application instances sharing the same TCP port on the same TCP/IP stack), members cannot be defined to distinguish between the individual server application instances. That is, the combination of the IP address, port, and protocol represents all of the applications sharing the port. Therefore, you cannot selectively quiesce workload requests to only some of the applications sharing the port. Consequently, if you quiesce a member that represents a shareport group, all of the application instances in the group are quiesced.

If an Agent is stopped or fails and is restarted, the quiesce states of any members it might have previously owned are lost. If this occurs, reenter the appropriate quiesce commands to regain the quiesce states that existed during the previous instance of the Agent.

If a member is moved from one system in a sysplex to another using sysplex functions such as VIPA backup, the quiesce state does not move with it. For example, if quiesced member A is using IP address 1.1.1.1 on system X and system X fails, IP address 1.1.1.1 could be moved to system Y. Member A would no longer be quiesced on the new system and, assuming that the application that member A is assigned to is available and active on system Y, new workload requests would be distributed to this application.

If you plan to take a sysplex system out of service, simply stopping the Agent running on that system is not always a wise alternative to issuing a system-level quiesce command on that system's Agent. If an Agent is simply shut down, there are rare cases where a load balancer might choose to continue routing new workload requests to the applications on that system.

z/OS Load Balancing Advisor configuration example

This topic includes a specific configuration example of the z/OS Load Balancing Advisor, two Load Balancing Agents, and some customization of PROFILE.TCPIP considerations.

In this example, as shown in Figure 125 on page 1267, load balancer LB1 distributes workload requests to two z/OS systems in a sysplex, SYSA and SYSB. SYSA is a CINET configuration with two TCP/IP stacks. SYSB is an INET configuration with one TCP/IP stack. The load balancer is connected to a LAN that also connects to each target TCP/IP stack in the sysplex, including the TCP/IP stack where the Advisor is running. All addresses in this example are IPv4, but the Advisor and Agents are enabled for IPv6.

This example configuration does not use subplexing or AT-TLS.

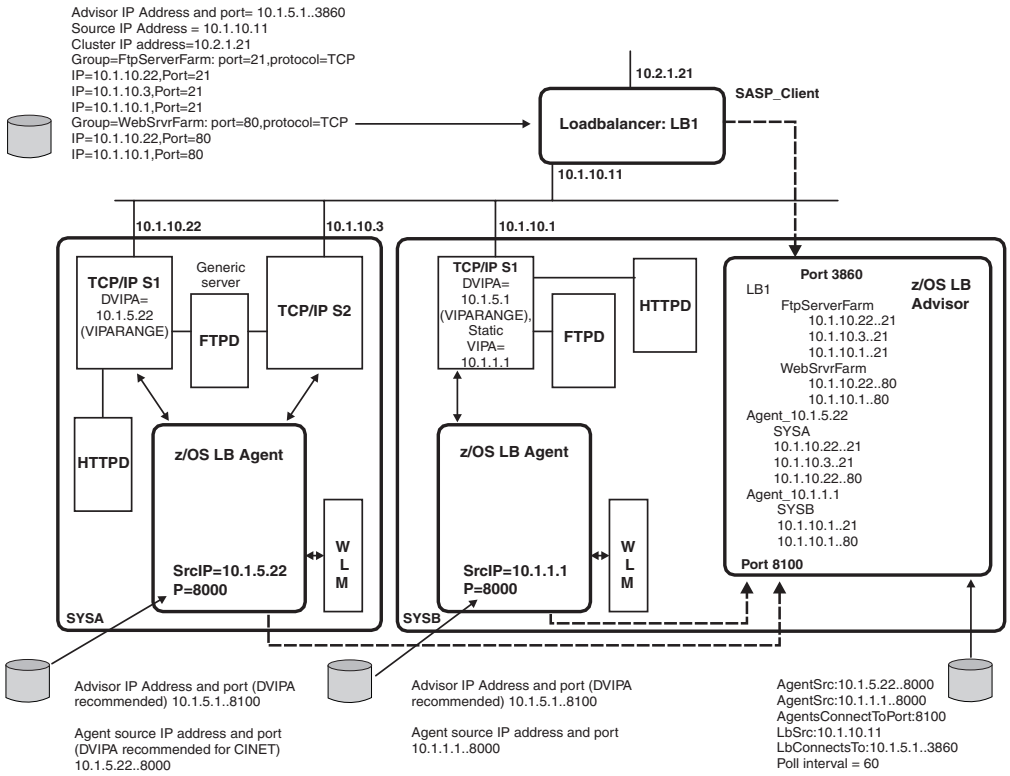

Figure 125. z/OS Load Balancing Advisor configuration example

Load balancer configuration details

The load balancer distributes two types of workload requests in this example, FTP and HTTP traffic, both of which use the TCP protocol. (Keep in mind that UDP workload requests can also be distributed if desired.) On SYSA, one FTP server is running, which is shared as a generic server between the two TCP/IP stacks. Also on SYSA, an HTTP server is bound to stack S1. On SYSB, an FTP and HTTP server are running.

The load balancer must be configured with the IP address and port of the Advisor's load balancing connection socket. In this example, the TCP/IP stack on SYSB has defined 10.1.5.1 as a dynamic VIPA. In addition, this same address and port is defined to the Advisor on the lb_connection_v4 statement in the Advisor's configuration file. The load balancer also uses one of its interfaces to communicate with the Advisor. The IP address assigned to this interface must be coded in the Advisor's lb_id_list statement. In this example, the load balancer uses the interface assigned to the address 10.1.10.11. For information on how to determine which interface the load balancer will use to communicate with the Advisor, consult the specific load balancer documentation.

The load balancer advertises its cluster IP address, 10.2.1.21, so that clients that want to connect to specific applications in the sysplex will connect to this cluster IP address as a proxy. Once the connection reaches the load balancer, to determine the actual target of the request, the load balancer consults the information that the Advisor has provided as well as possibly examining the content of the packet. The load balancer might substitute the target IP address in the packet header with the IP address of the member that is best suited to receive the new workload requests,

or simply forward the packet as is using the proper MAC address. For example, if a connection request came to the load balancer (10.2.1.21) for port 21 using protocol TCP, the load balancer would forward the packet to either 10.1.10.22, 10.1.10.3, or 10.1.10.1, depending upon which member is the better candidate at that point in time.

To distribute FTP workload requests to the sysplex, a group called FtpServerFarm is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 21, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 21, it consults this group to find a member to which it can forward the connection. Within this group are three members that can handle FTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 21, the second at 10.1.10.3 on port 21, and the third at 10.1.10.1 on port 21. The target applications represented by these members do not necessarily all have to be available at all times. The load balancer avoids trying to forward connections to target applications that are not currently available. Therefore, the list of target applications represented by the members in the group should be the entire set of possible members that could handle this workload, now or in the foreseeable future.

To distribute HTTP workload requests to the sysplex, a group called WebSrvrFarm is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 80, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 80, it consults this group to find a member to which it can forward the connection. Within this group are two members that can handle HTTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 80, and the second can be reached at 10.1.10.1 on port 80.

Advisor configuration details

There are two aspects of Advisor configuration, the Advisor configuration file itself, and the underlying PROFILE.TCPIP changes that go along with the remainder of the z/OS Load Balancing Advisor system configuration.

Following is an example Advisor configuration file:

```
debug_level 7                     # Error, Warning, Events-- the default

update_interval 60                # Agents update every  minute-- the default

wlm serverwlm                     # Request server-specific WLM weights

port_list
{
   21 wlm basewlm                 # Use system WLM weights for FTP
}

lb_connection_v4 10.1.5.1..3860   # DVIPA load balancer connects to

lb_id_list
{
   10.1.10.11                     # Load balancer's SASP client interface
}

agent_connection_port 8100        # Port Agents connect to

agent_id_list
```

```
{
   10.1.1.1..8000                # This system's Agent source
   10.1.5.22..8000               # SYSA's Agent source
}
```

In this example Advisor configuration file, the debug level is set to 7 in the optional debug_level statement. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

The optional update_interval statement is set to 60 seconds, which is also the default. This means that each Agent updates the Advisor with new information every minute. For some load balancer implementations, depending upon load balancer configuration, it might also determine how often the load balancer is updated with new information from the Advisor.

The wlm statement specifies the default WLM recommendation type to be used for all groups when calculating the net weights. The value of severwlm indicates that server-specific WLM recommendations will be requested of each Agent, unless overridden by the port_list statement (see next paragraph). Although server-specific WLM is the WLM recommendation type to be used for all groups except FTP in this example, there is still a possibility that WLM system weights might have to be used for some or all groups. For further details on the serverwlm value on the wlm statement, see *z/OS Communications Server: IP Configuration Reference*.

The port_list statement contains one port number, 21. The wlm keyword indicates that the WLM recommendation type will be overridden for all members using port 21 (FTP), to use WLM system weights rather than server-specific WLM weights when calculating the net weight. Multiple port numbers can appear in the port_list statement on separate lines, if you want to use WLM system weights for other groups of members.

The lb_connection_v4 statement includes DVIPA 10.1.5.1 and port 3860 (the default) as the address and port that load balancers use to connect to the Advisor. The load balancer specifies this address and port when defining the location of the Advisor.

The lb_id_list statement contains the address 10.1.10.11, which is the source IP address of the load balancer when the load balancer connects to the Advisor as a SASP client. If more than one load balancer is used to distribute workload requests to the sysplex, each load balancer needs to be represented in this statement list.

The agent_connection_port statement specifies that port 8100 is used to listen for connections from Agents in the sysplex. This same port appears on each Agent's advisor_id statement. This port is reserved on the TCP/IP stack that the Advisor runs on, and on any TCP/IP stacks that the Advisor could be moved to in the event of failure. Using this port, the Advisor opens a listening socket on the IPv4 or IPv6 unspecified address (0.0.0.0 or ::, respectively), depending upon the TCP/IP stack's IPv6 capability.

The agent_id_list statement contains the source IP address and port of each Agent in the sysplex. The 10.1.1.1 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSB uses to communicate with the Advisor. This same address and port combination appears on the agent_connection

statement in the Agent's configuration file on SYSB. The 10.1.5.22 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSA uses to communicate with the Advisor. This same address and port combination appears on the agent_connection statement in the Agent's configuration file on SYSA.

Agent configuration file on SYSB

Following is the example Agent configuration file on SYSB:

```
debug_level 7                  # Error, Warning, Events

advisor_id 10.1.5.1..8100      # DVIPA of Advisor Agent connects to

host_connection 10.1.1.1..8000 # Source address and port this Agent
                               #   uses to connect to the Advisor
```

In this example Agent configuration file for SYSB, the debug level is set to 7 in the optional debug_level statement. The debug_level statement for an Agent functions similarly to the way it functions for the Advisor.

The advisor_id statement is configured with the address 10.1.5.1 and port 8100. This tells the Agent which address and port the Advisor is using for connections from Agents. The address 10.1.5.1 is configured as a DVIPA on the Advisor's TCP/IP stack. The port of 8100 also appears on the agent_connection_port statement in the Advisor's configuration file, and is also reserved on the Advisor's TCP/IP stack.

The host_connection statement is configured with the address 10.1.1.1 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. The address is defined as a static VIPA on the TCP/IP stack that the Agent will run on. This address and port must also be specified in the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 on system SYSB.

Agent configuration file on SYSA

Following is the example Agent configuration file on SYSA:

```
debug_level 7                      # Error, Warning, Events

advisor_id 10.1.5.1..8100          # DVIPA of Advisor Agent connects to

host_connection 10.1.5.22..8000    # Source DVIPA and port this Agent
                                   #   uses to connect to the Advisor
```

This Agent configuration file is for the Agent running on SYSA. The debug_level and advisor_id statements are identical to the Agent configuration file on SYSB. The host_connection statement is configured with the address 10.1.5.22 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. This address and port must also be specified on the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 and S2 on system SYSA. This address is defined as a dynamic VIPA on both TCP/IP stacks on SYSA, in the event that one of the TCP/IP stacks fails.

Customization of PROFILE.TCPIP

Each TCP/IP profile in the sysplex must be updated to accommodate the z/OS Load Balancing Advisor.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSB follows:

```
VIPADYNAMIC
   ;Address LB & Agents use to reach Advisor fall into this subnet
   VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

DEVICE VIPA41 VIRTUAL 0    ; Static VIPA for Agent's source address
   LINK LVIPA41 VIRTUAL 0 VIPA41
   HOME 10.1.1.1 LVIPA41

PORT
   3860 TCP LBADV          ; SASP Workload Advisor (LB connections)
   8100 TCP LBADV          ; SASP Workload Advisor (Agent connections)
   8000 TCP LBAGENT        ; SASP Workload Agent (Advisor connection)
```

In this example, the address 10.1.5.1 would be within the subnetwork that has been reserved for dynamic VIPAs in the VIPARANGE statement. The load balancer and the Agents use this address to reach the Advisor. Using a dynamic VIPA (DVIPA) facilitates the movement of the Advisor to another TCP/IP stack in the event of failure. This address is defined in the lb_connection_v4 statement in the Advisor's configuration file, in the load balancer as the location of the Advisor [known generically as the SASP Global Workload Manager (GWM)], and on the advisor_id statement in each of the Agent's configuration files.

The address 10.1.1.1 is a static VIPA. The Agent on this system uses this address as its source IP address. Since SYSB is a single stack system (INET), a static VIPA is sufficient. If this were a CINET system like SYSA, a DVIPA would be best. This address appears on the agent_id_list statement in the Advisor's configuration file, as well as on the agent_connection statement in the Agent's configuration file on SYSB.

The ports used for the Advisor and Agent are reserved, as advised. Port 3860 is reserved for the Advisor and is used to communicate with load balancers. This port appears on the lb_connection_v4 statement in the Advisor's configuration file. Port 8100 is also reserved for the Advisor, and is the port that the Agents use to connect to the Advisor. This port appears on the agent_connection_port statement in the Advisor's configuration file, as well as on the advisor_id statement in each of the Agents' configuration files. Port 8000 is reserved for the Agent on this system and is used as the source port for the connection with the Advisor. This port appears on the agent_id_list statement in the Advisor's configuration file, as well as on the agent_connection statement in the Agent's configuration file on this system.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSA follows:

```
VIPADYNAMIC
   ;Address Agent uses as source will fall into this subnet
   VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
   3860 TCP LBADV          ; SASP Workload Advisor LB connections,
                           ;  in case Advisor is moved to this stack
   8100 TCP LBADV          ; SASP Workload Advisor Agent connections,
                           ;  in case Advisor is moved to this stack
   8000 TCP LBAGENT        ; SASP Workload Agent Advisor connection
```

In Figure 125 on page 1267, the DVIPA that the Agent uses as a source IP address on this system is shown belonging to stack S1. It could just as easily belong to stack S2, but for the purposes of this example the DVIPA belongs to stack S1.

In this updated portion of PROFILE.TCPIP, the address that the Agent uses as a source address when connecting to the Advisor, 10.1.5.22, is within the subnetwork that has been reserved for dynamic VIPAs on the VIPARANGE statement. Using a dynamic VIPA (DVIPA) facilitates the movement of the Agent to another TCP/IP stack on the same system in the event of failure. This address is defined on the host_connection statement in this Agent's configuration file, and in the agent_id_list statement in the Advisor's configuration file. The DVIPA that the Advisor would use, should the Advisor be moved to this stack, would also fall within this subnetwork.

The port that is used for the Agent is reserved, as advised. Additionally, ports that the Advisor would use if it were to be moved to this TCP/IP stack are also reserved.

The updated portion of PROFILE.TCPIP for stack S2 on system SYSA follows:

```
VIPADYNAMIC
   ;Address Agent uses as source will fall into this subnet
   VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
   3860 TCP LBADV          ; SASP Workload Advisor LB connections,
                           ;  in case Advisor is moved to this stack
   8100 TCP LBADV          ; SASP Workload Advisor Agent connections,
                           ;  in case Advisor is moved to this stack
   8000 TCP LBAGENT        ; SASP Workload Agent Advisor connection
```

This updated portion of the TCP/IP profile is identical to that of stack S1 on SYSA. This TCP/IP stack is capable of supporting the Advisor and the Agent running on this z/OS system, should it be necessary to move either to this TCP/IP stack.

Chapter 24. Automated domain name registration

The automated domain name registration (ADNR) application is a function that dynamically updates name servers with information about sysplex resources in near real time. As resources in the sysplex become available, Domain Name System (DNS) resource records are added to one or more name servers. As those resources become unavailable, the corresponding DNS resource records are removed from the name server. Clients that connect to sysplex resources using DNS names have a greater likelihood of connecting to an available resource in the sysplex. ADNR also removes the administrative burden of manually configuring and updating a name server to represent sysplex resources.

The DNS names managed by ADNR can be application-specific names. All instances of the same application within the sysplex can be represented by the same DNS name. Clients can therefore use one DNS name to connect to any available application instance within the sysplex. ADNR can also manage DNS names that map to specific application instances. These names are used when a client desires affinity to one particular application instance.

In addition to application-specific names, ADNR can also manage DNS names that generically represent the entire sysplex, as well as names that represent individual systems within the sysplex.

How connections are distributed within the sysplex is determined by name server and ADNR configuration. Typically, connections are fairly evenly spread out among the available application instances over time. Connections are not load balanced within the sysplex, as they are with load balancing solutions such as sysplex distributor and the z/OS Load Balancing Advisor.

ADNR supports both IPv4 and IPv6 addresses.

System overview

Figure 126 on page 1276 shows a z/OS sysplex containing four systems, a name server external to the sysplex, a name server in the sysplex, and several clients in the network. The z/OS Load Balancing Advisor and ADNR are running on one of the systems in the sysplex. An instance of the z/OS Load Balancing Agent is active on three of the sysplex systems. Three instances of a server application are active within the sysplex.

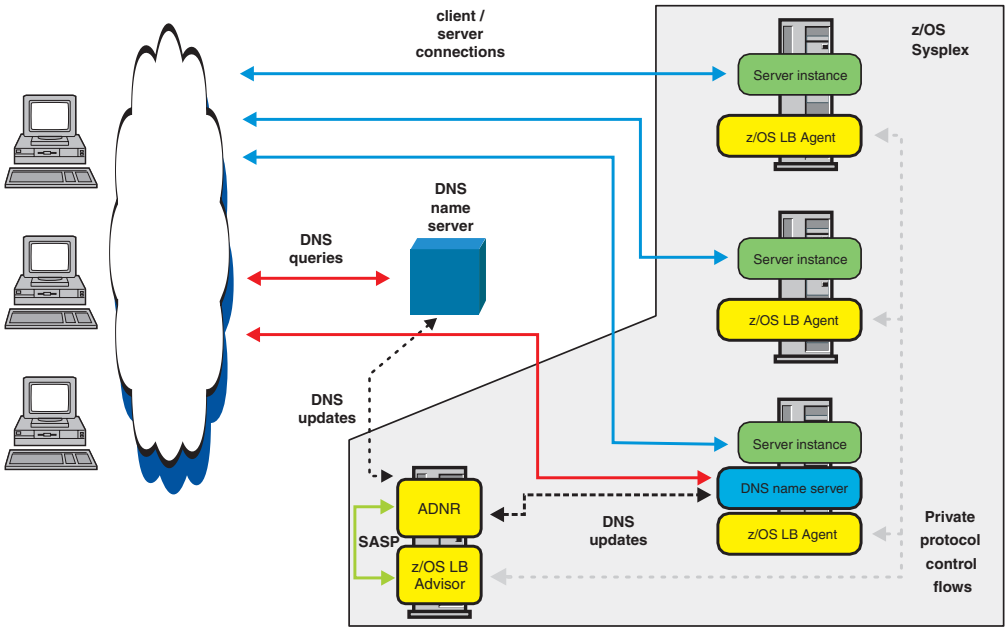

Figure 126. System overview

ADNR is configured with information about sysplex resources to which you want to assign DNS names. These resources are configured on a group basis. For example, to have ADNR manage DNS names in a name server for a sysplex containing several instances of a CICS listener application, all potential CICS listener instances for a given port in the sysplex are defined under the same group in the ADNR configuration file.

ADNR registers its configured information about sysplex resources with a z/OS Load Balancing Advisor application. The Advisor application disseminates this information to the z/OS Load Balancing Agents (Agents), which report back to the Advisor about the availability of the resources registered by ADNR. The Advisor then reports back to ADNR about which of its registered resources are active and which are not. The Advisor subsequently reports to ADNR any changes in the availability of those resources.

For each group of resources that the Advisor reports as available, ADNR adds a DNS name to the name server that represents the entire group of resources in that group, and maps that name to the IP addresses of the available resources in that group. Continuing with the CICS listener example, the IP address of each active CICS listener application is mapped to the name representing the entire group of CICS listener applications. The IP address of each inactive CICS application is not mapped to that DNS name. Clients then connect to their application using the name that ADNR added to the name server. The address or addresses returned to the client's resolver reflect only active application instances. Thus, the client can use one DNS name to connect to any active instance of an application. As application instances become unavailable, the addresses of those unavailable application instances are disassociated from that DNS name in the name server. If all application instances in that group become unavailable, the DNS name representing that group of applications is removed from the name server.

You can also configure ADNR to update the name server with the names of individual server instances, which map to IP addresses that can be used to reach those server instances as those server instances become available. Thus, if a client

needs to connect to a specific server instance, that name can be used to make the connection. As each individual server instance becomes unavailable, the DNS name representing the unavailable server instance is removed from the name server.

The name servers that ADNR manages can reside on z/OS or other platforms, as long as the name server supports RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. On z/OS, the BIND 9 name server supports this standard. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

For administrative purposes, it is advantageous to run ADNR within the same sysplex as the resources it manages. ADNR should run in a sysplex so that it can be moved to provide optimal availability. You can reduce network traffic between ADNR and the Advisor by running ADNR on the same system where the Advisor is running. If ADNR is managing z/OS name servers, network traffic between ADNR and the name server can also be reduced by running the name server on the same system as ADNR. In addition, the possibility of network outages disrupting communication between ADNR and the Advisor, and between ADNR and the name server, is eliminated by this configuration. In a steady-state sysplex environment, there is more traffic between the Advisor and ADNR than there is between ADNR and the name servers it manages. So, if you do not want to run both on the same system, it is more important that ADNR run on the same system as the Advisor than it is for the name server to run on the same system as ADNR.

Interaction with name servers

The name servers that ADNR manages require a one-time setup. These name servers must be configured as the primary master name servers for the zones managed by ADNR. The name servers can exist on z/OS or elsewhere. The name servers must support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Tip: The z/OS BIND 9 name server supports this standard.

For more background information about DNS, see Chapter 15, "Domain Name System," on page 775.

For more information about name server configuration considerations, see "Name server configuration considerations" on page 1294.

Interaction with the z/OS Load Balancing Advisor

The ADNR function is provided by the ADNR application, which uses the z/OS Load Balancing Advisor function.

Requirement: You must configure and deploy the z/OS Load Balancing Advisor and Agent to use ADNR.

An external load balancer is not required.

The ADNR application communicates with the Advisor using the Server/Application State Protocol (SASP). In SASP protocol terms, the Advisor is known as a Global Workload Manager (GWM). The terms Advisor and GWM are used interchangeably. From the GWM's perspective, the ADNR application appears as a load balancer. Despite its appearance as a load balancer to the GWM, ADNR does not perform load balancing. The z/OS Load Balancing Advisor supplies

sysplex resource availability and weight information to what it views as load balancers, including ADNR. ADNR uses the availability information but does not use the weight information.

For more information about this function, see Chapter 23, "z/OS Load Balancing Advisor," on page 1219.

For more information about z/OS Load Balancing Advisor configuration considerations, see "z/OS Load Balancing Advisor configuration considerations" on page 1292.

Enabling TLS/SSL for ADNR

Consider whether to use AT-TLS for security between ADNR and the z/OS Load Balancing Advisor. AT-TLS provides the ability to authenticate a client, check authorizations, and encrypt data. You must restrict the ability to establish a connection to the Advisor, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. Because ADNR acts as a client to the Load Balancing Advisor SASP port, it must be explicitly authorized to establish its connection to the Load Balancing Advisor.

You can use one or both of the following methods to authorize connection to the z/OS Load Balancing Advisor:

- You can explicitly configure the host_connection_addr keyword on the gwm statement in the ADNR configuration file, and the corresponding lb_id_list statement in the Advisor's configuration file.
- You can establish policies using the z/OS Policy Agent so that ADNR is required to use AT-TLS.

Although the configuration parameters might be sufficient in certain environments where the Load Balancing Advisor and ADNR reside inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important. For more information about using AT-TLS, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193. For more information about the Advisor, see Chapter 23, "z/OS Load Balancing Advisor," on page 1219.

Steps for configuring automated domain name registration

Perform the following steps to configure the automated domain name registration (ADNR) application.

1. Decide which sysplex resources should be managed by ADNR.
2. Decide on one or more domain names to be managed by ADNR.
3. Decide which name server or name servers are to be managed by ADNR.
4. Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage.
5. Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server.
6. Configure the z/OS Load Balancing Advisor (LBA) function.
7. Define security server profiles for ADNR.

8. Configure ADNR to automatically restart in case of application or system failure. (optional)
9. Configure and start syslogd. (optional, but required to have ADNR write log messages and trace data to syslogd)
10. Configure one ADNR application per sysplex.
11. Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run. (optional)
12. Start the TCP/IP stacks on which ADNR and the LBA applications are to run.
13. Start the z/OS Load Balancing Advisor and Agent.
14. Start the target applications that are to be managed by ADNR.
15. Start the ADNR application.
16. Verify that the ADNR system is functioning correctly. (optional)

These steps are described in detail in the following subtopics.

Step 1: Decide which sysplex resources should be managed by ADNR

ADNR can manage two types of sysplex resources, including server applications and the traditional DNS mappings of host names to IP addresses. Server applications are represented in ADNR as server groups using the server_groups statement. Traditional DNS host name-to-IP address mappings are represented as host groups using the host_groups statement. For more information about server groups and host groups, see "Identifying the sysplex resources to be managed by ADNR" on page 1286.

ADNR can dynamically create application-specific host names in a name server to represent a cluster of equivalent servers in the sysplex. For example, the name ztelnet.mvsplex.mycorp.com can represent all TN3270E Telnet server applications in the sysplex. Any TCP or UDP server application in the sysplex can be managed by ADNR and have application-specific host names dynamically added and removed from a name server to represent active instances of those servers. As server applications become available, ADNR dynamically adds resource records representing those instances to the name servers managed by ADNR. As those server applications or their systems become unavailable, ADNR dynamically deletes resource records representing those instances from the name servers it manages. These types of DNS names can be used to connect to any active instance of a particular type of server. ADNR also dynamically creates and removes application-specific host names that represent individual instances of server applications as they become available and unavailable.

Most IP addresses in the home lists of sysplex hosts can be dynamically added to the name server as traditional DNS name-to-IP address mappings. As IP addresses are removed from a home list (for example, by issuing a VARY TCPIP,,OBEYFILE command), the DNS resource records representing those IP addresses are dynamically removed from the ADNR-managed name servers. These types of DNS names can be used to connect to any resource in the sysplex, or on a particular sysplex host without regard to which servers are available on that system, such as when using the **ping** or **traceroute** commands.

The IP addresses that are added to DNS by ADNR can be interface addresses, static VIPAs, or dynamic VIPAs (DVIPAs). A small set of addresses cannot be managed by ADNR because of z/OS Load Balancing Advisor restrictions. For more information, see “Step 15: Configure the external load balancers” on page 1241 and the restriction that certain classes of IP addresses must not be coded for members in the load balancer.

You might want to make some sysplex resources visible to some set of clients and not visible to other sets of clients. For example, you might want to add DNS entries to make some sysplex resources visible to intranet clients, but not make the resources visible to Internet clients. There are several ways to accomplish this. Some methods can be accomplished with only name server configuration, others might involve ADNR configuration. For more information, see “Split DNS (views)” on page 1297.

Step 2: Decide on one or more domain names to be managed by ADNR

All resource records added to a name server have a domain suffix related to a name server zone. Typically, an enterprise's domain suffix is something like mycorp.com. Subdomains can exist under a domain, which have the subdomain name added before the parent's domain suffix, such as raleigh.mycorp.com and austin.mycorp.com.

Guideline: Because ADNR should be the only entity updating the zones it manages, ADNR should manage one or more unique sub-zones. For example, if your enterprise has a domain name of mycorp.com, ADNR can be configured to manage resources in a domain called mvsplex.mycorp.com.

The domain suffix of the resource records that ADNR creates is determined by the domain_suffix keyword of the zone keyword of the dns statement in the ADNR configuration file.

Step 3: Decide which name server or name servers are to be managed by ADNR

The name servers that ADNR manages can reside on z/OS or other platforms, as long as the name server supports RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. On z/OS, the BIND 9 name server supports this RFC. For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1555.

The name servers that ADNR communicates with can be existing name servers, or name servers you set up exclusively for ADNR. Each name server that ADNR is to communicate with is identified on the dns_id keyword of the dns statement.

You might also want to configure one or more secondary name servers for the ADNR-managed zones. Secondary name servers replicate zone data information from the master name server for those zones. Typically, secondary name servers are configured to avoid a single point of failure if a name server fails, and to reduce network traffic by locating secondary name servers in strategic areas of a network so that name server lookups traverse fewer hops in the network. For more information, see “Configuring a secondary name server” on page 800.

ADNR does not communicate directly with secondary name servers. Secondary name servers communicate directly with the master name server by performing

zone transfers. Ideally, because of the dynamic nature of the data in the zones that ADNR manages, secondary name servers need to be updated as soon as the master name server is updated by ADNR. Otherwise, the secondary name server contains stale information that does not accurately reflect the current availability of sysplex resources. Some name server implementations can minimize the latency with which secondary name servers are updated from their masters, if they have implemented RFC 1996, *A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)*. The z/OS BIND 9 name server supports this standard. For more information on z/OS BIND 9 name server options, see *z/OS Communications Server: IP Configuration Reference*. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Step 4: Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage

The name servers that ADNR communicates with must be configured as the primary master name servers of the zones that ADNR will manage. For more information and further references about configuring the zones that ADNR is to manage in the name server, see "Initial zone configuration" on page 1294.

Step 5: Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server

Typically, the DNS domains that ADNR manages are subdomains of an existing DNS domain. For resolvers to reliably find resource records in the ADNR-managed subdomains, the ADNR-managed subdomain must be delegated by its parent domain. This enables resolvers to find resource records in the ADNR-managed subdomain if those resolvers are not pointing directly to the ADNR-managed name server. DNS queries from resolvers can follow the DNS delegation tree downward from the root domain, if necessary, and find an authoritative name server for the ADNR-managed subdomain.

Delegating a subdomain from a parent involves updating the parent domain's zone data file. In the parent's zone data file, an NS record and an associated A or AAAA glue record is added to represent each authoritative name server for the child domain. For example, to delegate the ADNR-managed mvsplex.mycorp.com zone from the mycorp.com zone, the following resource records are added to the zone data file for the mycorp.com zone:

```
mvsplex  86400    IN NS    mvsnameserver.mvsplex.mycorp.com.
         86400    IN NS    networknameserver.mvsplex.mycorp.com.
mvsnameserver.mvsplex.mycorp.com.     86400      IN A       10.5.1.1
networknameserver.mvsplex.mycorp.com. 86400      IN AAAA    2001:0DB8:0:0:8:800:200C:417A
```

The example resource records delegate the mvsplex.mycorp.com zone to two authoritative name servers, one of which must be the master name server and the other a secondary name server.

Step 6: Configure the z/OS Load Balancing Advisor function

Configuring and running the z/OS Load Balancing Advisor (LBA) function is a corequisite to implementing ADNR. The z/OS Load Balancing Advisor application communicates with ADNR and serves as ADNR's Global Workload Manager (GWM). The z/OS Load Balancing Agents communicate with the Advisor application and supply it, and ultimately ADNR, with information about the availability of the resources that ADNR has registered with the Advisor. Therefore,

each system in the sysplex that contains resources that you want ADNR to manage must be running an Agent, and one system in the sysplex must be running an Advisor.

The Advisor views ADNR as a load balancer, although ADNR does not perform load balancing. ADNR merely uses the information to update the name servers based on the resource availability that the Advisor provides. Therefore, to enable ADNR to connect to the Advisor, the source IP address that ADNR uses to connect to the Advisor must be configured in the Advisor's lb_id_list statement, if AT-TLS is not used. For information about the lb_id_list statement, see *z/OS Communications Server: IP Configuration Reference*.

For complete information about configuring the Advisor and Agents, see "Steps for configuring the z/OS Load Balancing Advisor" on page 1222. While following those steps, you should skip step 10 to start the TCP/IP stacks that the Advisor and Agents will use until completing the TCP/IP profile customization for those stacks, described in "Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)" on page 1289. You should also skip steps 13 and 14 in those steps, starting the Agents and Advisor, until you reach "Step 13: Start the z/OS Load Balancing Advisor and Agent" on page 1290.

Step 7: Define security server profiles for ADNR

Create a USERID profile for ADNR as follows:

```
ADDUSER  ADNR     DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(nn) -
         HOME('/RDWR_working_directory') PROGRAM('/bin/sh'))
```

ADNR must have read and write access to the directory specified on the HOME keyword. This directory becomes ADNR's working directory. ADNR creates and deletes temporary files in this directory during its operation. The UID value, *nn*, can be zero or nonzero.

ADNR is a multi-threaded application. If you define an unusually large number of name servers or zones to ADNR, you should check to determine whether the maximum number of threads allowed per process, represented by the THREADSMAX value in BPXPRM*xx*, is going to be exceeded. The number of threads required for ADNR is determined in the following way: (number of dns statements) + (number of zone keywords within all dns statements) + 3. You can customize the maximum number of threads allowed for ADNR by specifying the THREADSMAX keyword on the ADDUSER command.

The program specified on the user ID assigned to run ADNR must be /bin/sh. For more information about specifying a user program and the ADDUSER command, see *z/OS Security Server RACF Command Language Reference*.

Add ADNR to the STARTED class profile:

```
RDEFINE  STARTED  ADNR.*           STDATA(USER(ADNR))
```

Grant explicit authority to all users that can start ADNR, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start ADNR.

Steps for granting authority to start ADNR

Perform the following steps to grant authority to start ADNR.

1. Ensure that the OPERCMDS class is active and RACLISTed, and that RACLIST processing is enabled:

   ```
   SETROPTS CLASSACT(OPERCMDS)
   SETROPTS RACLIST (OPERCMDS)
   ```

2. Define the following OPERCMDS class profile using a security product like RACF:

   ```
   RDEFINE  OPERCMDS (MVS.SERVMGR.ADNR) UACC(NONE)
   ```

3. Grant ADNR access to the OPERCMDS class:

   ```
   PERMIT   MVS.SERVMGR.ADNR CLASS(OPERCMDS) ACCESS(CONTROL) -
                             ID(userid)
   ```

4. Refresh the OPERCMDS class:

   ```
   SETROPTS RACLIST(OPERCMDS) REFRESH
   ```

5. See the EZARACF sample in SEZAINST for specific instructions.

   All commands that you can issue against ADNR are MODIFY commands, with the exception of the STOP command used to stop ADNR. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)

Automatically restarting ADNR minimizes the period of time that name servers do not accurately reflect the status of sysplex resources. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information about defining ARM policies, see *z/OS MVS Setting Up a Sysplex*.

ADNR registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBADNRelemsuffix
TERMTYPE=ALLTERM
```

The *elemsuffix* value is specified in the arm_element_suffix configuration statement. ADNR registers the element name EZBADNR concatenated with the *elemsuffix* value. If there is no arm_element_suffix statement, the ELEMNAME is EZBADNR. For example, if the following statement is configured:

```
arm_element_suffix SYS1
```

ADNR registers ELEMNAME=EZBADNRSYS1.

When ADNR registers with ARM using these values, then if ADNR fails or the system fails, ADNR can be restarted on any system in the sysplex.

An ARM policy or other automation software should be in place to quickly restart the TCP/IP stack that ADNR is running on if the TCP/IP stack fails. ADNR continues to run after its TCP/IP stack fails, and reconnects to its GWM once the TCP/IP stack is recovered.

Although this step is optional, performing it provides high availability to your target applications. In the event that ADNR fails, the name servers it manages are no longer updated with sysplex resource availability information. As a result, client connections might fail because the name server might resolve their requests to application instances that are not available, or be unable to resolve DNS requests to

any application when active application instances might actually exist. When ADNR is restarted, it again accurately reflects the availability of sysplex resources after its convergence period. The *convergence period* is twice the interval at which the Advisor normally updates ADNR with new information. The interval is determined by the update_interval statement in the Advisor's configuration file.

Guidelines:

- Each ADNR instance should have a unique ARM element name within a sysplex.
- Establish an ARM policy with TCP/IP at a lower level than ADNR, so that TCP/IP is restarted before ADNR is restarted. For more information, see *z/OS MVS Setting Up a Sysplex*.
- To enable ADNR to continue operating on another TCP/IP stack in a Common INET (CINET) environment in the case of TCP/IP stack failure, or to restart on another system in case of system failure, configure ADNR with a unique application-instance DVIPA. The unique application-instance DVIPA is coded on the host_connection_addr keyword of the gwm statement. For more information about unique application-instance DVIPAs, see "Configuring the unique application-instance scenario" on page 364.

Rule: AUTOLOG can be used to start ADNR when the TCP/IP stack is started, but it cannot be used for ADNR recovery. Using AUTOLOG for recovery requires port reservation, but ADNR does not listen on a port. Therefore, ADNR can appear in the TCP/IP AUTOLOG statement, but it cannot appear on the PORT statement. ADNR uses ephemeral ports when connecting to its GWM.

Requirement: ADNR does not run using a system key. Therefore, if you are using ARM registration, the started task ID needs to be permitted with UPDATE authority to the associated IXCARM.SYSTCPIP.EZBADNR* profile in the FACILITY class within the SAF product on your system. To enable ADNR to register to ARM, use the following RACF commands to define the profile and grant update access to the user ID that is assigned to start ADNR:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBADNR* UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBADNR* CLASS(FACILITY) ID(ADNR) ACCESS(UPDATE)
SETROPTS REFRESH RACLIST(FACILITY)
```

Restriction: If ADNR is using IPv6 for the GWM connection, or if ADNR is using IPv6 to connect to a name server, movement of ADNR is limited to those TCP/IP stacks that are enabled and configured for IPv6. For considerations for configuring z/OS for IPv6, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd)

ADNR writes most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For ADNR to be able to write log messages and trace data to syslogd, syslogd must be properly configured and started before ADNR is started.

Because you might be running ADNR on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and ADNR log output in separate files. For further information, see "Configuring the syslog daemon" on page 185.

Step 10: Configure one ADNR application per sysplex

ADNR reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan to enable ADNR to move within the sysplex in the case of failure, the ADNR configuration file or data set should be on shared DASD, to make it accessible to all systems in the sysplex if necessary. The ADNR configuration file is specified on the CONFIG DD statement in the ADNR start procedure. A sample start procedure is provided in EZBADNRS in SEZAINST.

The ADNR configuration file serves five basic purposes:

- Identifies the name servers to update and the zones to be updated in those name servers
- Identifies the GWM to connect to and IP address to bind to for communications with the GWM
- Identifies the sysplex resources to be managed by ADNR
- Uniquely identifies the ADNR instance
- Customizes optional statements

A sample ADNR configuration file is provided in EZBADNRC in SEZAINST.

Tip: Consistent with the Advisor and Agent configuration terminology, any statement or keyword containing the word *connection* refers to a local socket, and any statement containing the word *id* refers to a remote address and possibly a port.

The ADNR configuration file contains statements or keywords that reference other statements or keywords. All such references are made using labels.

Identifying the name servers to update and the zones to be updated in those name servers

Use the dns statement to identify the location of a name server to be managed by ADNR. This statement has a dns_id keyword that contains the IP address of a name server and optionally a port. You can code multiple dns statements.

Rule: In general, for data integrity reasons, multiple dns statements should not refer to the same name server. However, if you are configuring ADNR to work with a split DNS configuration, this is acceptable. For more information, see "Split DNS (views)" on page 1297.

The dns statement also contains one or more zone keywords that identify a zone in the name server to be updated. The domain suffix specified on the domain_suffix parameter must represent a zone previously configured in the name server that is being updated. For more information, see "Initial zone configuration" on page 1294.

The zone keyword contains three optional parameters, update_key, transfer_key, and ttl.

- The update_key parameter and the transfer_key parameter enable the use of digital signatures on requests sent from ADNR to the name server. The digital signatures provide a way for the name server to authenticate ADNR as a client that is authorized to update the name server and to receive zone transfer information. These digital signatures are called transaction signatures (TSIG). Use of TSIGs requires coordination between ADNR configuration and name

server configuration. For more information about TSIG security, see "Authorizing dynamic updates" on page 1294 and "Authorizing zone transfers" on page 1296.

- The ttl parameter determines how long resolvers and non-authoritative name servers keep ADNR-managed resource records cached. For more information, see "Near real-time availability information of sysplex resources" on page 1292.

Identifying the GWM to connect to and IP address to bind to for communications with the GWM

Specify the location of the GWM on the gwm_id keyword of the gwm statement. This keyword contains an IP address and optionally a port that the GWM uses to listen for connections from load balancers. From the GWM's point of view, ADNR is considered a load balancer.

Specify the IP address that ADNR will bind to for communications with the GWM on the host_connection_addr keyword of the gwm statement. If you are using AT-TLS, the host_connection_addr keyword is optional.

Rules:

- The IP address specified on the gwm_id keyword of the gwm statement must match the address specified on the lb_connection_v4 statement or the lb_connection_v6 statement in the Advisor configuration file.
- The port specified on the gwm_id keyword of the gwm statement must match the port specified on the Advisor's lb_connection_v4 or lb_connection_v6 statement, depending upon whether you specify an IPv4 or IPv6 address, respectively, on the gwm_id keyword.
- If an IPv4 address is specified on the gwm_id keyword of the gwm statement, an IPv4 address must be specified on the host_connection_addr keyword of the gwm statement. Similarly, if an IPv6 address is specified on the gwm_id keyword of the gwm statement, an IPv6 address must be specified on the host_connection_addr keyword of the gwm statement.

Guideline: For high availability, use a unique application-instance DVIPA for the address on the host_connection_addr keyword. This enables ADNR to be moved to another TCP/IP stack or another system in the event of TCP/IP stack or system failure.

Identifying the sysplex resources to be managed by ADNR

Specify which sysplex resources should be managed by ADNR using the host_group and server_group statements.

Host groups: The host_group statement identifies the set of IP addresses to update in a name server that represents a group of hosts. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the host_group statement and the IP addresses that exist in the home lists of the hosts in the sysplex. The DNS names that are dynamically added to the name server take the form *host_group_name.domain_suffix*, where *host_group_name* is the ADNR administrator-defined name of the group of hosts being registered to the GWM, and *domain_suffix* is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the host_group_name keyword of the host_group statement is used, followed by the value of the domain_suffix keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.

ADNR can also update name servers with DNS names representing individual host instances within the sysplex, using the member keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses that exist in the home list of a particular host in the sysplex. The DNS names that are dynamically added to the name server take the form *host_name.domain_suffix*, where *host_name* is the ADNR administrator-defined name of the member being registered to the GWM, and *domain_suffix* is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the host_name keyword of the host_group statement is used, followed by the value of the domain_suffix keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the host_group statement contains a member keyword containing an optional host_name parameter, the name server is updated with these types of DNS names.

A host_group statement can have multiple member keywords within it. One of the coded member keywords does not have to have a host_name parameter. The member without a host_name parameter is sometimes referred to as the *unnamed member*, while members with a host_name parameter are sometimes referred to as *named members*. The IP addresses associated with the unnamed member are ones that can potentially be dynamically added to the name server with the DNS name of the form *host_group_name.domain_suffix*. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if you do not configure one.

Result: The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that host group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, you configure one named member per system in the sysplex. Each named member contains IP addresses that cannot move to other systems in the sysplex.

Guideline: To provide reachability to the sysplex or system in case of interface failure, configure named members of host_group statements with static VIPAs. In addition, you can also code an unnamed member, and associate with it IP addresses that could potentially be moved from one system to another (DVIPAs).

Host names added to a name server using ADNR might be useful for situations when you want connectivity to the sysplex or a host in the sysplex, but the presence of a particular server is not required. For this reason, host group names would be useful for utilities such as ping or traceroute.

Server groups: The server_group statement identifies the set of IP addresses to update in a name server that represents a cluster of equivalent servers in the sysplex. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the server_group statement and the IP addresses on which each server in the group can be reached in the sysplex. The DNS names dynamically added to the name server take the form *server_group_name.domain_suffix*, where *server_group_name* is the ADNR administrator-defined name of the group of servers being registered to the GWM, and *domain_suffix* is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the server_group_name keyword of the server_group statement is used, followed by the value of the

domain_suffix keyword of the zone referenced in the server_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.

ADNR can also update name servers with DNS names representing individual server instances within the sysplex, using the member keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses on which the server can be reached on a particular host in the sysplex. The DNS names dynamically added to the name server take the form *server_name.server_group_name.domain_suffix*, where *server_name* is the ADNR administrator-defined name of the member being registered to the GWM, *server_group_name* is the ADNR administrator-defined name of the group of servers being registered to the GWM, and *domain_suffix* is the domain suffix name specified in a zone parameter on a dns statement. To construct the DNS name, the value of the server_name parameter of the server_group statement is used, followed by the value of the server_name keyword of the server_group statement, followed by the value of the domain_suffix keyword of the zone referenced in the host_group statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the server_group statement contains a member keyword containing an optional server_name parameter, the name server is updated with these types of DNS names.

A server_group statement can have multiple member keywords within it. One of the coded member keywords does not have to have a server_name parameter. The member without a server_name parameter is sometimes referred to as the *unnamed member*, while members with a server_name parameter are sometimes referred to as *named members*. The IP addresses associated with the unnamed member are ones that can be dynamically added to the name server with the DNS name of the form *server_group_name.domain_suffix*. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if one is not configured.

Result: The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that server group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, if affinity to a particular server instance is important, you configure one named member per server instance in the sysplex. If affinity to a particular server instance is not important, configuring only an unnamed member suffices.

Guideline: For high availability to the target applications to prevent reachability problems in the event of interface failure, IP addresses in server_group statements should either be static or dynamic VIPAs. If the target application is enabled to move from one TCP/IP stack to another, DVIPAs are appropriate for the server group. Otherwise, static VIPAs are appropriate.

Uniquely identifying this ADNR instance

ADNR appears as a load balancer to the GWM that it connects to. Each load balancer must uniquely identify itself to the GWM. Therefore, each ADNR instance must be uniquely identified, to distinguish it from other ADNR instances, as well as external load balancers that connect to a GWM using SASP. Use the uuid (universally unique ID) statement of the ADNR configuration file to uniquely identify an ADNR instance.

According to the SASP protocol, each load balancer should be universally unique from all other load balancers. In practical terms, only load balancers that connect to the same GWM must be unique.

Guideline: To prevent possible future uuid conflicts among load balancer and ADNR, the uuid configured for each ADNR instance should be universally unique.

Customizing optional statements

Customize the optional statements in the ADNR configuration file.

The optional debug_level statement determines how much log data is captured in the ADNR's log file.

Restriction: In most cases, you should not customize the debug_level statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default value might make diagnosing a problem more difficult.

Technically, the host_group and server_group statements are optional. They can be omitted to flush a name server of all ADNR-managed resource records. However, if you omit these statements, ADNR will not manage name servers for the sysplex until the ADNR configuration file is updated with host_group and server_group statements and the MODIFY REFRESH command is issued. When no host_group or server_group statements are configured, the ipaddrlist statement is also optional. For more information, see “Flushing a zone” on page 1300.

The key statement defines the key file used in creating digital signatures, which is used when specifying transaction signatures (TSIGs) for zone updates and zone transfers. For more information about keys, see “Authorizing dynamic updates” on page 1294 and “Authorizing zone transfers” on page 1296.

Guideline: Key files must have access permissions that allow ADNR to read the file, either as the file's owner or as a member of the associated group.

Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)

The TCP/IP profiles can optionally be customized to better accommodate ADNR, the Advisor, and Agents. For information about Advisor and Agent TCP/IP profile customization, see “Step 9: Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)” on page 1235. You might have already performed the steps for customizing the Advisor and Agent TCP/IP profiles in “Step 6: Configure the z/OS Load Balancing Advisor function” on page 1281.

If you use dynamic VIPAs for ADNR, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions include VIPARANGE with MOVEABLE NONDISRUPTIVE. For more specific information, see “Using dynamic VIPAs” on page 359.

If you are using AT-TLS, you need to perform several steps to set up the z/OS Policy Agent, enable ADNR's TCP/IP stack for AT-TLS, and so on. For more information, see “Step 9: Customize the TCP/IP profiles of the TCP/IP stacks that the Advisor and Agents will run on (optional)” on page 1235. For ADNR, you

need to customize the AT-TLS policies that are identified with the CommonTTLSConfig and TTLSConfig statements.

Tip: Because ADNR and the Agent are both client applications to the Advisor, you can define AT-TLS policy rules similar to the LBAdvisorAgentRule and the LBAgentRule for ADNR.

Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run

You can start ADNR before or after you start the TCP/IP stack it uses. If the TCP/IP stack that ADNR uses terminates or is not yet started, ADNR remains active and establishes communication with the TCP/IP stack when it becomes active. For additional information about the Advisor and Agents, see "Step 10: Start the TCP/IP stacks that the Advisor and the Agents will use" on page 1240.

Step 13: Start the z/OS Load Balancing Advisor and Agent

You can start the z/OS Load Balancing Advisor and Agents before or after you start ADNR. If you start ADNR before you start the Advisor, an eventual action message, EZD1272E, is displayed until the Advisor is active and a connection is successful. When a successful connection is established, ADNR issues message EZD1270I, and the Advisor issues message EZD1263I indicating that a load balancer connected. At the same time, the eventual action message is converted to a non-action message (DOMed). If Agents were not active at the time that ADNR and the Advisor established a connection, Agents report on any ADNR-registered resources that the Agent owns when the Agent becomes active. ADNR updates its name servers with that information at that time.

Step 14: Start the target applications that are to be managed by ADNR

ADNR can manage TCP and UDP server applications. No modifications are necessary to these applications, their configurations, or start procedures.

Step 15: Start the ADNR application

As ADNR connects to the Advisor, an MVS console message appears on the MVS console of the system on which ADNR is running. Simultaneously, a message appears on the Advisor's MVS console, indicating that a load balancer connected. If ADNR fails to connect to the Advisor, an eventual action message is displayed on ADNR's MVS console until the connection is successful. ADNR must be started from a job control procedure residing in a procedure library. It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make ADNR run non-swappable. You should not override this entry to make ADNR run swappable.

Step 16: Verify that the ADNR system is functioning correctly (optional)

View the MVS console of the ADNR system after you have started it to verify that the application started correctly and is still running. If there are any failure messages, see the appropriate message description for the proper corrective action. View the syslogd file of the ADNR system to see whether any error or warning messages were issued.

Use the following commands to verify that ADNR is functioning correctly:

- If connectivity cannot be established, ADNR issues the eventual action message `EZD1272E, ADNR CONNECTION ATTEMPT TO GWM gwmipaddress FAILED`. If this message is issued and the GWM is active, verify that routing exists between the IP addresses used by the GWM and ADNR.
- Verify that ADNR is started and connected to the expected Advisor by issuing ADNR's MODIFY *procname*,DISPLAY,GWM,DETAIL command. Verify that the GWM IP address and port is the expected IP address and port of the Advisor to which you intended to connect.
- From the Advisor, issue the MODIFY *procname*,DISPLAY,LB command to list the LB indexes known to the Advisor. Identify the LB index representing ADNR, and then issue the Advisor MODIFY *procname*,LB,INDEX=*lb-index* command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for the Advisor, see *z/OS Communications Server: IP System Administrator's Commands*.
- Verify that server and host groups have been properly registered to the GWM by issuing ADNR's MODIFY *procname*,DISPLAY,GWM,GROUPS,DETAIL command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for ADNR, see *z/OS Communications Server: IP System Administrator's Commands*.
- Verify that Agents are aware of members that they own by issuing the MODIFY *procname*,DISPLAY,MEMBERS Agent command. Any ADNR-registered IP addresses owned by the system where the Agent is running should appear in the display.
- Verify that ADNR is able to communicate properly with the name servers it manages by issuing ADNR's MODIFY *procname*,DISPLAY,DNS,ZONES,SUMMARY command. Verify that the ZONE STATUS field is or changes to SYNCHRONIZED after the convergence period expires. For the definition of the convergence period, see "Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)" on page 1283. If any zone status begins with the value NOT_RESPONSIVE, there is either a connectivity problem between ADNR and the name server, or there is a configuration mismatch between ADNR and the name server. For more information about diagnosing unresponsive zones, see *z/OS Communications Server: IP Diagnosis Guide*. If ADNR is unable to properly communicate with a name server, ADNR issues eventual action message EZD1278E, which remains until the problem is resolved.
- Verify that name servers reflect the availability status of the sysplex resources that you have configured with ADNR. Issue ADNR's MODIFY *procname*,DISPLAY,ZONES,ZONEID=*zone_label*,DETAIL command for each zone configured to ADNR, or issue the MODIFY *procname*,DISPLAY,ZONES,DETAIL to view all zones. Verify that the DNS RR STATUS field for each resource record display is PRESENT for each resource that is available in the sysplex.
- Use the z/OS UNIX **dig** command to perform a zone transfer of the ADNR-managed zones, and verify that the zone contents match the expected content, based on the members configured to ADNR and the availability status of those members in the sysplex. The **dig** command to use has the following form:

  ```
  dig @name_server_address  domain_name axfr
  ```

  Tip: If zone transfers were restricted by name server configuration to clients from specific IP addresses or from clients that have digitally signed their

requests (TSIG), you might have to issue the **dig** command with the **-b** option or the **-k** option to, respectively, force the request to originate from a specific IP address or be digitally signed with the proper signature. For more information about the **dig** command, see *z/OS Communications Server: IP System Administrator's Commands*.

- Verify that ADNR is functioning correctly when using AT-TLS:
  - Use the **pasearch** command from the z/OS UNIX shell to query information from the Policy Agent. For more information about displaying policy based networking information, see *z/OS Communications Server: IP System Administrator's Commands*.
  - Use the Netstat TTLS/-x command to display z/OS Load Balancing Advisor and ADNR AT-TLS policies. For more information about the Netstat TTLS/-x report, see *z/OS Communications Server: IP System Administrator's Commands*.

z/OS Load Balancing Advisor configuration considerations

The z/OS Load Balancing Advisor solution consists of a z/OS Load Balancing Advisor application, and one or more z/OS Load Balancing Agents, per sysplex. For more information about the z/OS Load Balancing Advisor solution, see Chapter 23, "z/OS Load Balancing Advisor," on page 1219.

Connectivity considerations

ADNR connects to the Advisor. The Advisor can use an access control list (ACL) to determine which load balancers are permitted to connect to it. From the Advisor's perspective, ADNR is considered to be a load balancer.

Rules:

- If you are not using AT-TLS, the Advisor's lb_id_list statement must include the IP address coded on the host_connection_addr keyword of the ADNR gwm statement. If you are using AT-TLS for all ADNR-Advisor connections, the lb_id_list statement and host_connection_addr keyword are ignored. If you are defining external load balancers that are not using TLS/SSL, the lb_id_list statement is required.
- The IP address and port coded on the Advisor's lb_connection_v4 or lb_connection_v6 statement must match the IP address and port coded on the gwm_id keyword of the ADNR gwm statement, depending on the address family used.

Guideline: For availability reasons, the IP address coded on the gwm_id keyword of the ADNR gwm statement should be a unique application-instance DVIPA.

Near real-time availability information of sysplex resources

To take advantage of the near real-time availability information that ADNR can provide regarding sysplex resources, clients must query the ADNR-managed name servers relatively frequently rather than use cached information from a previous name server query. The length of time that name server information is cached is typically controlled by the Time To Live (TTL) value received from the name server. A TTL is associated with each resource record in a name server, and the TTL information is part of the information that the resolver receives when the name server successfully responds to a query. ADNR provides a mechanism to define the TTL for name server resources it manages.

ADNR permits the TTL to be defined to a specific value per zone, or it can be set to a value determined by the GWM, which is the default. When the TTL value is the default value determined by the GWM, it takes on the update_interval value in the Advisor's configuration file.

Guideline: Allowing the GWM to set the TTL for an ADNR zone by using the default TTL value enables clients to obtain the most accurate, near real-time sysplex resource availability information, without wasting network resources with unnecessary DNS queries.

Because ADNR can be configured to use a GWM-defined interval to set the TTL value, the GWM can dynamically change this interval. The z/OS Load Balancing Advisor does not support dynamically changing this interval, but a future Advisor implementation or other future GWM implementations might. If this occurs, ADNR has the capability to find out about the new GWM interval only when the connection to the GWM is re-established.

z/OS Load Balancing Advisor and Agent operational considerations

Several operational characteristics of the z/OS Load Balancing Advisor and Agent can affect ADNR.

Advisor operational considerations

For ADNR to accurately maintain the resource records that represent available sysplex resources in its managed name servers, the Advisor and all Agents in the sysplex need to be active. If the Advisor stops, ADNR can no longer receive information about the current availability of sysplex resources, and consequently, the resource records in the name servers that ADNR manages eventually become stale. That is, resource records are left in the name server representing sysplex resources that are no longer available, or resource records are not added to the name server to represent sysplex resources that have become available. Because of the ramifications of the Advisor becoming unavailable, you should perform the necessary configuration for optimal availability of the Advisor. For more information, see “Step 5: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1225.

Agent operational considerations

If an Agent in the sysplex stops, all resource records in the ADNR-managed name servers that represent sysplex resources managed by that Agent are removed from the name server. This makes it appear as though the resources are unavailable when they actually might be available. For this reason, it is important to perform the necessary configuration for optimal availability of each Agent. For more information, see “Step 5: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)” on page 1225.

The Agent is also capable of making resources appear unavailable to ADNR by quiescing them with the Agent's MODIFY QUIESCE command. All resource records in a name server associated with a quiesced member are removed and are not added back until the member is enabled with the Agent's MODIFY ENABLE command, or if the Agent is stopped and restarted.

Name server configuration considerations

The name servers that ADNR manages can reside on z/OS or other platforms, as long as the name server supports RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. On z/OS, the BIND 9 name server supports this RFC. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Many of the subjects discussed in this topic are applicable to other name server implementations. For the z/OS BIND 9 name server, specific instructions are provided for how to accomplish configuration objectives. For other name server implementations, consult the appropriate product documentation.

Initial zone configuration

ADNR cannot create a zone in a name server. It can only add and delete resource records from an existing zone. The zones that ADNR manages must initially be configured to the appropriate name servers. This involves defining the zone and a small set of resource records in the zone. This includes the SOA record, the appropriate NS records, and the A or AAAA glue records.

For the z/OS BIND 9 name server, see "Step 1: Create the configuration file for BIND 9–DNS" on page 784 and "Step 4: Create the domain data files (master name server only)" on page 787.

Rule: Do not configure any valuable A or AAAA resource records in the zone data files that ADNR will manage. ADNR deletes any type A or AAAA resource records that were not added by ADNR, with the exception of glue resource records (see "Updates to an ADNR-managed zone" on page 1295). These resource records are deleted when ADNR starts, or during MODIFY REFRESH processing.

Restriction: ADNR does not support DNSSEC signed zones.

Authorizing dynamic updates

Name servers can be configured to allow dynamic updates from only specific entities. If a name server that ADNR updates is configured to restrict which entities can update the name server, ADNR must be specifically permitted to update that name server. Name servers typically permit dynamic updates from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they might require authentication with digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration. Other possible options for lessening the impact of the unpredictability of the source IP address that ADNR uses include using a subnet in the name server's ACL. However, this allows updates from any entity in that subnet, which compromises security.

Guideline: Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the z/OS BIND 9 name server, dynamic updates are allowed by ACL using the allow-update statement, or by digital signatures using the update-policy or the allow-update statement.

When dynamic updates are permitted using digital signatures (TSIG), the name server and ADNR must be configured with the same shared cryptographic key. You can generate the key using the dnssec-keygen utility. Then you define the key to the name server and reference the key from name server zone definitions that want to use it.

For z/OS BIND 9, for information about how to create a TSIG key and define it to the name server, see "TSIG" on page 821.

You must also define the TSIG key to ADNR using the key configuration statement, and then reference the TSIG key from the update_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key key file name is actually specified on the update_key keyword.

Updates to an ADNR-managed zone

Typically, zones managed by ADNR should not be updated by any entity other than ADNR. This includes manual editing of the zone data file, or dynamic updates from any other source. Many name server implementations strongly advise against manually editing the zone data file of a dynamic zone, such as the zones managed by ADNR. Editing these files has the potential to corrupt the file, or the updates can be lost. However, in general from a name server perspective, dynamic updates using a tool such as nsupdate are allowed for dynamic zones. In the case of ADNR-managed zones, certain types of dynamic updates can be made by entities other than ADNR. Table 61 shows which types of resource records can be dynamically added and deleted by entities other than ADNR.

Table 61. Dynamic updates of ADNR-managed zones by other entities

Allowed dynamic updates	Disallowed dynamic updates
All resource record types other than A and AAAA	A and AAAA resource records that are not considered glue records
A and AAAA resource record types that are considered glue records	
Tip: Glue records are A or AAAA records that store the IP addresses of authoritative name servers.	

Any disallowed resource records that appear in dynamic update requests to ADNR-managed zones are accepted by the name server, but are subject to being deleted by ADNR at a later time.

Rule: ADNR uses a special domain name for determining whether a name server is active and configured correctly to allow dynamic updates. At times, ADNR dynamically performs an update-add and an update-delete of the following resource record:

```
ibmsaspddnsdnsprobe IN A 0.0.0.0
```

In the unlikely event that this same resource record is added to an ADNR-managed zone by an entity other than ADNR, it is subject to being deleted by ADNR in the future.

Update forwarding

Update forwarding is a DNS concept in some name server implementations that enables dynamic updates to be sent to a name server that is not the primary master name server for the zone being updated. The name server that receives the dynamic update request forwards the update to the primary master name server.

Rule: To avoid possible zone data-integrity issues, ADNR must be configured to update only the primary master name server for a zone. That is, the IP address of a name server on the dns_id keyword of the dns statement must be an address of the primary master name server for the zone identified on the domain_suffix keyword, and must not be the IP address of a secondary name server for that zone.

Authorizing zone transfers

Zone transfers are operations that are typically performed between authoritative name servers of a particular zone. A zone transfer occurs when all or part of the contents of a zone is sent from the name server to the requester. ADNR requests zone transfers from the primary master name server of the zones it manages. Name servers can be configured to allow zone transfers only from specific entities. If the name servers that ADNR is to update are configured to restrict which entities can perform zone transfers, ADNR must be specifically permitted to perform them. Name servers typically permit zone transfers from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they can require authentication using digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration.

Guideline: Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the z/OS BIND 9 name server, zone transfers are allowed by ACL or by digital signatures, both by using the allow-transfer statement.

You must define the TSIG key to ADNR using the key configuration statement, and then reference the key from the transfer_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key key file name is actually specified on the transfer_key keyword.

Limiting the duration of an outbound zone transfer

With some name server implementations, you can limit the amount of time that an outbound zone transfer is allowed to run. Setting this time interval to a value that is too short can have adverse affects on ADNR's ability to communicate with the name server. ADNR must request full zone transfers from the name servers it manages. If the period of time allowed for a zone transfer is shorter than the

amount of time it normally takes to transfer an ADNR-managed zone, ADNR cannot successfully manage that zone; adjust the name server configuration to provide adequate time for a full zone transfer.

For the z/OS BIND 9 name server, the amount of time to allow for an outbound zone transfer is specified on the max-transfer-time-out option.

Limiting the total number of simultaneous outbound zone transfers

With some name server implementations, you can limit the total number of simultaneous zone transfer requests that are served. Setting this number too low can have adverse affects on ADNR's ability to communicate with the name server. When setting this limit, take into account the number of secondary name servers that use this name server as the master name server for their zones, as well as the number of ADNR-managed zones that are configured under this name server. During ADNR initialization and after a MODIFY REFRESH command, ADNR requests simultaneous zone transfer requests for each zone it manages. Consider the number of zones configured under the same dns statement when you are setting zone transfer limits in the name server.

For the z/OS BIND 9 name server, the total number of simultaneous outbound zone transfers allowed is specified on the transfers-out option.

The .digrc file

ADNR uses the z/OS UNIX **dig** command to perform zone transfers from managed zones. The z/OS UNIX .digrc file can provide defaults for each user for the **dig** command. This file is read and used if it appears in the user's home directory. Because this file can cause ADNR to function incorrectly, ADNR fails initialization if this file is found in ADNR's working directory. However, ADNR does not search for this file after initialization. ADNR's working directory is specified when ADNR is defined to the security server (RACF).

Rule: Do not put the .digrc file in ADNR's home directory.

Split DNS (views)

Split DNS is a method in some name server implementations that enables zone data to appear differently depending on which client queries the name server. For example, Internet clients might be restricted to a subset of resource records in a zone, while intranet clients might have access to all resource records in a zone.

The z/OS BIND 9 name server implementation supports split DNS through the view statement. For information about the view statement, see *z/OS Communications Server: IP Configuration Reference*.

If you want to configure split DNS for an ADNR-managed zone, there are some special considerations. When implementing split DNS for a domain, the zone data is kept in separate files in the name server for each view of the zone. This implies that the data is disjointed, and in many respects ADNR must treat each view like a separate zone. When performing dynamic updates to a split DNS zone, the name server might determine which view to update based upon the source IP address of the nsupdate client. The z/OS BIND 9 name server uses this criteria to determine which view to update, and ADNR is the update client in this regard. Therefore, ADNR must use separate source IP addresses to update each view. This can be accomplished in the following ways:

- Configure separate ADNR applications for each view.

  By configuring an ADNR application for each view, a unique source IP address can be associated with each ADNR instance using job-specific source IP addressing. The source IP address assigned to ADNR needs to be configured appropriately in the name server. For the z/OS BIND 9 name server, the source IP address of the ADNR instance that you want to have update a specific view would appear in that view's match-clients statement.

  The easiest way for each ADNR instance to use unique source IP addresses is to run each instance on separate systems or TCP/IP stacks. If each ADNR instance must run on the same TCP/IP stack, you can use job-specific source IP addressing to provide unique source IP addresses. This involves mapping the ADNR job names to the source IP address to be used using the JOBNAME entry in the SRCIP statement block of the TCP/IP profile. However, each ADNR instance spawns multiple address spaces, whose job names are the ADNR start procedure name with a numerical digit appended (for example, the *ADNR* job spawns the *ADNR1* and *ADNR2* jobs). To use this method, job-specific source IP addressing has to specify the ADNR start procedure name followed by a wildcard when specifying the job name. Also, to avoid conflicting job names of the spawned address spaces among the multiple ADNR instances, you need to name the start procedures of the ADNR jobs so that the spawned job names do not conflict. For example, the start procedure names of *ADNRP* and *ADNRT* spawn unique job names among their instances, such as *ADNRP1* and *ADNRT1*; create unique source IP addresses by coding JOBNAME ANDRP* *source_ip_address1* and JOBNAME ADNRT* *source_ip_address2*.
- Understand and exploit TCP/IP's source IP address selection algorithm.

  By understanding and exploiting TCP/IP's source IP address selection algorithm you can configure ADNR and locate name servers in the network, so that ADNR uses appropriate source IP addresses to dynamically update the appropriate views. For more information, see "Source IP address selection" on page 218.

  This technique involves coding separate dns statements in the ADNR configuration file, specifying different IP addresses for each dns statement (of the same multi-homed name server) and using the separate dns statements to update different views. If configured correctly, and depending on the IP address of the name server, the source IP address of ADNR can be influenced to match the IP address in the match-clients statement of the appropriate view in the name server.

  The most predictable way to assign the correct source IP address for each separate view in this scenario is to use the DESTINATION entry in the SRCIP statement block of the TCP/IP profile. For example, if two dns statements with different IP addresses are coded in the ADNR configuration file, where each represents different views in the same name server, two DESTINATION entries are coded in the SRCIP statement of the TCP/IP profile. One DESTINATION entry contains the IP address from one of the dns statements as the destination IP address, and the second DESTINATION entry contains the IP address from the other dns statement as the destination IP address. The source IP address contained in each DESTINATION entry matches one of the IP addresses in the match-clients statement in the name server configuration file of the appropriate view to be updated.

Zone transfer formats

Some name server implementations have the capability to send multiple resource records in a DNS message during a zone transfer operation, instead of just one resource record per DNS message. The process of sending multiple resource

records per DNS message is described in RFC 2671, *Extension Mechanisms for DNS (EDNS0)*. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Sending multiple resource records per DNS message is more efficient than sending just one. ADNR performs zone transfer requests from the name servers it manages. ADNR supports receiving zone transfers in either format, but is more efficient at processing the format that contains multiple resource records per DNS message.

The z/OS BIND 9 name server sends multiple resource records per DNS message by default. However, some name server implementations do not support receiving zone transfers using this format. For this reason, some name servers might be configured to use the less efficient format when sending zone data to a secondary name server. The z/OS BIND 9 name server supports specification of the zone transfer format on the transfer-format option. This option can be specified on a server statement, which can be used to set the option only when sending zone transfer information to ADNR, so that other name servers are unaffected by the setting.

ADNR configuration considerations

This topic describes ways to change the ADNR configuration file and how to maintain zone data integrity.

Changing the ADNR configuration file

The ADNR MODIFY *procname*,REFRESH command provides a way to dynamically change the ADNR configuration file. Because the command does not support a file name or dataset specification, changes must be made to the same configuration file that was used when ADNR was started.

Restriction: Make all changes to the ADNR configuration file dynamically while ADNR is running. Changing the configuration file without using the MODIFY REFRESH command can create orphaned resource records in a name server. Orphaned resource records are resource records that are left in a name server and that ADNR has lost the ability to manage. The presence of these orphaned resource records might inaccurately direct client connections to sysplex resources that are not actually available.

Tip: Before making changes to the ADNR configuration file, save a backup copy of the original file under a different file name or dataset name.

You can make changes to the ADNR configuration file while ADNR is stopped, instead of using the MODIFY REFRESH command, if you take precautions to prevent orphaned resource records or you are sure that clients will no longer have their resolvers pointing to a name server with orphaned resource records. Unless you use the MODIFY REFRESH command to make changes, the following types of changes to the ADNR configuration file create orphaned resource records in name servers:

- Removing a dns statement
- Removing a zone keyword from a dns statement
- Changing the domain_suffix keyword value on a dns statement
- Changing the IP address or port of a name server on the dns_id keyword of a dns statement

Flushing a zone

Flushing a zone refers to deleting all ADNR-managed resource records from an ADNR-managed zone. Flushing a zone is not a normal occurrence, but might be a useful administrative tool in certain situations. You can flush all zones, or just specific zones.

Flush all zones by removing all host_group and server_group statements from the ADNR configuration file and issuing a MODIFY REFRESH command. You might flush all zones when resource records are inadvertently orphaned in a name server. The orphans can be removed by ADNR by restoring a copy of the previous configuration file, removing all host_group and server_group statements, and then issuing a MODIFY REFRESH command. When the command has completed, you can issue another MODIFY REFRESH command using the latest ADNR configuration file to return to the configuration that you want to use.

You flush individual zones in much the same way as you flush all zones. Instead of removing all host_group and server_group statements from the ADNR configuration file, you remove only those statements that reference the zone or zones that you want to flush.

Maintaining zone data integrity

To ensure the integrity of resource records in the name server zones that ADNR is managing, several guidelines should be followed.

Guidelines:

- Use the MODIFY REFRESH command to change the ADNR configuration.
- If you have modified the ADNR configuration, issue a MODIFY REFRESH command before stopping ADNR. Do not stop and restart ADNR before issuing this command.
- Do not stop ADNR until a MODIFY REFRESH command has completed.
- If message EZD1273I is issued indicating that ADNR was unable to delete a zone during a MODIFY REFRESH operation, take other steps to delete the resource records added by ADNR. This might include flushing the zone, after the underlying problem that prevented ADNR from deleting the zone is resolved. For more information, see “Flushing a zone.”
- Do not configure multiple zones for the same domain suffix that references the same multi-homed name server.
- Do not manually edit the name server's zone data file for any zone managed by ADNR.
- Do not allow any entity other than ADNR to perform dynamic updates to the zones managed by ADNR.
- Do not employ update forwarding for ADNR-managed zones.

Steps for using the ADNR application in a sysplex subplexing environment

Before you begin: In a sysplex subplexing environment, there are some additional considerations for using ADNR. Each subplex containing resources that were managed by ADNR before the sysplex was split into subplexes requires its own set of z/OS Load Balancing Advisor and Agent applications, and its own ADNR application, to continue to enable ADNR to manage DNS names for those subplex resources. Each subplex ADNR instance will communicate with the Advisor application in its subplex. Each subplex ADNR instance will update separate DNS

zones. The ADNR instances for different subplexes cannot update the same zone, because each zone can be updated by only one ADNR application and ADNR can communicate with only one Advisor instance. There must be a one-to-one correspondence between a subplex and a DNS zone.

Perform the following steps to use ADNR in a sysplex subplexing environment.

1. Plan how the new subdomains representing each subplex will fit into your DNS hierarchy.
2. Configure the name servers that will be updated for the new subplex domains.
3. Define and configure one Advisor per subplex.
4. Update the Agent configuration files to communicate with the Advisor running in its subplex.
5. Define one ADNR application per subplex.
6. Assign the host_group and server_group statements from the sysplex ADNR configuration to their correct subplex domains.
7. Configure the new ADNR instances to update the name server and zone for its subplex.
8. Configure the new ADNR instances to communicate with the subplex Advisor.
9. (Optional) Update resolver configuration files.
10. Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that ADNR will manage.
11. Verify that each subplex ADNR is functioning correctly.

These steps are described in detail in the following subtopics.

Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy

Decide whether the new subdomain names should exist at the same level as the existing subdomain representing the sysplex that is being divided into subplexes, whether the new subdomains should become child domains of the existing sysplex domain, or whether there will be a mixture of the two.

For example, if the existing subdomain for the sysplex is mvsplex.mycorp.com, the new subdomains that represent the subplexes can be at the same level in the DNS hierarchy, such as mvsplex1.mycorp.com and mvsplex2.mycorp.com. Alternatively, you can create the new subdomains as child domains of the existing sysplex domain, such as subplex1.mvsplex.mycorp.com and subplex2.mvsplex.mycorp.com.

For the following examples, assume that the sysplex and ADNR are configured as shown in Table 62.

Table 62. Base sysplex and ADNR configuration

Sysplex A Domain=mvsplex.mycorp.com	
Host1	Host2

Table 62. Base sysplex and ADNR configuration (continued)

z/OS Load Balancing Agent	z/OS Load Balancing Agent
z/OS Load Balancing Advisor for sysplex A	
ADNR for sysplex A updating zone mvsplex.mycorp.com	

To convert this sysplex to a subplexing environment, one of the subplexes can use the existing domain name as the existing sysplex, and the other subplexes become subdomains of that domain, as shown in Table 63.

Table 63. ADNR application in a sysplex subplexing environment; Example 1

Sysplex A (No DNS domain)	
Host1 Member of subplex EZBT0211 Domain=mvsplex.mycorp.com	Host2 Member of subplex EZBT0212 Domain=subplex0212.mvsplex.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone mvsplex.mycorp.com	ADNR for subplex EZBT0212 updating zone subplex0212.mvsplex.mycorp.com

Another possibility is to assign each subplex as a child domain of the original sysplex domain, as shown in Table 64. In this case, the existing sysplex domain no longer contains any resource records that represent hosts or server applications, but instead is merely the parent of the new subplex subdomains.

Table 64. ADNR application in a sysplex subplexing environment; Example 2

Sysplex A Domain=mvsplex.mycorp.com (Only delegates the child domains. Contains no sysplex resources.)	
Host1 Member of subplex EZBT0211 Domain=subplex0211.mvsplex.mycorp.com	Host2 Member of subplex EZBT0212 Domain=subplex0212.mvsplex.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone subplex0211.mvsplex.mycorp.com	ADNR for subplex EZBT0212 updating zone subplex0212.mvsplex.mycorp.com

Another alternative is to create new domain names for each of the subplexes at the same level of the DNS hierarchy as the existing sysplex domain, and retire the existing sysplex domain name, as shown in Table 65.

Table 65. ADNR application in a sysplex subplexing environment; Example 3

Sysplex A (No DNS domain)

Table 65. ADNR application in a sysplex subplexing environment; Example 3 (continued)

Host1 Member of subplex EZBT0211 Domain=mvsplex0211.mycorp.com	Host2 Member of subplex EZBT0212 Domain=mvsplex0212.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone mvsplex0211.mycorp.com	ADNR for subplex EZBT0212 updating zone mvsplex0212.mycorp.com

Step 2: Configure the name servers that will be updated for the new subplex domains

Configure the name server or name servers with the new zones to represent the new subdomain names created for the new subplexes.

You can use the same name server that was used for the sysplex zones, or another name server or name servers. These name servers must meet the existing requirements for ADNR, as specified in “Step 3: Decide which name server or name servers are to be managed by ADNR” on page 1280. Configure any security requirements in the name server for the new zones, such as access control lists or shared keys. Delegate the new zones as child zones from their parent name servers.

If you are not planning to use the existing sysplex domain name, remove that zone from the name server configuration file on the primary and secondary name servers. Update the parent zone so that it no longer delegates to the zone that you are removing.

Step 3: Define and configure one Advisor per subplex

To configure one Advisor instance per subplex, see “Steps for configuring automated domain name registration” on page 1278.

Configuration includes creating the start procedure JCL, performing the required security product commands (for example, RACF), performing the actions to make the Advisor highly available in case of application or system failure, customizing the TCP/IP profiles, customizing the WLM policies for the Advisor, and so on.

Step 4: Update the Agent configuration files to communicate with the Advisor running in its subplex

Update the security mechanisms that allow the Agent to communicate with its Advisor.

You might need to update the Agent's host_connection statement to point to the Advisor running in its subplex, and the Advisor's agent_id_list statement to allow a connection from this Agent.

If you are using AT-TLS for security, see “Enabling TLS/SSL for ADNR” on page 1278 and “Enabling TLS/SSL for z/OS Load Balancing Advisor (optional)” on page 1236.

Step 5: Define one ADNR application per subplex

If resources in a subplex were previously managed by ADNR, to define one ADNR application per subplex, see the following steps (in "Steps for configuring automated domain name registration" on page 1278):

- "Step 7: Define security server profiles for ADNR" on page 1282
- "Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)" on page 1283
- "Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd)" on page 1284
- "Step 10: Configure one ADNR application per sysplex" on page 1285
- "Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)" on page 1289

Also, for special considerations when migrating ADNR to a subplexing environment, see the following:

- "Step 6: Assign the host_group and server_group statements from the sysplex ADNR configuration to their correct subplex domains"
- "Step 7: Configure the new ADNR instances to update the name server and zone for its subplex" on page 1305
- "Step 8: Configure the new ADNR instances to communicate with the subplex Advisor" on page 1305

Guideline: In a Common INET (CINET) environment, use stack affinity to ensure that each subplex ADNR instance is using a TCP/IP stack that is in the subplex. For an example of the JCL to use to establish affinity, see adnrproc.sample.

Step 6: Assign the host_group and server_group statements from the sysplex ADNR configuration to their correct subplex domains

For each host_group statement in the original ADNR configuration, identify the subplexes that contain the hosts that are in the group. Create a host_group statement in each new ADNR configuration file of the subplex that contains such a host. Configure the *zone_label* of each host_group statement to point to a zone statement that represents the zone that will represent the subplex. Configure the *dns_label* of the host_group statement to point to a dns statement that represents the name server that owns the specified zone. Create ipaddrlist statements that the host_group statements can reference, such that the IP addresses in them belong to the subplex.

For each server_group statement in the original ADNR configuration, identify the subplexes that contain the server instances that are in the group. Create a server_group statement in each new ADNR configuration file of the subplex that contains such a server instance. Configure the *zone_label* of each server_group statement to point to a zone statement that represents the zone that will represent the subplex. Configure the *dns_label* of the host_group statement to point to a dns statement that represents the name server that owns the specified zone. Create ipaddrlist statements that the server_group statements can reference, such that the IP addresses in them belong to the subplex.

Step 7: Configure the new ADNR instances to update the name server and zone for its subplex

To configure the dns statements of each subplex ADNR instance so that the correct name server and zone are updated for each subplex, see "Identifying the name servers to update and the zones to be updated in those name servers" on page 1285.

You specified the name server or name servers to be updated in "Step 2: Configure the name servers that will be updated for the new subplex domains" on page 1303. The zones that will be updated for each subplex ADNR were determined in "Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy" on page 1301.

Step 8: Configure the new ADNR instances to communicate with the subplex Advisor

Configure the gwm statement of each new ADNR instance to communicate with the Advisor that represents that subplex.

Each subplex should have an Advisor that communicates with an ADNR instance, unless there are no resources in that subplex that are to be managed by ADNR. Each new ADNR instance should have a UUID on the uuid statement that is universally unique.

Step 9: Update resolver configuration files (optional)

Users who were using DNS names to connect to resources in the sysplex will be affected by converting to a sysplex subplexing environment. Some DNS names that existed before the migration will no longer exist, and users will need to use new DNS names to connect to the subplex resources.

For example, users that used the name ftp.mvsplex.mycorp.com might now need to use the domain name of the subplex that they are now required to use, such as ftp.mvsplex0212.mycorp.com. You can make some of this transition more transparent to the users by adding the new domain names to the resolver configuration files that are in use throughout your network. Consider adding the new domain names to the resolver configuration SEARCH directive.

Step 10: Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that are to be managed by ADNR

See the following steps (in "Steps for configuring automated domain name registration" on page 1278):

- "Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run" on page 1290
- "Step 13: Start the z/OS Load Balancing Advisor and Agent" on page 1290
- "Step 14: Start the target applications that are to be managed by ADNR" on page 1290
- "Step 15: Start the ADNR application" on page 1290

Step 11: Verify that each subplex ADNR is functioning correctly

To verify that each subplex ADNR is functioning as expected, see "Step 16: Verify that the ADNR system is functioning correctly (optional)" on page 1290.

Operating ADNR

When ADNR is operational, you can do the following:

- Change the logging level of ADNR to suit your needs (optional)
- Change the ADNR configuration dynamically
- Interpret ADNR display information

Changing the logging level of ADNR

Optionally, you can change the logging level of ADNR to suit your needs. The amount of information that is logged by ADNR can be modified dynamically using the following command:

```
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level should be carefully considered. The IBM default value of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see "Customizing optional statements" on page 1289.

Changing the ADNR configuration dynamically

You can change the ADNR configuration dynamically using the ADNR MODIFY *procname*,REFRESH command. For more information, see "Changing the ADNR configuration file" on page 1299.

Interpreting ADNR display information

For information about the MODIFY command for ADNR, including sample ADNR display information and descriptions of the output, see *z/OS Communications Server: IP System Administrator's Commands*.

Diagnosing problems

ADNR must communicate with a GWM and at least one name server. Problems with this communication are obvious because there is an eventual action message on the console. Problems communicating with a name server are manifested as an eventual action message concerning the name server and separate messages for each zone under the name server, indicating that the zone is unresponsive. Configuration problems with one zone (for example, TSIG key mismatches) are manifested by an eventual action message regarding the name server and a message indicating that the particular zone is unresponsive. In all cases, successful resolution of the underlying problem results in the removal of the eventual action message. For problems communicating with the GWM and for problems communicating with a name server, see *z/OS Communications Server: IP Diagnosis Guide*.

Regardless of the problem communicating with a name server, ADNR sends health probes in 60-second intervals to test the reachability of the name server and determine whether ADNR and the name server have been compatibly configured. If the problem is transient (for example, a network glitch, or the name server was stopped and quickly restarted), ADNR detects when the name server is again reachable and recovers. If the problem is not transient, it is possible that the ADNR configuration, name server configuration, or both need to be changed. If only the name server configuration needs to be changed, the health probes detect when ADNR and the name server have been compatibly configured and ADNR recovers.

After starting ADNR, after restarting ADNR's GWM, or after issuing a MODIFY REFRESH command, ADNR might be delayed for a period of time before its name servers are updated with the latest sysplex availability information. In all of these cases, after ADNR connects to a GWM, ADNR waits twice the GWM's polling interval before attempting to update its managed name servers. This period of time is called the convergence period. For the definition of convergence period, see “Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)” on page 1283. The purpose of the convergence period is to avoid making premature decisions about which sysplex resources are available or unavailable until all Agents in the sysplex have had sufficient time to receive the data registered by ADNR and report back to the Advisor, and in turn ADNR, on the availability status of those resources. Once the convergence period has expired, ADNR updates its managed name servers with the latest sysplex availability information. Henceforth, ADNR updates its managed name servers immediately upon receiving updated status information from the GWM.

Upon starting ADNR or issuing a MODIFY REFRESH command, ADNR resynchronizes itself with its managed name servers. This process consists of performing an asynchronous zone transfer from the name servers of each zone managed by ADNR, and then updating the name servers using this data and the latest ADNR configuration and sysplex resource availability information. Depending on the number of sysplex resources configured to ADNR and the update_interval value configured on the Advisor, the resynchronization and reconciliation process can take longer than the convergence period when the convergence period is short and the zones are large. When the zone status reaches SYNCHRONIZED, this process has completed and the zone should reflect the latest status information from the sysplex.

ADNR configuration example

This topic includes a specific configuration example of ADNR. This example assumes that the z/OS Load Balancing Advisor solution is installed.

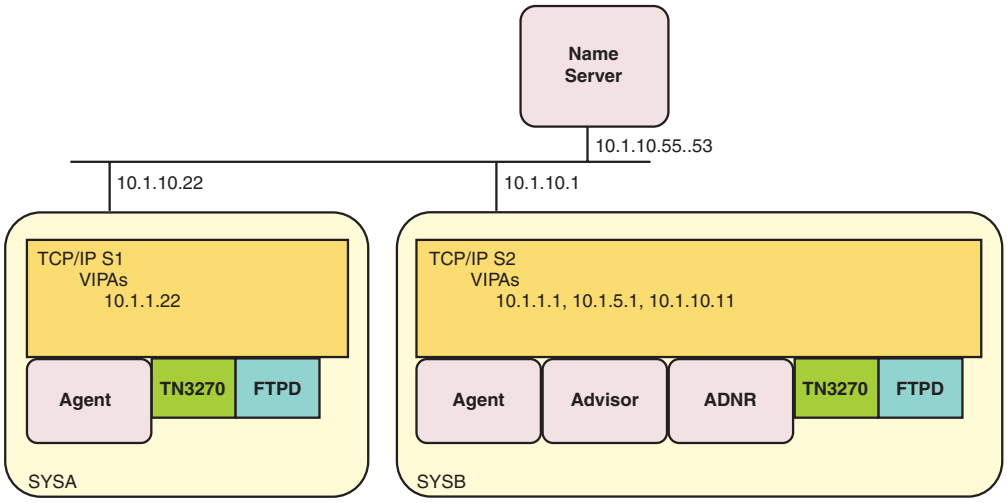

Figure 127. ADNR configuration example

In Figure 127, two systems, SYSA and SYSB, are in a sysplex. The z/OS Load Balancing Advisor solution is configured and deployed in the sysplex, with the

Advisor and ADNR running on SYSB and an Agent running on both SYSA and SYSB. The TN3270E Telnet server and FTPD are active on both systems. ADNR manages a name server in the network.

Following is an example of an ADNR configuration file. The numbers in the left margin were added for annotation purposes and are used in the description that follows the example. This example configuration does not use subplexing or AT-TLS.

```
001 debug_level             7               # Error, Warning, Event
002
003 uuid                    mycorp_sysplex_adnr
004
005 dns                     network_name_server # Label used by other stmts
006                                         #  and commands

124   }
125 } # end of server_group
```

- Line 1:

  In this example ADNR configuration file, the debug level is set to 7 in the optional debug_level statement on line 1. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

- Line 3:

  The uuid statement on line 3 uniquely identifies this ADNR from all other ADNR instances and external load balancers. In this example, it is simply a character string giving some useful information about the location of the ADNR application.

- Line 5:

  There is one name server that ADNR will manage in this example, which is represented by the dns statement on line 5. The statement is given a label of network_name_server that is used for references from other statements, like host_group and server_group, and might be used in display commands. This dns statement is referenced on lines 30, 82, and 114.

- Line 8:

  The dns_id keyword within the dns statement on line 8 tells ADNR how to reach the name server. The name server configured is at address 10.1.10.55, listening on port 53. The port is not explicitly specified because the default port is being used.

- Line 10:

  The zone keyword within the dns statement on line 10 indicates which zones ADNR manages at the name server indicated on the dns_id keyword. There can be multiple zone keywords in this statement. However, in this example, only one zone is managed by ADNR in this name server. The zone keyword has the label mvsplex.mycorp.com_zone, which is used for references from other statements like host_group and server_group. In this example, the zone is referenced on lines 31, 83, and 116.

- Line 14:

  The domain_suffix keyword within the zone keyword on line 14 assigns the domain suffix to be used for all updates to the zone. In this example, the domain suffix of mvsplex.mycorp.com is appended to the host names that ADNR creates when it adds resource records to the name server. In this example, one of the resource records added to the name server is ztelnet.mvsplex.mycorp.com. Because the zone keyword containing this domain suffix is under the dns statement representing the name server at 10.1.10.55, this implies that the name server at 10.1.10.55 is configured as the primary master name server for the mvsplex.mycorp.com domain.

- Line 20:

  The gwm statement on line 20 describes how ADNR communicates with the GWM. The gwm statement has a label of z/os_lba_advisor.

- Line 22:

  The gwm_id keyword on line 22 identifies the IP address and port on which the GWM is listening for connections from load balancers. In this example, the GWM is located at 10.1.5.1 and is listening on port 3860 for load balancer connections. The port of 3860 on the gwm_id keyword does not need to be

specified because that is the default port for this keyword. However, it is explicitly coded in this example for clarity. ADNR establishes a long-lived TCP connection to the GWM.

- Line 23:

  The host_connection_addr keyword of the gwm statement on line 23 identifies the source IP address that ADNR uses when connecting to the GWM. The host_connection_addr keyword is optional if you are using AT-TLS. In this example, 10.1.10.11 is used. The GWM might require configuration to enable a load balancer to connect from this address. Because the Advisor is acting as the GWM, it requires either that the source IP address of all load balancers that connect to it appear in an access control list or that AT-TLS is used. This list is defined by the lb_id_list statement in the Advisor. Therefore, in this example, 10.1.10.11 must appear in the Advisor's lb_id_list statement to enable ADNR to connect to it.

- Line 26:

  The host_group statement defines a set of IP addresses to potentially add to the ADNR-managed name server, which simply represents the hosts in the sysplex. They are used to map names for the hosts to IP addresses in the name server. This is one of the traditional uses of resource records in a name server. In this example, production_sysplex is the label for this host_group on line 26. This label can be used in display commands. There can be multiple host_group statements in an ADNR configuration file, although only one is shown in this example.

- Lines 29 and 31:

  The host_group_name keyword identifies the DNS host name that is associated with all IP addresses identified in this host_group statement. The value of the host_group_name keyword, `prodplex` on line 29 in this example, is prepended to the domain suffix identified by the zone keyword of this host_group statement on line 31. In this example, all IP addresses identified by the ipaddrlist statements in this host_group statement have the potential to be added to the name server with the name prodplex.mvsplex.mycorp.com. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all ipaddrlist keywords in this host_group statement, with the addresses that exist in the union of all home lists in the sysplex. This assumes that an Agent is running on all systems in the sysplex. If an address is removed from the home list of a system in the sysplex (for example, using VARY TCPIP,,OBEYFILE), all resource records associated with that IP address are update-deleted from the ADNR-managed name server. Similarly, if an IP address is added to the home list of a system in the sysplex and that address is already represented in this host_group statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming that all IP addresses configured to this host group actually exist in the sysplex, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

  ```
  prodplex.mvsplex.mycorp.com   IN A  10.1.1.22
  prodplex.mvsplex.mycorp.com   IN A  10.1.10.22
  prodplex.mvsplex.mycorp.com   IN A  10.1.1.1
  prodplex.mvsplex.mycorp.com   IN A  10.1.10.1
  ```

  Thus, the DNS name prodplex.mvsplex.mycorp.com can be used by a client to reach any system in the sysplex. Because there is no guarantee that a server is listening on each of these addresses, this DNS name should not be used by clients to connect to servers in the sysplex. This DNS name is probably most useful for utilities like ping and traceroute.

- Line 30:

  The dns keyword in the host_group statement on line 30 identifies the name server that is to be updated for this host group. The dns keyword identifies this name server by the label network_name_server, which is a label on a dns statement (line 5 in this example). Thus, in this example, the names for this host_group statement are added to the name server located at 10.1.10.55.

- Line 31:

  The zone keyword of the host_group statement on line 31 identifies the zone to which the names for this host group are to be added. In this example, the label mvsplex.mycorp.com_zone matches a zone keyword label in the dns statement on line 10. Because multiple zone keywords are possible in a dns statement, the zone within the dns statement must be identified from all host_group and server_group statements. The zone keyword in the host_group statement is how the domain suffix is determined for this host_group statement.

- Lines 36 and 45:

  This host_group statement contains two member definitions on lines 36 and 45. Both of these member definitions are named members because they contain a host_name keyword. An unnamed member has no host_name keyword. You can code one unnamed member per host_group. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that host group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that host group, in addition to any IP addresses coded in the unnamed member itself. An explicitly coded unnamed member might be useful for configuring movable dynamic VIPAs that do not always belong to a specific host.

- Line 40:

  The first member definition in this host_group statement contains the host_name keyword with a value of `sysa`. All IP addresses that are coded in this member belong to the sysa system. The value `sysa` of the host_name keyword on line 40 is prepended to the domain suffix for this host group to create the name sysa.mvsplex.mycorp.com. Assuming that all IP addresses configured to this member actually exist on sysa, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

  ```
  sysa.mvsplex.mycorp.com    IN A  10.1.1.22
  sysa.mvsplex.mycorp.com    IN A  10.1.10.22
  ```

  Thus, the DNS name sysa.mvsplex.mycorp.com can be used to specifically connect to the sysa system. This name might be useful for ping or traceroute.

- Line 45:

  The second member definition in the host_group statement on line 45 represents IP addresses that are to be associated with the sysb system, like the first member definition associated IP addresses with the sysa system. Assuming that all IP addresses configured to this member actually exist on sysb, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

  ```
  sysb.mvsplex.mycorp.com    IN A  10.1.1.1
  sysb.mvsplex.mycorp.com    IN A  10.1.10.1
  ```

  Similar to the first member definition, the sysb.mvsplex.mycorp.com DNS name can be used to specifically connect to the sysb system.

- Lines 41, 42, 50, and 51:

  The two ipaddrlist keywords in each of the two members of the host_group statement (lines 41, 42, 50, and 51) specify the IP addresses that belong to this host group. As this example shows, multiple ipaddrlist keywords are allowed

and the group represents the union of all ipaddrlist statements in the host_group statement. Each ipaddrlist statement can contain multiple IP addresses, although this example has only one IP address per ipaddrlist statement. In this host_group statement, the two ipaddrlist keywords in the first member (lines 41 and 42) reference ipaddrlist statements with the labels sysa_vipa_addrs and sysa_non_vipa_addrs at lines 56 and 61, and the two ipaddrlist keywords in the second member (lines 50 and 51) reference the ipaddrlist statements with the labels sysb_vipa_addrs and sysb_non_vipa_addrs at lines 66 and 71. Thus, the IP addresses 10.1.1.22 and 10.1.10.22 are associated with this host group, as are the IP addresses 10.1.1.1 and 10.1.10.1, as reflected in the IP addresses associated with the name prodplex.mvsplex.mycorp.com as previously shown. Furthermore, the IP addresses of the first member, 10.1.1.22 and 10.1.10.22, are associated with system sysa, as reflected in the IP addresses associated with the name sysa.mvsplex.mycorp.com, and the IP addresses in the second member, 10.1.1.1 and 10.1.10.1, are associated with system sysb, as reflected in the IP addresses associated with the name sysb.mvsplex.mycorp.com.

- Lines 56, 61, 66, and 71:

  This example shows four ipaddrlist statements, each with one IP address, at lines 56, 61, 66, and 71. There can be multiple ipaddrlist statements and each can have multiple IP addresses. Each ipaddrlist statement has a label that is referenced from host_group and server_group statements. The labels in this example are sysa_vipa_addrs, sysa_non_vipa_addrs, sysb_vipa_addrs, and sysb_non_vipa_addrs. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in ipaddrlist statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in ipaddrlist statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

- Lines 58, 63, 68, and 73:

  The ipaddr keyword on lines 58, 63, 68, and 73 identifies a single IP address to register. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in ipaddrlist statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in ipaddrlist statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

- Lines 76 and 108:

  This example shows two server_group statements; one at line 76 to represent the TN3270E Telnet servers in the sysplex, and the other at line 108 to represent the FTP daemons in the sysplex. The server_group statements are used to create DNS names in the name server that map to IP addresses, which can actually be used to reach an active instance of the server.

- Line 76:

  The first server_group statement on line 76 is given the label tn3270_group. This label can be used in display commands. This group represents TN3270E Telnet servers in the sysplex.

- Line 79:

  The port keyword on line 79 in the first server_group statement indicates the port that the TN3270E Telnet servers listen on, which is 23 in this example.

- Line 80:

  The protocol keyword on line 80 in the first server_group statement indicates the protocol of the listening application (TCP or UDP). Because the TN3270E Telnet server is a TCP application, the value for this keyword is TCP.

- Line 81:

The server_group_name keyword on line 81 identifies the DNS host name that is associated with all IP addresses identified in this server_group statement. The value of the server_group_name keyword, `ztelnet` in this example, is prepended to the domain suffix identified by the zone keyword of this server_group statement. In this example, all IP addresses identified by the ipaddrlist statements in this server_group statement have the potential to be added to the name server with the name ztelnet.mvsplex.mycorp.com. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all ipaddrlist keywords in this server_group statement, with the addresses on which the server instances in the sysplex are available. In the case of TCP applications, this is the set of IP addresses that the servers are listening on, and for UDP applications, this is the set of IP addresses to which the servers are bound. This assumes that an Agent is running on all systems in the sysplex. The TN3270E Telnet server listens on INADDR_ANY, so in effect, it listens on all IP addresses available. If a server instance is stopped (or abnormally terminates), all resource records associated with that server instance are update-deleted from the ADNR-managed name server. Similarly, if a new server instance in that group is started and an IP address on which that server instance is available is already coded in the server_group statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming the TN3270E Telnet servers are running on sysa and sysb, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

```
ztelnet.mvsplex.mycorp.com    IN A  10.1.1.22
ztelnet.mvsplex.mycorp.com    IN A  10.1.1.1
```

Thus, the DNS name ztelnet.mvsplex.mycorp.com can be used to reach any available TN3270E Telnet server in the sysplex.

- Lines 82 and 83:

  On lines 82 and 83, the dns and zone keywords of the server_group statement serve the same purpose as those keywords on the host_group statement.

- Lines 87 and 97:

  There are two named members defined in the server_group statement on lines 87 and 97. Named members contain a server_name keyword, but unnamed members do not. As in host_group statements, you can code one unnamed member per server group. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that server group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that server group, in addition to any IP addresses coded in the unnamed member itself. The IP addresses in the unnamed member, whether explicitly coded or not, are associated with the group name. In this example, the IP addresses of the unnamed member for this server_group statement are associated with the name ztelnet.mvsplex.mycorp.com. Coding an explicit unnamed member without any named members might suffice for servers where affinity to a particular instance is not needed. Also, if an application instance is freely movable from one system to another, or from one TCP/IP stack to another, coding an unnamed member without any named members might be acceptable. In this case, code the DVIPAs on which the application could be reached in the unnamed member. If, however, it is important for clients to be able to connect to specific instances of a server, you must code separate named members for each instance.

- Line 91:

The first member definition in this server_group statement contains the server_name keyword with a value of `telnetprimary` at line 91. All IP addresses that are coded in this member are IP addresses that one instance of the TN3270E Telnet server could potentially be listening on. The value `telnetprimary` of the server_name keyword is prepended to the DNS name created for the server group to create the name telnetprimary.ztelnet.mvsplex.mycorp.com. Assuming that the IP address configured to this member actually exists on sysa, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

```
telnetprimary.ztelnet.mvsplex.mycorp.com    IN A  10.1.1.22
```

Thus, the DNS name telnetprimary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysa.

- Line 97:

  The second member definition in this server group on line 97 is similar to the first, with the exception that this member identifies an application instance on system sysb instead of the one on system sysa. Assuming that the IP address configured to this member actually exists on sysb, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

  ```
  telnetsecondary.ztelnet.mvsplex.mycorp.com  IN A  10.1.1.1
  ```

  Thus, the DNS name telnetsecondary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysb.

- Line 108:

  The second server_group statement on line 108 is similar to the server_group statement for the TN3270E Telnet servers, except that it represents FTP daemons in the sysplex. Thus, the value of the port keyword specifies the port number on which the FTP daemon listens. The server_group_name value specifies a name that is appropriate to a group of equivalent FTP daemons. This server group has one unnamed member and no named members. Thus, the resource records that can potentially be added to the name server are as follows:

  ```
  zftp.mvsplex.mycorp.com    IN A  10.1.1.22
  zftp.mvsplex.mycorp.com    IN A  10.1.1.1
  ```

ADNR display examples

The displays in this topic use the example configuration described in "ADNR configuration example" on page 1307. The numbers in the left margin were added for annotation purposes and are used in the descriptions of the displays. Only a subset of the possible types of displays are shown in this example. For more examples of the MODIFY command for ADNR, see *z/OS Communications Server: IP System Administrator's Commands*.

The following display shows information about the gwm:

```
01 F ADNR,DISP,GWM,DETAIL
02 EZD1254I GWM DETAIL
03 GWM LABEL        : Z/OS_LBA_ADVISOR
04  GWM STATUS      : CONVERGENCE_PENDING
05  GWM TIMESTAMP   : 10/19/05 18:32:52
06  GWM IPADDR..PORT: 10.1.5.1..3860
07  LOCAL IPADDR    : 10.1.10.11
08  UUID            : MYCORP_SYSPLEX_ADNR
09  UPDATE INTERVAL : 60
10  LAST UPDATE     : N/A
11 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

  The GWM LABEL field on line 3 is taken from the gwm statement label on line 20 of the example ADNR configuration file. All labels and names in ADNR displays are displayed in uppercase regardless of how they appear in the ADNR configuration file.
- Line 4:

  The GWM STATUS on line 4 is CONVERGENCE_PENDING, which is a transient state meaning that the ADNR host_group and server_group information has successfully been registered with the GWM, and ADNR is waiting for a timer to expire before updating the name servers with information from this GWM.
- Line 5:

  The GWM TIMESTAMP field on line 5 shows the date and time when the most recent update of the GWM STATUS field occurred.
- Line 6:

  The GWM IPADDR..PORT field shows the IP address and port of the GWM. These values are taken from the gwm_id keyword of the gwm statement on line 22 of the example configuration file.
- Line 7:

  The LOCAL IPADDR field is the source IP address that ADNR uses when communicating with the GWM. The value of 10.1.10.11 was taken from the host_connection_addr keyword on line 23 of the example configuration file.
- Line 8:

  The UUID field value on line 8 is taken from the uuid statement on line 3 of the example configuration file.
- Line 9:

  The update interval of 60 seconds is determined by GWM configuration. For the z/OS Load Balancing Advisor, this value is determined by the Advisor's update_interval statement.
- Line 10:

  The LAST UPDATE field on line 10 shows the most recent date and time that status information was received from the GWM on any of the sysplex resources that ADNR registered with the GWM. The value `N/A` indicates that no status updates have been received yet.
- Line 11:

  The number of records displayed on line 11 indicates the number of GWMs actually displayed. Currently, this value is always 1, because only one GWM is supported.

The following display was created after the convergence timer expired. The GWM's status changes to GWM_ACTIVE on line 4. Any status updates from the GWM will now be reflected in the name servers, provided that the name servers are reachable and configured correctly.

```
01 F ADNR,DISP,GWM,DETAIL
02 EZD1254I GWM DETAIL
03 GWM LABEL        : Z/OS_LBA_ADVISOR
04  GWM STATUS      : GWM_ACTIVE
05  GWM TIMESTAMP   : 10/19/05 18:34:55
06  GWM IPADDR..PORT: 10.1.5.1..3860
07  LOCAL IPADDR    : 10.1.10.11
```

```
08  UUID            : MYCORP_SYSPLEX_ADNR
09  UPDATE INTERVAL : 60
10  LAST UPDATE     : 10/19/05 18:35:29
11 1 OF 1 RECORDS DISPLAYED
```

The following display summary shows the host groups and server groups that were defined:

```
01 F ADNR,DISP,GWM,GROUPS
02 EZD1254I GWM GROUP SUMMARY
03 GWM LABEL        : Z/OS_LBA_ADVISOR
04  GWM STATUS      : GWM_ACTIVE
05  GROUP LABEL     : PRODUCTION_SYSPLEX
06   GROUP NAME     : PRODPLEX
07  GROUP LABEL     : TN3270_GROUP
08   GROUP NAME     : ZTELNET
09  GROUP LABEL     : FTP_GROUP
10   GROUP NAME     : ZFTP
11 3 OF 3 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Lines 3 and 4:

  Lines 3 and 4 show the same information as the DETAIL display.
- Lines 5, 7, and 9:

  The GROUP LABEL fields on lines 5, 7, and 9 show the labels of the groups that were defined to ADNR on lines 26, 76, and 108, respectively, in the example ADNR configuration file.
- Lines 6, 8, and 10:

  The GROUP NAME fields on lines 6, 8, and 10 show the names from the host_group_name or server_group_name keywords on lines 29, 81, and 113, respectively, of the example ADNR configuration file.
- Line 11:

  The number of records displayed on line 11 indicates the number of groups actually displayed. When the number of groups defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of groups that were omitted from the display as a result of the MAX parameter value.

The following display shows the details of one group, and demonstrates how a label can be used in a display command:

```
01 F ADNR,DISP,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX,DETAIL
02 EZD1254I GWM GROUP DETAIL
03 GWM LABEL        : Z/OS_LBA_ADVISOR
04  GWM STATUS      : GWM_ACTIVE
05  GWM TIMESTAMP   : 10/20/05 13:15:19
06  GWM IPADDR..PORT: 10.1.5.1..3860
07  LOCAL IPADDR    : 10.1.10.11
08  UUID            : MYCORP_SYSPLEX_ADNR
09  UPDATE INTERVAL : 60
10  LAST UPDATE     : 10/20/2005 13:17:21
11  GROUP LABEL     : PRODUCTION_SYSPLEX
12   GROUP NAME     : PRODPLEX
13   GROUP TYPE     : HOST
14   DNS LABEL      : NETWORK_NAME_SERVER
15   ZONE LABEL     : MVSPLEX.MYCORP.COM_ZONE
16   MEMBER HOSTNAME:
17    IPADDR        : 10.1.1.22
18     AVAIL        : YES
19     FLAGS        :
```

```
20     UPDATE COUNT : 1
21    IPADDR        : 10.1.10.22
22     AVAIL        : YES
23     FLAGS        :
24     UPDATE COUNT : 1
25    IPADDR        : 10.1.1.1
26     AVAIL        : YES
27     FLAGS        :
28     UPDATE COUNT : 1
29    IPADDR        : 10.1.10.1
30     AVAIL        : YES
31     FLAGS        :
32     UPDATE COUNT : 1
33   MEMBER HOSTNAME: SYSA
34    IPADDR        : 10.1.1.22
35     AVAIL        : YES
36     FLAGS        :
37     UPDATE COUNT : 1
38    IPADDR        : 10.1.10.22
39     AVAIL        : YES
40     FLAGS        :
41     UPDATE COUNT : 1
42   MEMBER HOSTNAME: SYSB
43    IPADDR        : 10.1.1.1
44     AVAIL        : YES
45     FLAGS        :
46     UPDATE COUNT : 1
47    IPADDR        : 10.1.10.1
48     AVAIL        : YES
49     FLAGS        :
50     UPDATE COUNT : 1
51 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Lines 3–10:

  Lines 3 through 10 show information described in previous display examples.
- Line 11:

  The GROUP LABEL field on line 11 matches the value on the GROUPID keyword on the MODIFY DISPLAY command.
- Line 13:

  The GROUP TYPE field on line 13 indicates that this group was defined as a host_group versus a server_group.
- Line 14:

  The DNS LABEL field on line 14 is the label referenced by the dns keyword on line 30 of the example ADNR configuration file, which indicates which name server is to be updated with the information from this group.
- Line 15:

  The ZONE LABEL field on line 15 is the label referenced by the zone keyword on line 31 of the example ADNR configuration file, which indicates which zone in the name server is to be updated with the information from this group.
- Line 16:

  The MEMBER HOSTNAME field on line 16 is blank, indicating that this is the unnamed member for this group. Because an unnamed member was not explicitly configured for this group, this member represents the virtual unnamed member that is created for you.
- Lines 17, 21, 25, and 29:

The IPADDR values on lines 17, 21, 25, and 29 represent the IP addresses that are automatically added to the unnamed member. These four addresses represent the union of all IP addresses coded in all members of this group.

- Lines 18, 22, 26, and 30:

  The AVAIL flags on lines 18, 22, 26, and 30 all indicate that the GWM has reported these resources as available. For IPADDRs in a host group such as this, this means the Agent owning these IP addresses is active and these addresses exist in a home list in the sysplex.

- Lines 19, 23, 27, and 31:

  The FLAGS field for each of the IP addresses on lines 19, 23, 27, and 31 is empty. If the AVAIL flags were NO for any of these IP addresses, the FLAGS field would give an indication as to why. For a list of the possible flags that can appear for the MODIFY command for ADNR, and their explanations, see *z/OS Communications Server: IP System Administrator's Commands*.

- Lines 20, 24, 28, and 32:

  The UPDATE COUNT fields on lines 20, 24, 28, and 32 indicate the number of times that the availability status, as sent from the GWM, has changed for these IP addresses.

- Lines 33 and 42:

  The MEMBER HOSTNAME fields on lines 33 and 42 represent the named members that were configured in the group at lines 36 and 45 of the example ADNR configuration file. Only the IP addresses explicitly coded to these members appear in the display of these members, in contrast to the unnamed member. The remainder of the fields in these named members are equivalent to the information displayed in the unnamed member.

The following display shows information about the name server that ADNR is updating:

```
01 F ADNR,DISP,DNS,DETAIL
02 EZD1254I DNS DETAIL
03 DNS LABEL        : NETWORK_NAME_SERVER
04  DNS STATUS      : ACTIVE
05  DNS IPADDR..PORT: 10.1.10.55..53
06  ZONES DEFINED   : 1
07  ZONES ACTIVE    : 0
08 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

  The DNS LABEL field value NETWORK_NAME_SERVER is taken from the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the MODIFY command for ADNR, see *z/OS Communications Server: IP System Administrator's Commands*.

- Line 5:

  The DNS IPADDR..PORT field value of 10.1.10.55..53 indicates that ADNR communicates with a name server at address 10.1.10.55 on port 53. This IP address and port are taken from the dns_id keyword on line 8 of the example configuration file.

- Line 6:

  The ZONES DEFINED field on line 6 indicates that there is one zone configured under this dns statement in the ADNR configuration file.

- Line 7:

The ZONES ACTIVE field on line 7 indicates that the zone defined under this dns statement cannot yet be updated by ADNR. In a steady state environment, the number of active zones should match the number of defined zones. If the numbers do not match, this could be an indication of a configuration problem, a network problem, or the zone could be in the middle of the resynchronization process. For more information on the resynchronization process, see "Operating ADNR" on page 1306.

- Line 8:

  The number of records displayed on line 8 indicates the number of DNSs actually displayed. When the number of DNSs defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of DNSs that were omitted from the display as a result of the MAX parameter value.

The following display shows summary information about the zones that ADNR is updating:

```
01 F ADNR,DISP,DNS,ZONES,SUMMARY
02 EZD1254I DNS ZONE SUMMARY
03 DNS LABEL        : NETWORK_NAME_SERVER
04  DNS STATUS      : ACTIVE
05  ZONE LABEL      : MVSPLEX.MYCORP.COM_ZONE
06   ZONE STATUS    : SYNCHRONIZED
07 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

  The DNS LABEL field on line 3 indicates that information for a specific name server and its zones immediately follows. The field value is taken from the label on the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the MODIFY command for ADNR, see *z/OS Communications Server: IP System Administrator's Commands*.

- Line 5:

  The ZONE LABEL field on line 5 indicates that information for the indicated zone follows. The value for this field is taken from the label on the zone keyword (line 10 of the example configuration file) of the dns statement.

- Line 6:

  The ZONE STATUS field on line 6 shows the state of the zone. The value of SYNCHRONIZED is the expected, steady-state value for a zone. For an explanation of all of the zone states displayed on the MODIFY command for ADNR, see *z/OS Communications Server: IP System Administrator's Commands*.

- Line 7:

  The number of records displayed on line 7 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.

The following display shows the status of the resource records that ADNR manages in the name server:

```
001 F ADNR,DISP,DNS,ZONES,DETAIL
002 EZD1254I DNS ZONE DETAIL
003 DNS LABEL        : NETWORK_NAME_SERVER
004  DNS STATUS      : ACTIVE
```

```
005  DNS IPADDR..PORT: 10.1.10.55..53
006  ZONES DEFINED   : 1
007  ZONES ACTIVE    : 1
008  ZONE LABEL      : MVSPLEX.MYCORP.COM_ZONE
009   ZONE STATUS    : SYNCHRONIZED
010   DOMAIN SUFFIX  : MVSPLEX.MYCORP.COM.
011   ZONE TIMESTAMP : 10/20/05 14:42:05
012   TSIG FLAGS     :
013   DNS RR LABEL   : PRODPLEX
014    DNS RR STATUS : PRESENT
015    TTL           : 60
016    CLASS         : IN
017    TYPE          : A
018    RDATA         : 10.1.1.22
019    GWM LABEL     : Z/OS_LBA_ADVISOR
020    GROUP LABEL   : PRODUCTION_SYSPLEX
021    LAST UPDATE   : 10/20/05 14:42:02
022   DNS RR LABEL   : PRODPLEX
023    DNS RR STATUS : PRESENT
024    TTL           : 60
025    CLASS         : IN
026    TYPE          : A
027    RDATA         : 10.1.1.1
028    GWM LABEL     : Z/OS_LBA_ADVISOR
029    GROUP LABEL   : PRODUCTION_SYSPLEX
030    LAST UPDATE   : 10/20/05 14:42:02
031   DNS RR LABEL   : PRODPLEX
032    DNS RR STATUS : PRESENT
033    TTL           : 60
034    CLASS         : IN
035    TYPE          : A
036    RDATA         : 10.1.10.1

137    GROUP LABEL   : TN3270_GROUP
138    LAST UPDATE   : 10/20/05 14:42:02
139 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 12:

  The TSIG FLAGS field on line 12 indicates which type of TSIG keys are being used, if any. In this example, the update_key and transfer_key keywords were not specified for the zone under this DNS. If they had been specified, an indicator or indicators would be displayed on this line showing which types of TSIG keys are being used.

- Lines 13, 49, 67, 85, 103, 121, and 130:

  The DNS RR LABEL fields indicate the portion of the DNS name of the resource record before the domain suffix is appended. Some unique examples are on lines 13, 49, 67, 85, 103, 121, and 130. Some of these labels can be compound, like TELNETPRIMARY.ZTELNET and TELNETSECONDARY.ZTELNET on lines 121 and 130. Compound labels are created for named members of server groups. The two named members were configured in a server_group statement on lines 87 and 97 of the example ADNR configuration file. The label PRODPLEX on line 13 represents the resource records for the virtual unnamed member of the host_group statement on line 26 of the example ADNR configuration file. The labels SYSA on line 49 and SYSB on line 67 represent the named members of the host group on line 36 and 45 of the example ADNR configuration file. The label ZFTP on line 85 represents the unnamed member of the server group on line 120 of the example ADNR configuration file. The label ZTELNET on line 103 represents the virtual unnamed member of the server group on line 108 of the example ADNR configuration file. The label TELNETPRIMARY.ZTELNET on line 121 represents the named member on line 87 of the example ADNR configuration file, and the label TELNETSECONDARY.ZTELNET on line 130 represents the named member on line 97 of the example ADNR configuration file.

- Line 14:

  The fields labeled DNS RR STATUS (for example, line 14) indicate whether or not the resource record is present in the name server. Resource records representing available resources in the sysplex have a value of PRESENT, while resource records representing unavailable resources in the sysplex have a value of NOT_PRESENT.

- Line 15:

  The fields labeled TTL (for example, line 15) indicate the time to live value associated with the resource record. For more information, see “Near real-time availability information of sysplex resources” on page 1292.

- Line 16:

  The fields labeled CLASS (for example, line 16) indicate the resource record class. All ADNR-managed resource records have a class value of IN.

- Line 17:

  The fields labeled TYPE (for example, line 17) indicate the resource record type. ADNR-managed resource records are either A for IPv4 addresses or AAAA for IPv6 addresses.

- Line 18:

  The fields labeled RDATA (for example, line 18) contain the IPv4 or IPv6 address that is in the resource record.

- Line 19:

The fields labeled GWM LABEL (for example, line 19) match the label of the gwm statement on line 20 of the example ADNR configuration file.

- Line 20:

  The fields labeled GROUP LABEL (for example, line 20) indicate the group definition that is responsible for the creation of the resource record. This makes it possible to correlate this resource record with the MODIFY ADNR,DISPLAY,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX output to see the GWM data that is related to this resource record.

- Line 21:

  The fields labeled LAST UPDATE (for example, line 21) indicate the most recent time that the status of the resource record has changed from PRESENT to NOT_PRESENT, or from NOT_PRESENT to PRESENT.

- Line 139:

  The number of records displayed on line 139 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.

Chapter 25. Simple Network Management Protocol

This topic describes how to configure:

- Simple Network Management Protocol (SNMP) agent (osnmpd)
- z/OS UNIX **snmp** or **osnmp** command
- NetView SNMP command
- SNMP subagents
- Open Systems Adapter (OSA) support
- Trap forwarder daemon

Before you configure, read "Understanding search orders of configuration information" on page 19. It covers important information about data set naming and search sequences.

SNMP overview

SNMP is a set of protocols that describes management data and the protocols for exchanging that data between heterogeneous systems. The protocols include both the description of the management data, defined in the Management Information Base (MIB), and the operations for exchanging or changing that information. By implementing common protocols, management data can be exchanged between different platforms with relative ease.

SNMP defines an architecture that consists of:

- Network management applications
- Network management agents and subagents
- Network elements, such as hosts and gateways

The SNMP network management application can ask agents for specific information about network elements. Conversely, agents can tell the network management application when something happens to one or more network elements. The protocol used between the network management application and agents is SNMP. The transport protocol for SNMP requests is the User Datagram Protocol (UDP).

SNMP defines both the network management data and the ways in which the data is retrieved or changed by the network management application. Examples of network management data include device definitions, counts of packets received at the IP layer, TCP connection data, and so forth. The information about the network elements is stored in the Management Information Base (MIB), which is supported by the SNMP agent and its subagents. A MIB variable (or MIB object) is a specific instance of data in a collection of objects related to a common management area. The collection is called a MIB module. Each MIB object is identified by an object identifier (OID), which is a dotted-decimal value, and by a textual name. For example, the sysUpTime MIB object, which indicates how long ago the SNMP agent initialized, is defined as follows:

```
Textual name      Object identifier (OID)
  sysUpTime         1.3.6.1.2.1.1.3
```

The z/OS Communications Server Network Management agent and subagents, also called SNMP agent and SNMP subagents, support many standard (RFC-based)

MIB modules. The SNMP TCP/IP subagent also supports enterprise-specific MIB modules. For information on MIB modules supported by the z/OS Communications Server SNMP agent and subagents, see the SNMP agent capabilities statement, shipped as file /usr/lpp/tcpip/samples/mvstcpip.caps. Additionally, enterprise-specific MIBs are documented in the /usr/lpp/tcpip/samples directory. See "TCP/IP subagent" on page 1328 for more information on enterprise-specific MIB modules supported by the TCP/IP subagent. For a complete list of MIB objects supported by the SNMP agent and subagents shipped with z/OS Communications Server, see *z/OS Communications Server: IP System Administrator's Commands*.

Network management application

The stations that monitor network elements run network management applications. In z/OS Communications Server, the z/OS UNIX **snmp** (or **osnmp**) command provides SNMP network management from the z/OS UNIX shell. The NetView SNMP command provides network management from the NetView command line. The z/OS UNIX **snmp** and **osnmp** commands perform exactly the same function. Both commands can be used to retrieve or change data from SNMP and monitor for asynchronous events known as notifications. An unconfirmed notification is called a trap. A confirmed notification is called an inform.

For information about the syntax and use of the **snmp** and NetView SNMP commands, see *z/OS Communications Server: IP System Administrator's Commands*.

SNMP protocols

This topic provides an overview of the different SNMP protocols and their capabilities. For more detailed information on the security models for each of these SNMP protocols, see "Overview of SNMP security models" on page 1327.

SNMPv1

SNMPv1, standardized in 1988, is the first and most commonly used version. It became very popular and is probably the most widely deployed of the SNMP generations today. The SNMPv1 standards define support for SNMP GET, GETNEXT, and SET operations, and for asynchronous event notifications called TRAPs. However, SNMPv1 does not support some later MIB object types, such as 64-bit counters. SNMPv1 also uses community-based security, which is not very secure.

SNMPv2

The SNMPv2 protocol standards made several attempts to address the security issues associated with the SNMPv1 protocol, with the party-based security model SNMPv2p, the user-based security model SNMPv2u, and the community-based security model SNMPv2c.

Although these attempts were not successful in addressing the major security issues, SNMPv2 did provide several improvements over SNMPv1, especially in the area of data retrieval with the support of SNMP GETBULK operations, and SNMPv2 continued providing community-based security with SNMPv2c.

SNMPv3

SNMPv3 was architected in the late 1990s, and in December of 2002 become a standard. It is currently defined in RFCs 3410 through 3415 [see Appendix G, "Related protocol specifications," on page 1555]. SNMPv3 uses the basic SNMP management system and operations of SNMPv1 and SNMPv2, but adds an entirely new security architecture. The SNMPv3 architecture is modularized so that

portions of it can be enhanced over time without requiring that the entire architecture to be replaced. SNMPv3 defines a framework that, among other things, includes the following:

- Message processing model (SNMPv3)
- User-based security model
- View-based access control model

The framework is structured so that multiple models can be supported concurrently and replaced over time. For example, although there is a new message format for SNMPv3, messages created with the SNMPv1 and SNMPv2c formats are still supported. Similarly, the user-based security model can be supported concurrently with previously used community-based security models. In addition, SNMPv3 added other key updates to the protocol, such as the following:

- Improved notification support

  A new notification type, INFORM, is like a TRAP that requires an acknowledgement. If the acknowledgment is not received, the INFORM is resent.
- Trap filtering

  With SNMPv3, a TRAP can also be filtered at the sender.
- Dynamic configuration

  The SNMP agent can be dynamically configured using MIB modules defined in RFC 3584 and RFCs 3411 through 3415.

SNMP agent

In z/OS Communications Server, the SNMP agent is a z/OS UNIX application. It supports a maximum SNMP response packet size of 65535 bytes, and supports the following SNMP protocols:

- SNMPv1
- SNMPv2c
- SNMPv3

SNMPv2c offers protocol enhancements such as the GETBULK operation. SNMPv3 provides a network management framework that allows the use of user-based security in addition to, or instead of, the community-based security supported in SNMPv1 and SNMPv2c. The view-based access control model supported in SNMPv3 allows granular access control for MIB objects with either the user-based or community-based security models. SNMPv3 also enables dynamic changes to the SNMP agent configuration.

Overview of SNMP security models

SNMP security has evolved from community-based security to a modularized architecture that provides message security and access control.

SNMPv1 and SNMPv2c: The security model used by SNMPv1 and SNMPv2c is the community-based security model. In this model, an SNMP community is made up of an SNMP agent along with SNMP manager entities. Managers typically request management data from the agents. Each SNMP community is represented using an octet string called the community name. When the manager communicates with the agents, it uses the community name as a password to get access to the management resources. Because the community name is sent in every packet in clear view, these communications are not secure.

The access control mechanism provided by SNMPv1 is very simple. A community is allowed access to read or write objects in a management information base (MIB) tree. In most implementations, a community has access to all of the objects in the MIB, and you cannot restrict the access to a particular part of the MIB tree.

SNMPv3: SNMPv3 addresses the basic lack of security inherent in the previous SNMP versions by providing message security and access control. For message security, it introduces the User-Based Security Model (USM), which provides for authentication and privacy. Additionally, access control is provided with View-Based Access Control Model (VACM). Both USM and VACM provide for secure communications when you use SNMPv3.

User-Based Security Model (USM)

This model was designed to provide message security. USM supports both authentication (data integrity, data authentication) and privacy (protection against disclosure of message payload). For authentication, the protocols supported are HMAC-MD5 and HMAC-SHA. For privacy, CBC-DES (56-bit) is the supported symmetric encryption protocol.

View-Based Access Control Model (VACM)

VACM is used to provide access control. With VACM, users are defined to groups that are allowed to access different views or parts of the management data (MIB objects), depending on defined data access privileges.

SNMP subagents

A subagent extends the set of MIB variables supported by an SNMP agent. z/OS Communications Server supports the following subagents:

- TCP/IP subagent
- OMPROUTE subagent
- TN3270E Telnet subagent
- Network SLAPM2 subagent

For a complete list of MIB objects, see *z/OS Communications Server: IP System Administrator's Commands*.

The OSA-Express Direct subagent is also shipped with the z/OS Communications Server product, but is supported by the zSeries OSA Support Group.

TCP/IP subagent

The TCP/IP subagent in z/OS Communications Server is a z/OS UNIX application that runs in its own task in the TCP/IP address space. This subagent supports many standard (RFC-based) MIB objects. In addition, it supports MIB objects in the following enterprise-specific MIB modules:

- The IBM 3172 enterprise-specific MIB.
- The IBM MVS TCP/IP enterprise-specific MIB. This MIB defines objects to extend standard MIB tables, supports retrieval and change of TCP/IP address space configuration parameters, and provides management support for the environments where Asynchronous Transfer Mode (ATM) is used.

For a more detailed list of all the data supported by the TCP/IP subagent, see *z/OS Communications Server: IP System Administrator's Commands*.

Both the TCP/IP subagent and the OSA-Express Direct subagent support management data for OSA-Express features. You should use the OSA-Express Direct subagent to obtain this management data, for the following reasons:

- Because the OSA-Express Direct subagent communicates directly with the OSA-Express features, it does not require the OSA/SF and IOASNMP applications.
- The OSA-Express Direct subagent provides more OSA management data than the TCP/IP subagent.
- Because of the support provided by the OSA-Express Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent's OSA management data support, and decide to switch to using the OSA-Express Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application. For more information about this subagent, see "OSA-Express Direct subagent" on page 1330. For information on the TCP/IP subagent's dependency on OSA/SF and IOASNMP, see "Step 4: Configure the Open Systems Adapter support" on page 1353.

The TCP/IP subagent support evolves with each release. New MIB objects might be supported, and, occasionally, old ones might be removed for functions that are no longer relevant. This is particularly true for the MIB objects in the IBM MVS TCP/IP enterprise-specific MIB. This MIB's definition is shipped as file /usr/lpp/tcpip/samples/mvstcpip.mi2. For details of the changes for each release, see the REVISION sections of this MIB module file.

The TCP/IP subagent in z/OS Communications Server provides SET support, enabling remote configuration of some TCP/IP address space parameters. The TCP/IP subagent is configured and controlled by the SACONFIG statement in the PROFILE.TCPIP data set. Systems where SNMP support is not required can disable the subagent and save system resources.

OMPROUTE subagent

The OMPROUTE subagent implements the Open Shortest Path First (OSPF) MIB variable containing OSPF protocol and state information.

The OMPROUTE subagent supports selected MIB objects defined in RFC 1850.

For a detailed description of the OMPROUTE subagent, see *z/OS Communications Server: IP Configuration Reference*.

TN3270E Telnet subagent

The SNMP TN3270E Telnet subagent provides Telnet transaction data for monitored Telnet connections using the SNMP protocol. For more information about configuring the TN3270E Telnet subagent, see the TNSACONFIG statement in *z/OS Communications Server: IP Configuration Reference*.

Network SLAPM2 subagent

The z/OS Communications Server Network SLAPM2 subagent (nslapm2) enables network administrators to retrieve data to determine whether the current set of Network SLAPM2 policy definitions are performing as needed or whether adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. For more information about the Network SLAPM2 MIB, see usr/lpp/tcpip/samples/slapm2.mi2.

For a detailed description of the nslapm2 subagent, see the information on Policy Agent and policy applications in *z/OS Communications Server: IP Configuration Reference*.

OSA-Express Direct subagent

The OSA-Express Direct subagent supports management data for OSA-Express features. The OSA-Express Direct subagent is shipped with the z/OS Communications Server product, but is supported by the zSeries OSA Support Group. The MVS started procedure name of this subagent is IOBSNMP.

The TCP/IP subagent also supports management data for OSA-Express features, but you should use the OSA-Express Direct subagent to obtain this management data for the following reasons:

- Because the OSA-Express Direct subagent communicates directly with the OSA-Express features, it does not require the OSA/SF and IOASNMP applications.
- The OSA-Express Direct subagent provides more OSA management data than the TCP/IP subagent.
- Because of the support provided by the OSA-Express Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent's OSA management data support, and decide to switch to using the OSA-Express Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application. For information on the TCP/IP subagent's dependency on OSA/SF and IOASNMP, see "Step 4: Configure the Open Systems Adapter support" on page 1353. For a complete understanding of the management data provided by the OSA-Express Direct subagent, see *zEnterprise 196, System z10, System z9 and eServer zSeries OSA-Express Customer's Guide and Reference*.

Key generation commands

The **pwtokey** and **pwchange** commands are provided to enable generation and change of keys used for authentication and encryption with SNMPv3.

For more information about **pwtokey**, see *z/OS Communications Server: IP Configuration Reference*. For information about **pwchange**, see *z/OS Communications Server: IP System Administrator's Commands*.

Distributed Protocol Interface

The DPI is an application interface used by the SNMP agent to communicate with subagents. With DPI, you can dynamically add, delete or replace management variables supported by the SNMP agent and its subagents. z/OS Communications Server provides DPI V2.0 for z/OS UNIX C socket users and DPI V1.1 for traditional C socket users. DPI V2.0 provides additional function, making it easier to write subagents and simplifying the task of developing and administering your application.

For more information about the DPI, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Trap forwarder daemon

The trap forwarder daemon enables multiple SNMP managers to receive SNMP traps from the same TCP/IP stack. The trap forwarder daemon listens for traps on a port, usually the well-known port 162, and forwards the traps to all configured managers.

For more information about the trap forwarder daemon, see *z/OS Communications Server: IP Configuration Reference*.

Processing an SNMP request

Figure 128 illustrates the flow of processing an SNMP request when the request is for data supported by the TCP/IP subagent.

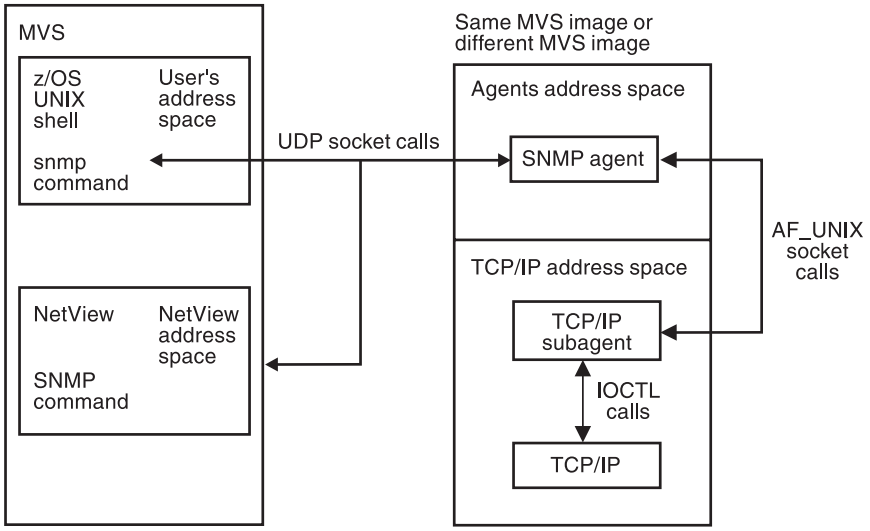

Figure 128. Overview of SNMP support

This list illustrates the sequence of events from the time you issue an SNMP command until you receive the response:

1. The user issues a NetView SNMP or z/OS UNIX **snmp** command.
2. The command processor validates and encodes the request in a Protocol Data Unit (PDU), and sends it to the SNMP agent.
3. The SNMP agent validates the request and, if necessary, sends it to an SNMP subagent. Requests for agent-oriented objects are handled by the agent and all others are handled by a subagent. To determine which objects are handled by the agent and which by a subagent, see the Management Information Base Appendix in *z/OS Communications Server: IP System Administrator's Commands*.
4. The agent sends the response to the originator of the request. The command processor displays the response.

Note: Although not shown in Figure 128, other subagents, such as the OMPROUTE subagent, the Network SLAPM2 subagent, and the TN3270E Telnet subagent shipped as part of z/OS Communications Server, also communicate with the SNMP agent using AF_UNIX socket calls or TCP socket calls from their own address spaces.

The SNMP agent and the SNMP subagents record trace information via the z/OS UNIX syslog daemon using the *daemon* facility. For detailed information regarding

syslogd and specifying the daemon facility in the /etc/syslog.conf configuration file, see "Logging of system messages" on page 34.

Deciding on SNMP security needs

The SNMP agent supports SNMPv1, SNMPv2c, and SNMPv3 security.

Community-based security

SNMPv1 and SNMPv2c are community-based security, where a community name (or password) is passed with a request. If the community name is recognized as one that can be used by the IP address from which the request originates, the SNMP agent processes the request.

User-based security

SNMPv3 provides a more powerful and flexible framework for message security and access control. Message security involves providing:

- Data integrity checking, to ensure that the data was not altered in transit
- Data origin verification, to ensure that the request or response originates from the source from which it claims to have come
- Message timeliness checking and, optionally, data confidentiality, to protect against eavesdropping

Access control is the ability to control exactly what data an individual user can read or write.

The SNMPv3 architecture introduces the User-Based Security Model (USM) for message security and the View-Based Access Control Model (VACM) for access control. The architecture supports the concurrent use of different security, access control, and message processing models. For example, community-based security can be used concurrently with USM.

USM uses the concept of a user for which security parameters (levels of security, authentication and privacy protocols, and keys) are configured at both the agent and the manager. Messages sent using USM are better protected than messages sent with community-based security, where passwords are sent in the clear and displayed in traces. With USM, messages exchanged between the manager and the agent have data integrity checking and data origin authentication. Message delays and message replays (beyond what happens normally due to a connectionless transport protocol) are protected against with the use of time indicators and request IDs. Data confidentiality, or encryption, is also available.

The use of VACM involves defining collections of data (called views), groups of users of the data, and access statements that define which views a particular group of users can use for reading, writing, or receipt in a notification.

The SNMP agent can be configured to use USM and VACM by specifying SNMPD.CONF information. SNMPv3 also introduces the ability to dynamically configure the SNMP agent using SNMP SET commands against the MIB objects that represent the agent's configuration. These MIB objects are defined in RFC 3584 and RFC 3411 through 3415. This dynamic configuration support enables addition, deletion, and modification of configuration entries either locally or remotely. Remote modification of user keys can be especially useful.

Decide on your security needs—community-based or user-based.

If you are satisfied with the security of your existing configuration, you can continue to use community-based security with no migration. If you would like to take advantage of USM or VACM, or if you have some SNMP managers that use SNMPv3, you will need to migrate your configuration. Note that USM can be used only when both the SNMP agent and the manager requesting the data support USM, as the z/OS Communications Server SNMP agent and the **snmp** command do. VACM can be used even for community-based requests, but doing so requires migration of existing community name and trap destination definitions in PW.SRC and SNMPTRAP.DEST to SNMPD.CONF.

Even if your managers continue to be community-based, there are important advantages to migrating your PW.SRC information to SNMPD.CONF format:

- Enables users to make use of the access control mechanism provided with SNMPv3 with community-based security.
- Provides the ability to dynamically configure the z/OS SNMP agent using MIBs.
- Provides a way of easing into SNMPv3 user-based security.
- Does not require any changes to the manager configuration.

Following is a list of the advantages and disadvantages of using each type of security.

Table 66. Security advantages and disadvantages

SNMPv1/SNMPv2c advantages	**SNMPv3 disadvantages**
Widely implemented on many platforms.	Not yet implemented on many platforms.
Easy to configure.	More robust configuration options.
SNMPv1/SNMPv2c disadvantages	**SNMPv3 advantages**
Legacy standards-based administrative model.	New standards-based administrative model.
SNMPv1 and SNMPv2c allow particular IP addresses to access all data or no data.	SNMPv3 allows a particular user to access particular data.
Not very robust (password sent in PDU).	Robust (data integrity and data origin authentication).
Any user that can read data can also change the data (for objects defined as read-write).	The ability to change data can be limited to specific users.
No data confidentiality.	Encryption available.
Configuration changes require restarting of SNMP agent.	Configuration changes for USM and VACM can be made dynamically, either locally or remotely.

For more information about security, see “Creating user keys” on page 1340.

Step 1: Configure the SNMP agent

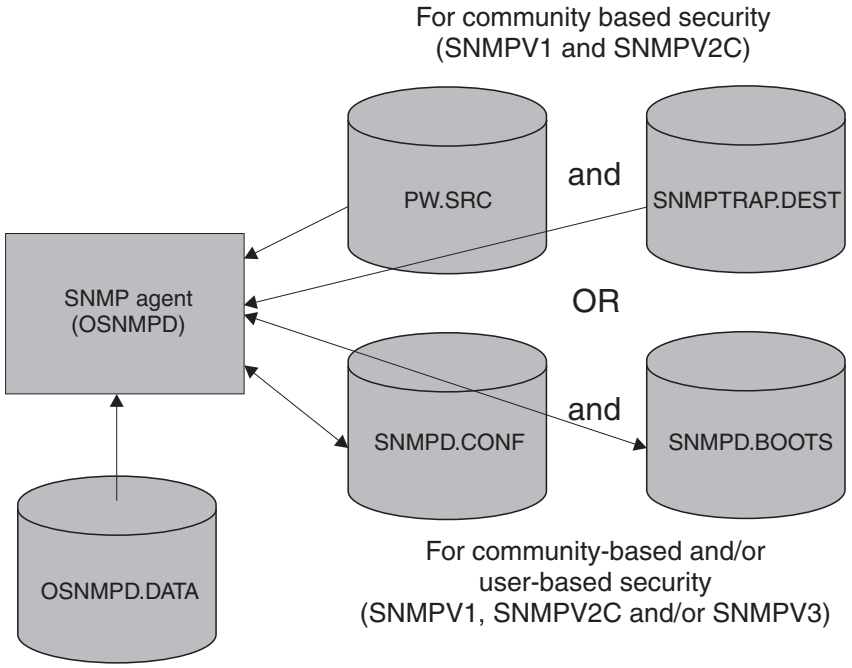

Figure 129. Configuration files for SNMP agent

Configure the SNMP agent (OSNMPD) based upon your security need. The SNMP agent accepts both SNMPv1 and SNMPv2c requests for community-based security. The SNMP agent can be configured to also use the User-based Security Model and the View-based Access Control Model. You should assign the SNMP agent and all the SNMP subagents to the same WLM service class so that they all have the same dispatching priority. Timeouts can occur if the SNMP subagents are set to a lower dispatching priority than the SNMP agent.

To configure the SNMP agent, perform the following tasks:

- "Provide TCP/IP profile statements"
- Depending upon whether you want to use USM and VACM, do one of the following:
  - If you are using community-based security and do not need USM or VACM, see "Provide community-based security and notification destination information" on page 1336.
  - If you want the flexibility of using USM or VACM or community-based security, see "Provide community-based and user-based security and notification destination information" on page 1338.
- "Provide MIB object configuration information" on page 1343
- See *z/OS Communications Server: IP Configuration Reference* for more information about OSNMPD parameters.

Provide TCP/IP profile statements

Update the following configuration statements in *hlq*.PROFILE.TCPIP:

AUTOLOG
PORT

There are two primary TCP/IP ports used by the SNMP agent, one for receiving incoming requests and one for sending traps to managers.

The default port used by the SNMP agent to receive incoming requests is 161. If you want the agent to use port 161 for this purpose and want to insure that no other application uses this port, you must specify the following PORT statement in your profile data set:

```
PORT
  161 UDP OSNMPD              ; SNMP Agent port for SNMP requests
```

If the agent will be started from the z/OS shell, reserve the port instead for z/OS UNIX by typing *OMVS* instead of *OSNMPD*.

If you want to define a port other than 161 for SNMP requests, you must do the following:

1. Start the agent with the **-p** parameter.
2. Configure management applications to use the new port:
   - For the **snmp** command, make an entry in the OSNMP.CONF file with the correct port number. For details on creating this entry, see the description for *targetAgent* in the OSNMP.CONF statement in the *z/OS Communications Server: IP Configuration Reference*.
   - Where supported, configure other management applications to use the new port.
3. Configure subagents to use the new port:
   a. Specify the port number to use on the SACONFIG profile statement for the TCP/IP subagent.
   b. Specify the port number to use on the ROUTESA_CONFIG profile statement for the OMPROUTE subagent.
   c. Specify the port number to use on the **-p** parameter when starting the Network SLAPM2 subagent.
   d. Specify the port number to use on the TNSACONFIG profile statement for the TN3270E Telnet subagent.
   e. If you are using DPI subagents other than those supplied with z/OS Communications Server, set the SNMP_PORT environment variable to enable user-written subagents to connect to the agent.

The SNMP agent uses port 162, by default, for sending traps to the managers specified in SNMPTRAP.DEST or SNMPD.CONF file. Port 162 should be reserved for the management application primarily responsible for trap processing. If your environment requires multiple management applications at the same IP address to receive traps, consider using the Trap Forwarder Daemon. See “Step 5: Configure the trap forwarder daemon” on page 1357 for more details. If the SNMP query engine is typically used for processing traps and other applications, such as snmp, that are only occasionally used, the following port reservations are recommended.

```
PORT
  162 UDP SNMPQE  ; SNMPQuery Engine
```

You must also reserve additional ports for use by the **snmp** command by specifying

```
nnnnn UDP OMVS
```

where *nnnnn* is a number in the range 0–65535 and *nnnnn* is used as the **-p** parameter value on the **snmp trap** command.

If you want the SNMPQE and OSNMPD address spaces to be started automatically when the TCPIP address space is started, then include SNMPQE and OSNMPD in the AUTOLOG statement:

```
AUTOLOG
  SNMPQE                    ; SNMP Query Engine
  OSNMPD                    ; SNMP Agent
ENDAUTOLOG
```

Provide community-based security and notification destination information

If you are using only community-based security without the view-based access control model, see the following subtopics to configure the security and trap destinations.

Provide community name information

SNMP agents are accessed by remote network management stations and by SNMP subagents. To allow network management stations to send inquiries to the SNMP agent, and SNMP subagents to connect to the SNMP agent, you can provide PW.SRC information that defines a list of community names and IP addresses that can use these community names. The community name operates as a password when accessing objects on, or connecting to, a destination SNMP agent. The subagents pass the community name to the agent on the connect request.

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as SOURCEVIPA is not in effect on the IPCONFIG profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent's authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the HOME list or the IP address specified on a PRIMARYINTERFACE TCP/IP profile statement. If SOURCEVIPA is in effect, the IP address used by the agent to verify the subagent's authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the HOME statement in *z/OS Communications Server: IP Configuration Reference*. Check the Netstat HOME/-h output to verify the IPv4 primary interface address of the stack.

The PW.SRC information is optional. If no PW.SRC information is found and no community name is specified for the **-c** parameter at agent invocation, then the SNMP agent will accept requests with a community name of 'public' from any IP address. If a PW.SRC file exists, but is empty, and if no community name is specified on the **-c** parameter at the agent invocation, then no requests will be accepted by the agent.

Note: Verify that there is no SNMPD.CONF file because this file can only be used with SNMPv3. If an SNMPD.CONF file is found, the PW.SRC file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

PW.SRC example: The PW.SRC statements could be specified as follows:

```
passwd1 9.0.0.0      255.0.0.0
passwd2 129.34.81.22 255.255.255.255
IPv6passwd3 12ab::0 16
IPv6passwd4 39B3::F430:03EE 128
```

The PW.SRC statements specify community names and hosts that can use each community name. The format of a statement is:

community_name desired_network snmp_mask

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

The community name of an incoming SNMP request is compared to the known community names. If a match is found, then the IP address of the incoming request is logically ANDed with the *snmp_mask* of the PW.SRC statement. The result of the logical ANDing process is compared with the *desired_network*. If they match, the request is accepted.

In the case of a password definition to be used by an IPv6 address or range of IPv6 addresses, the *snmp_mask* can be specified as a prefix value. The prefix specifies the number of bits to be used to construct an IPv6 address mask.

In the preceding example, if a request for *community_name* `passwd1` is received from the IP address 9.34.22.122, IP address 9.34.22.122 is ANDed with 255.0.0.0. The result is 9.0.0.0, which equals the specified *desired_network* for `passwd1`, so this request is accepted. In `passwd2`, if the *community_names* match, only requests from host 129.34.81.22 are accepted. The password `IPv6passwd3` can be used by any IPv6 address that starts with 12ab.

If the *community_name* values do not match, or the IP address ANDed with the *snmp_mask* does not match, an `AUTHENTICATION_FAILURE` trap is sent if both of the following are true:

- A destination entry exists in SNMPTRAP.DEST.
- Authentication failure traps have been enabled. These traps are enabled by either setting MIB object snmpEnableAuthenTraps.0 to 1, or specifying the following statement in the OSNMPD.DATA configuration information:

  ```
  snmpEnableAuthenTraps 1
  ```

A *desired_network* and *snmp_mask* of all zeros allows anyone with the correct *community_name* to make requests. However, the passwords for IPv4 addresses and the passwords for IPv6 addresses are stored and handled separately. Defining a password for use by both IPv4 and IPv6 addresses requires two entries in PW.SRC. Likewise, defining a password to be used by all addresses (both IPv4 and IPv6) requires two entries as follows:

```
passwd5 0.0.0.0 0.0.0.0
passwd5 0::0 0
```

Note: By default, the SNMP agent and the **snmp** command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIPA is configured. This is a change introduced in V2R10; previously, the SNMP agent and the **snmp** command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the PW.SRC file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this

change in behavior, if desired. This can be done for the SNMP agent by invoking it with the **-a** option. Similarly, you can do the same for the UNIX **snmp** command by either invoking it from the command line with the **-a** option, or by coding NOSVIPA in the command's OSNMP.CONF configuration file.

Provide trap destination information

Traps are unsolicited messages that are sent by an SNMP agent to an SNMP network management station. An SNMP trap contains information about a significant network event. The management application running at the management station interprets the trap information sent by the SNMP agent.

Note: When the SNMP agent starts, it retrieves an IP address for itself. If it retrieves an IPv6 colon-hexadecimal address, when it sends traps the source IP address in each trap will be 0.0.0.0.

For a detailed description of the SNMP trap types provided by z/OS CS, see *z/OS Communications Server: IP System Administrator's Commands*.

The SNMP agent Distributed Protocol Interface allows subagents other than those shipped with z/OS Communications Server (which might be running on another host) to generate SNMP traps. This can allow for support of other types of traps. For more information about SNMP DPI, see the *z/OS Communications Server: IP Programmer's Guide and Reference*.

To use traps, you must provide SNMPTRAP.DEST information defining a list of managers to which traps are sent. The SNMPTRAP.DEST information is optional. If no trap destination file is found, then the SNMP agent sends traps to the IP address of the SNMP agent and issues a warning message indicating that defaults are in effect. If a trap destination file exists, but is empty, no traps are sent.

Note: Verify that there is no SNMPD.CONF file. If an SNMPD.CONF file is found, the SNMPTRAP.DEST file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

SNMPTRAP.DEST example: The SNMPTRAP.DEST statements could be specified as follows:

```
# SNMP Trap Destination information
124.34.216.1 UDP
39B3::F430:03EE UDP
MVSSYS2      UDP
```

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

Provide community-based and user-based security and notification destination information

If you want to use user-based security, either concurrently with or instead of community-based security, you must configure security definitions and notification destinations. To allow SNMP subagents to connect to the SNMP agent using user-based security, you must configure community-based security definitions. The

SNMP subagents pass the community name to the agent on the connect request. The community name operates as a password when the SNMP subagents connect to the SNMP agent.

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as SOURCEVIPA is not in effect on the IPCONFIG profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent's authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the HOME list or the IP address specified on a PRIMARYINTERFACE TCP/IP profile statement. If SOURCEVIPA is in effect, the IP address used by the agent to verify the subagent's authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the HOME statement in *z/OS Communications Server: IP Configuration Reference*. Check the Netstat HOME/-h output to verify the IPv4 primary interface address of the stack.

SNMPv3 provides the ability to configure the agent dynamically, from either a local or remote host, and to make changes in the configuration while the SNMP agent is running. Doing SNMP agent configuration dynamically requires a good understanding of how the SNMP SET commands can be issued to create new rows or to change or delete existing rows, as well as familiarity with the SNMP engine configuration tables defined in RFCs 3584 and 3411 through 3415. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

As an alternative to dynamically configuring the SNMP agent, z/OS Communications Server supports a configuration file to be read at agent initialization called the SNMPD.CONF file. Dynamic configuration changes made with SNMP SET commands to the SNMP agent configuration entries will be written out to the SNMPD.CONF file, so they will continue to be in effect even after the SNMP agent is restarted.

SNMPD.CONF file

The SNMPD.CONF file defines the SNMP agent security and notification destinations. If the SNMPD.CONF file exists, the agent can support SNMPv1, SNMPv2c, and SNMPv3 requests. If no SNMPD.CONF file exists, the agent will support only SNMPv1 and SNMPv2c requests.

Note: If the SNMPD.CONF file is found, the PW.SRC file and the SNMPTRAP.DEST files are not used.

SNMPD.CONF dynamic configuration: If the SNMPD.CONF information is located in an MVS data set rather than a z/OS UNIX file, special considerations must be made to support dynamic configuration changes to the SNMP agent's configuration. If dynamic configuration changes are made, the file is rewritten to reflect the changes. Therefore, consider the following when allocating the SNMPD.CONF file to an MVS data set:

- The record length (LRECL) should be 512 bytes to accommodate the longest possible entry.
- The use of a member of a partitioned data set is tolerated but not recommended. Because the file might be rewritten often, frequent compression of the partitioned data set may become necessary. In addition, locking on the file is done at the data set level, not at the member level, so other members of the

partitioned data set would not be usable while the SNMP agent was running (once a dynamic configuration change had been made).

SNMPD.CONF example: A sample SNMPD.CONF file is shipped as /usr/lpp/tcpip/samples/snmpd.conf.

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

The sample OSNMP.CONF file used by the **snmp** command contains entries that match the sample SNMPD.CONF data set. See "Configure the z/OS UNIX snmp command" on page 1346 for additional information on configuring the **snmp** command.

Note: By default, the SNMP agent and the **snmp** command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIPA is configured. This is a change introduced in V2R10; previously, the SNMP agent and the **snmp** command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the SNMPD.CONF file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this change in behavior, if desired, by invoking the SNMP agent with the **-a** option or by using either the **-a** option or the NOSVIPA option in the **snmp** command's OSNMP.CONF configuration file.

SNMPD.BOOTS

The SNMP agent uses the SNMPD.BOOTS configuration file to support SNMPv3 security. This file contains agent information used to authenticate the SNMPv3 requests. The SNMPD.BOOTS keeps the agent identifier and the number of times the agent reboots. If no SNMPD.BOOTS file exists when the agent is started, the agent creates one. You may want to add comments to the beginning of this file. If a file does exist, the agent uses the values specified in the file for setting its engineID and engineBoots values. If the file exists but contains incorrect values for engineID or engineBoots, the agent issues a message and terminates.

Notes:

1. The recommended approach is to allow the SNMP agent to create the file.
2. If the SNMPD.BOOTS file is not provided, the SNMP agent creates the file. If multiple SNMPv3 agents are running on the same MVS image, use the environment variable to specify different SNMPD.BOOTS files for the different agents. For security reasons, ensure unique engineIDs are used for different SNMP agents.

Creating user keys

Authentication

Authentication is generally required for SNMPv3 requests to be processed (unless the security level requested is 'noAuth'). When authenticating a request, the SNMP agent verifies that the authentication key sent in an SNMPv3 request can be used to create a message digest that matches the message digest created from the authentication key defined for the user.

The **snmp** command uses the authentication key found on an entry in the OSNMP.CONF configuration file. It needs to correlate with the authentication key specified on a USM_USER entry for that user in the agent's SNMPD.CONF configuration file.

As an alternative to storing authentication keys in the client configuration file, the **snmp** command allows user passwords to be stored. If the **snmp** command is configured with a password, the code generates an authentication key (and privacy key if requested) for the user. These keys must, of course, produce the same authentication values as the keys configured for the USM_USER in the agent's SNMPD.CONF file or configured dynamically with SNMP SET commands. However, the use of passwords in the client configuration file is considered less secure than the use of keys in the configuration file.

The authentication key is generated from two pieces of information:

- The specified password.
- The identification of the SNMP agent at which the key will be used. If the agent is an IBM agent and its engineID was generated using the vendor-specific engineID formula, the agent may be identified by IP address or host name. Otherwise, the engineID must be provided as the agent identification.

A key that incorporates the identification of the agent at which it will be used is called a localized key. It can be used only at that agent. A key that does not incorporate the engineID of the agent at which it will be used is called nonlocalized.

Keys stored in the **snmp** command's configuration file, OSNMP.CONF, are expected to be nonlocalized keys. Keys stored in the SNMP agent's configuration file, SNMPD.CONF, can be either localized or nonlocalized, though the use of localized keys is considered more secure.

Encryption

Keys used for encryption are generated using the same algorithms as those used for authentication. However, key lengths might differ. For example, an HMAC-SHA authentication key is 20 bytes long, but a localized encryption key used with HMAC-SHA is only 16 bytes long. The SNMP agent, z/OS UNIX **snmp** command, and the SNMP manager API use the first 16 bytes of the HMAC-SHA authentication key as the localized encryption key (also called the privacy key).

z/OS Communications Server provides a facility called *pwtokey* that enables conversion of passwords into localized and nonlocalized authentication and privacy keys. The pwtokey procedure takes as input a password and an identifier of the agent and generates authentication and privacy keys. Since the procedure used by the pwtokey facility is the same algorithm used by the **snmp** command, the person configuring the SNMP agent can generate appropriate authentication and privacy keys to put in the SNMPD.CONF file for a user, given a particular password and the IP address at which the agent will run.

Use the **pwtokey** command to convert passwords into authentication and privacy keys. See *z/OS Communications Server: IP System Administrator's Commands*.

Migrating community-based configuration to SNMPD.CONF format

If you want to continue to use community-based security but take advantage of some of the new SNMPv3 functions, or if you want to use the new SNMPv3 user-based security along with community-based security, you need to migrate your current configuration, defined in PW.SRC and SNMPTRAP.DEST, to SNMPD.CONF format. For information about the necessary steps for migrating PW.SRC and SNMPTRAP.DEST to SNMPD.CONF, see *z/OS Communications Server: IP Configuration Reference*.

Provide secure access to agent from subagents

An SNMP subagent can connect to the z/OS Communications Server SNMP agent by using the DPI API (the DPI API is documented in *z/OS Communications Server: IP Programmer's Guide and Reference*) and specifying either a z/OS UNIX or a TCP connection. You can control access to the agent from subagents for both types of connections.

Connecting to the agent through z/OS UNIX

For subagents that specify a z/OS UNIX connection to the agent, a z/OS UNIX path name is used for the connection. You can configure this path name by either specifying it on the **-s** agent initialization parameter or specifying it as the value of the dpiPathNameForUnixStream MIB object in OSNMPD.DATA. The default path name is /var/dpi_socket.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the -C agent initialization parameter.

For more detailed information about file access permission bits and handling security for your files, see *z/OS UNIX System Services User's Guide*. If you need to change the file access permission bits for the path name after the agent has initialized, you can use the z/OS UNIX **chmod** command. For more information about the **chmod** command, see *z/OS UNIX System Services Command Reference*.

Connecting to the agent through TCP

For subagents specifying a TCP connection, you can use the installation's SAF-compliant security product [such as the z/OS Security Server (RACF)] to control which of the SNMP subagents are permitted to connect to the SNMP agent. One security product resource name can be created per TCP/IP stack per MVS image. The security product resource name is specified in the following format:

```
EZB.SNMPAGENT.sysname.tcpprocname
```

where *sysname* is the name of the MVS system image and *tcpprocname* is the TCP/IP started procedure name.

The profile must be created under the SERVAUTH class. After creating the profiles, use the security product to define the user IDs of those subagents which should be permitted to connect via TCP to the SNMP Agent. Authorization failures are documented by security product failure messages and SNMP agent traces.

Note: If you use this authorization function, only SNMP subagents which are associated with the same TCP/IP stack as the SNMP agent will be permitted to connect to the agent. Local SNMP subagents associated with other TCP/IP stacks, or remote SNMP subagents, will not be permitted to connect. Also, any subagents which connected to the SNMP agent before the agent security product resource name was created will not have been authorized via the security product.

You can use the control statements in the sample JCL job provided in SEZAINST(EZARACF) to define this authorization. For example, if you wanted to permit any SNMP subagents associated with a user ID of USER2 to connect to the SNMP agent you could use the following definitions:

```
RDEFINE SERVAUTH EZB.SNMPAGENT.MVSA.TCP1 UACC(NONE)
PERMIT EZB.SNMPAGENT.MVSA.TCP1  ACCESS(READ) CLASS(SERVAUTH) ID(USER2)
```

Allowing subagents with duplicate identifiers to connect

When an SNMP subagent connects to the SNMP agent, an SNMP object identifier (OID) value is used as the subagent identifier. For subagents connecting using the DPI V2.0 API, the subagent supplies its OID during the connection process. All the Communications Server subagents use the DPI V2.0 API when connecting to the agent.

For subagents connecting using the DPI V1.1 API, the agent assigns a constant OID value to the subagent. Therefore, if more than one DPI V1.1 subagent connects to the agent, all the DPI V1.1 subagents are identified with the same OID value.

The SUBAGENT-MIB, supported by the SNMP agent, defines the MIB object, saAllowDuplicateIDs, that can be used to configure whether the agent should allow subagents with duplicate OID values to connect. By default, the SNMP agent sets the value of this object to 1, which allows subagents with duplicate OID values to connect. You can configure the value of this MIB object using the OSNMPD.DATA configuration file. For more information about this file, see "Provide MIB object configuration information." If you do not want the agent to allow subagents with duplicate OID values to connect, set the value of this MIB object to 2.

Provide MIB object configuration information

An installation can set values for selected MIB objects by providing OSNMPD.DATA information. A sample of OSNMP.DATA is installed as file /usr/lpp/tcpip/samples/osnmpd.data. See *z/OS Communications Server: IP Configuration Reference* for syntax information. If no OSNMPD.DATA file is found, the defaults for these MIB objects are as follows:

Object	Default
dpiPathNameForUnixStream	The default is /var/dpi_socket. This is the z/OS UNIX path name that is used in accepting requests from subagents that communicate with the agent over z/OS UNIX connections.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the -C agent initialization parameter.

For more detailed information about file access permission bits and handling security for your files, see *z/OS UNIX System Services User's Guide*. If you need to change the file access permission bits for this path name after the agent has initialized, you can use the z/OS UNIX **chmod** command. For more information about the **chmod** command, see *z/OS UNIX System Services Command Reference*.

sysDescr

If the environment variable HOSTNAME exists, its value is used. Otherwise, the default value identifies the z/OS system under which the agent is running. The maximum length of this object is 255 octets.

sysContact

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysLocation

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysName

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysObjectId

1.3.6.1.4.1.2.3.13

Note: sysObjectID is defined as the vendor's authoritative identification of the network management subsystem contained in the entity. That is, it is intended to uniquely identify the SNMP agent. Changing this value is not recommended and will be disabled in a subsequent release.

sysServices

A single octet with a default of 0. See the RFC 1907 description for this object.

snmpEnableAuthenTraps

Default value is 2, which means traps are disabled.

saDefaultTimeout

5 seconds.

saMaxTimeOut

600 seconds.

saAllowDuplicateIDs Default is 1, which means multiple instances of a subagent (that is, where the subagent identifier for all the subagents is the same) are allowed to connect to the SNMP agent. To prevent multiple instances of a subagent from connecting to the SNMP agent, set the value to 2.

Note: Because a subagent identifier cannot be specified for subagents connecting using the DPI V1.1 API, the SNMP agent assigns the same constant identifier for all DPI V1.1 subagents. Therefore, this object must be set to 1 to allow multiple DPI V1.1 subagents to run concurrently. For more information about subagent identifiers, see "Allowing subagents with duplicate identifiers to connect" on page 1343.

For information about where these MIB objects are defined, see *z/OS Communications Server: IP User's Guide and Commands*.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

Start the SNMP agent

The SNMP agent (OSNMPD) runs in a separate address space that executes load module EZASNMPD. OSNMPD can be started with or without parameters. When starting OSNMPD from MVS, add the parameters to the PARMS= keyword on the EXEC statement of the OSNMPD cataloged procedure. When starting OSNMPD from z/OS UNIX, specify the desired parameters on the **osnmpd** command. See *z/OS Communications Server: IP Configuration Reference* for the command syntax.

If the SNMP agent encounters any errors processing its configuration files, error messages are written to the syslog daemon, not to the console.

Sample JCL procedure for starting OSNMPD from MVS

Update cataloged procedure OSNMPD by copying the sample in SEZAINST(OSNMPDPR) to your system or recognized PROCLIB. Change the data set names as required to suit your local configuration. The OSNMPD address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

You can pass parameters to the agent on the PARMS= keyword on the EXEC statement of the OSNMPD cataloged procedure. See *z/OS Communications Server: IP Configuration Reference* for the command syntax and parameter information. You can specify any agent parameters that you want, as shown in the following example:

```
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM='-c abc -d 255 -p 761'
```

In this example, the agent will use port 761 to accept requests, community name abc will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see the *z/OS Communications Server: IP Diagnosis Guide*.

Starting OSNMPD from z/OS UNIX

To run the SNMP agent in background, you must add an ampersand (&) to the command and the issuer of the command must be in z/OS UNIX superuser mode. For a detailed explanation of the **osnmpd** parameters, see *z/OS Communications Server: IP Configuration Reference*.

Any agent parameters you wish to specify may be added as shown in the following example:

```
osnmpd -c abc -d 255 -p 761
```

In this example, the agent will use port 761 to accept requests, community name 'abc' will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see *z/OS Communications Server: IP Diagnosis Guide*.

Step 2: Configure the SNMP commands

The two SNMP client applications provided with z/OS Communications Server are:

- **snmp** command in the z/OS shell
- SNMP command from the NetView environment

The SNMP command in the NetView environment requires the use of the NetView product. It supports SNMP version 1. The **snmp** command in the z/OS shell supports SNMP versions 1, 2, and 3. Depending on your requirements, you might decide to configure either or both of these clients, or to use an SNMP client on another platform.

Configure the z/OS UNIX snmp command

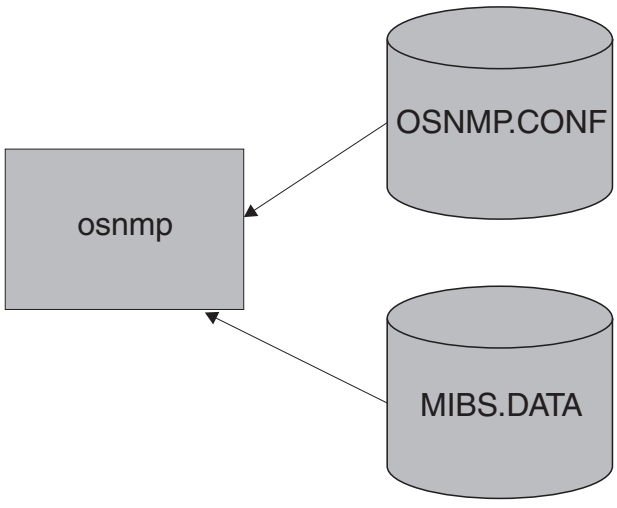

Figure 130. Configuration files for **snmp**

The z/OS UNIX **snmp** command is used to send SNMP requests to SNMP agents on local or remote hosts, or to receive SNMP traps or notifications. You can also use the synonym, **osnmp**, as the name of this command. The requests can be SNMPv1, SNMPv2c, or SNMPv3. For SNMPv2c and SNMPv3 requests, the OSNMP.CONF configuration file is required. The *winSNMPname* specified on an OSNMP.CONF statement can be used as the value of the **-h** parameter on the

snmp command. For a detailed explanation of the parameters you can specify on the **snmp** command, see *z/OS Communications Server: IP System Administrator's Commands*.

To configure the **snmp** command, perform the following tasks:

- The **snmp** command needs to be able to resolve the name of the host, on which the command is executing, to the host's IP address. You can provide this information either by configuring a domain name server or by configuring local host files. For information about the search order used to locate local host files, see the local host tables entry in Table 37 on page 760. As part of its support for the SNMPv3 protocol, the command also uses this IP address when creating its SNMPv3 engineID value.
- Provide **snmp** configuration information
- Provide user MIB object information

Provide snmp configuration information

The OSNMP.CONF file is used to define target agents and, for SNMPv3, the security parameters to be used in sending requests to them.

The contents of the file, regardless of location, are the same. Only the first file found is used. A sample of this file is installed as file /usr/lpp/tcpip/samples/snmpv2.conf. This sample should be copied and modified for your installation. See *z/OS Communications Server: IP Configuration Reference* for more information.

Examples:

- Example 1:

  The following entry defines an SNMPv2c node for **snmp**:

  ```
  mvs1     9.67.113.79 snmpv2c
  ```

  where *mvs1* is the name used with the **-h** parameter on the **snmp** command and *9.67.113.79* is the IP address of the SNMPv2c agent.

- Example 2:

  The following entry defines an SNMPv3 node:

  ```
  v3mak   127.0.0.1 snmpv3 u1 - - AuthNoPriv  HMAC-MD5 7a3e34265e0e029f27d8b4235ecfa987 - -
  ```

  where *v3mak* is the name used on the **-h** parameter of the **snmp** command. An SNMP request sent using this entry uses USM user name *u1* using HMAC-MD5 authentication but no encryption.

- Example 3:

  The following entry defines an SNMPv3 node. The needed authentication and privacy keys will be generated from the password *u6password*.

  ```
  v3sap   127.0.0.1 snmpv3 u6 u6password - AuthNoPriv   HMAC-SHA -   - -
  ```

  The USM user is *u6*. The authentication protocol is HMAC-SHA, and no encryption is used.

- Example 4:

  The following entry defines an SNMPv3 node:

  ```
  v3mpk_ipv6 ::1 snmpv3 u1 - - AuthPriv HMAC-MD5 7a3e34265e0e029f27d8b4235ecfa987 DES eac02a0d9fe90eca7911fdcaba20deae
  ```

  where *v3mpk_ipv6* is the name used on the **-h** parameter of the **snmp** command. An SNMP request sent using this entry uses USM user name *u1* using HMAC-MD5 authentication and CBC 56-bit DES encryption.

Provide MIB object information in MIBS.DATA

Like other SNMP managers, when you enter the z/OS UNIX **snmp** command you can specify the object identifier (OID) of the MIB object whose value you want to retrieve. If the MIB object is supported by one of Communication Server's SNMP functions, you can also use the MIB object textual name on the z/OS UNIX **snmp** command, instead of the object identifier. All the MIB objects supported by Communications Server functions are listed in the MIB objects appendix in *z/OS Communications Server: IP System Administrator's Commands*.

For example, to retrieve the SNMP agent sysUpTime MIB object, you can enter either of the following commands:

- ```
  snmp -v get sysUpTime.0
  sysUpTime.0 = 289700
  ```
- ```
  snmp -v get 1.3.6.1.2.1.1.3.0
  sysUpTime.0 = 292700
  ```

The 1.3.6.1.2.1.1.3 value is the OID for the sysUpTime MIB object.

If you have user-defined MIB objects or MIB objects from other products, and you want to use the textual names for these MIB objects on the z/OS UNIX **snmp** command, you can define these objects to the **snmp** command using the MIBS.DATA file. A sample of the MIBS.DATA file is installed as file /usr/lpp/tcpip/samples/mibs.data. Copy this sample and modify it for your installation. For the search order used to locate the MIBS.DATA file, see "Understanding search orders of configuration information" on page 19.

If other products provide files using MIBS.DATA syntax, append the statements from their files to your MIBS.DATA file so that these statements are accessible to the **snmp** command. For example, the IBM OSA-Express Direct subagent provides a file in MIBS.DATA syntax so that the textual names of its OSA-Express management data can be used with the z/OS UNIX **snmp** command. For information about how to obtain this file, see *zEnterprise 196, System z10, System z9 and eServer zSeries OSA-Express Customer's Guide and Reference*.

MIBS.DATA statement syntax

The format of a statement in the MIBS.DATA file is:

```
character_object_name object_identifier object_type
```

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

Configure the NetView SNMP command

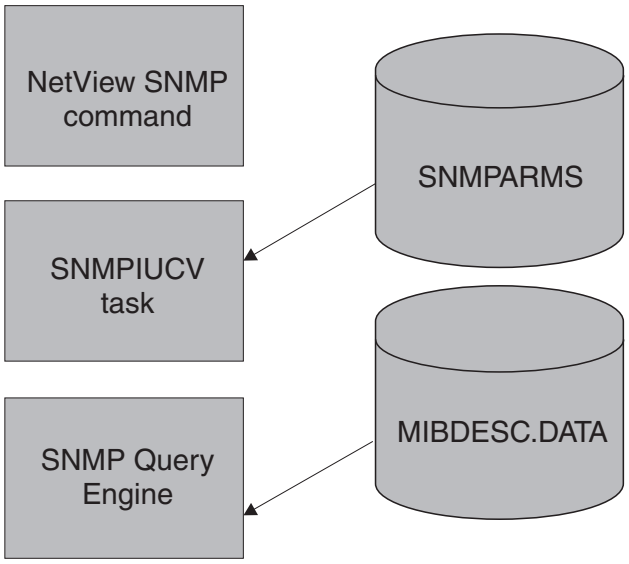

Figure 131. Configuration files for NetView SNMP

The SNMP command in the NetView environment can be used to send SNMP version 1 requests to SNMP agents on either local or remote hosts. The SNMP command requires the command processor itself, the SNMPIUCV task for inter-address space communication, and the SNMP query engine, which creates the packets sent to the SNMP agent. The NetView SNMP command and the SNMP query engine support only community-based security.

Configure the SNMP query engine

Update the SNMPQE cataloged procedure by copying the sample in SEZAINST(SNMPPROC) to your system or recognized PROCLIB. Specify SNMP parameters and change the data set names as required to suit your local configuration. The SNMPQE address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

The SNMP query engine (SQESERV) needs access to the *hlq*.MIBDESC.DATA data set for the MIB variable descriptions. You can find a sample of this data set in SEZAINST(MIBDESC).

MIBDESC.DATA data set: The MIBDESC.DATA data set defines the short names for MIB variables. Short names are the character representation for the ASN.1 variable names. For example, sysUpTime is the short name for 1.3.6.1.2.1.1.3.0 (the MIB variable that stores the time since the SNMP agent was last restarted). Short names are generally shown as a combination of upper and lowercase characters, though SNMP on z/OS Communications Server ignores these case distinctions. Variable names must always be in ASN.1 language when they are sent to an SNMP agent. You can always use ASN.1 language to specify the variable names in an enterprise-specific tree (assuming that the agent supports them). You can use these short names to specify the MIB variables.

When you issue an SNMP GET, GETNEXT, or SET command, and specify the variable name in ASN.1 notation, the SNMP Query Engine uses that name and sends it in the SNMP packet to the agent. When you issue an SNMP GET, GETNEXT, or SET command, and specify the short name for the variable (for

example, sysDescr), the SNMP Query Engine looks for that name in the MIBDESC.DATA data set and uses the ASN.1 name specified in the data set when it sends the SNMP packet to the agent.

The SNMPQE address space must be able to access the MIBDESC.DATA data set.

You can change the short names in the MIBDESC.DATA data set to the equivalent in your national language. You can also leave the current names and add the equivalent names in your national language. However, the SNMP MIBVNAME function returns only the first entry found in the data set that satisfies the search. In addition, all enterprise-specific variables used by hosts in your network should be added to this data set.

Entries in the data set do not need to be in a specific sequence. Each name starts on a new line. The following shows the line format.

```
short_name asn.1_name type time_to_live
```

Each variable on the line is separated by either one or more spaces or tabs. An asterisk (*) in column 1 indicates that the line is a comment line.

Following is a sample MIBDESC.DATA line with a sysDescr variable translated in Dutch and a few enterprise variables added (in this example, company ABC received 1.3.6.1.4.1.42 as the ASN.1 number for their enterprise):

```
*-------------------------------------------------------------*
* MIB Variable name | ASN.1 notation        | Type     | TTL  *
*-------------------------------------------------------------*
* Following is Dutch name for sysDescr
systeemBeschrijving  1.3.6.1.2.1.1.1.         display    900
sysDescr             1.3.6.1.2.1.1.1.         display    900
  ...
  other entries
  ...
* Following are Enterprise-Specific variables for company ABC
ABCInfoPhone         1.3.6.1.4.1.42.1.1       display    900
ABCInfoAddress       1.3.6.1.4.1.42.1.2       display    900
```

The TTL field contains the number of seconds that a variable lives in the Query Engine's internal cache. If there are multiple requests for the same variable within the TTL period, the variable value is obtained from the cache, and unnecessary network traffic is avoided.

You can define multiple short names or text names for the same variable, as shown with the Dutch translation of the sysDescr variable. In this case, the SNMP Query Engine returns the first value in the table on an SNMP MIBVNAME request. In the previous example, the SNMP Query Engine would return `systeemBeschrijving` and not `sysDescr`. The name returned is in mixed case.

When the SNMP Query Engine receives a short name or text name in a GET, GETNEXT, or SET request, it compares the name against the entries in the MIBDESC.DATA data set. This comparison is not case-sensitive. For example, a request for `SYSDESCR`, `SysDescr`, or `sysDescr` matches the `sysDescr` entry with an ASN.1 notation of `1.3.6.1.2.1.1.1.`.

When the SNMP Query Engine receives an SNMP response, it looks up the variable in the MIBDESC.DATA table Type field for information about translating the value into displayable characters. The information contained in the Type field is case-sensitive and must be specified in lowercase.

Note: If you are using SNMP to receive response or trap PDUs which contain enterprise-specific variables, the variables must be added to the MIBDESC.DATA data set.

Specifying the SNMPQE parameters: The SQESERV module can be configured to start without parameters or you can add any of the following parameters to PARMS=' in the PROC statement of the SNMPQE cataloged procedure. For example,

```
//SNMPQE   PROC MODULE=SNMPQE,PARMS='-h MVSA'
```

See *z/OS Communications Server: IP Configuration Reference* for the command syntax.

See *z/OS Communications Server: IP Diagnosis Guide* for more information on tracing.

Setting up authorization for SNMPQE: To create RAW sockets necessary for SNMP PING requests, the user ID associated with the SNMPQE started task must have superuser authority (z/OS UNIX UID of 0), or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class.

Configure NetView as an SNMP monitor

To configure the NetView interface as an SNMP monitor, perform each of the following tasks:

- Configure for SNMPIUCV
- Configure for the SNMP command processor
- Configure for the SNMP messages
- Update the SNMP initialization parameters

Configure for SNMPIUCV: SNMPIUCV is the NetView optional task that handles IUCV communication between the NetView program and the SNMP query engine. SNMPIUCV resides in the SEZADSIL data set.

Add the following TASK statement for SNMPIUCV to the DSIDMN member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
TASK  MOD=SNMPIUCV,TSKID=SNMPIUCV,PRI=5,INIT=Y
```

This statement causes SNMPIUCV to start automatically when the NetView program is started.

If you specify INIT=N instead of INIT=Y in the TASK statement for SNMPIUCV, a NetView operator can start the SNMPIUCV task by entering the following:

```
START TASK=SNMPIUCV
```

The SNMPIUCV task tries to connect through IUCV to the SNMP query engine. If this fails, it retries the connect as specified by the SNMPQERT keyword in the SNMPARMS member of the SEZADSIP data set. The default is every 60 seconds.

Configure for the SNMP command processor: SNMP is the command processor that allows NetView operators and CLISTs to issue SNMP commands. SNMP resides in the SEZADSIL data set. This data set should be concatenated to the STEPLIB DD statement in the NetView start procedure.

Add the following statement to the DSICMD member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
SNMP  CMDMDL  MOD=SNMP,ECHO=Y,TYPE=R,RES=Y
```

After the SNMPIUCV task is started, you can issue the SNMP command. The SNMP command passes a request to the SNMPIUCV task to forward to SNMPQE. The return code represents a request number that is associated with the request. The responses are returned asynchronously and contain this request number. The operator or CLIST must use the request number to correlate the response to the request.

Configure for the SNMP messages: The NetView SNMP messages reside in the SEZADSIM data set as DSISNM*nn*, where *nn* is the number of the member. The valid message members are DSISNM00 through DSISNM05, DSISNM10, DSISNM12, and DSISNM99. The data set containing these members should be added to the DSIMSG DD statement in the NetView start procedure.

Update the SNMP initialization parameters: SNMPIUCV reads the SNMPARMS member in the SEZADSIP data set at startup. This data set contains the initialization parameters for SNMP. The data set containing SNMPARMS should be added to the DSIPARM DD statement in the NetView startup procedure. See *z/OS Communications Server: IP Configuration Reference* for detailed information for the SNMP parameter data set (SNMPARMS).

Step 3: Configure the SNMP subagents

There are several SNMP subagents shipped with z/OS Communications Server:

- The TCP/IP subagent reports information about the TCP/IP stack. For details on configuring this subagent, see "TCP/IP subagent configuration" on page 1353.
- The OMPROUTE subagent reports information specific to OSPF. The ROUTESA_CONFIG statement is used in the OMPROUTE configuration file to configure the OMPROUTE subagent. For details on ROUTESA_CONFIG, see *z/OS Communications Server: IP Configuration Reference*.
- The Network SLAPM2 subagent reports information about defined policies and performance statistics related to traffic using those policies. For configuration information about the Network SLAPM2 subagent, see Chapter 17, "Quality of service," on page 873.
- The TN3270E Telnet subagent reports information about TN3270E Telnet server connections and monitoring values. For information on the TNSACONFIG statement and the parameters needed to start the TN3270E Telnet subagent, see *z/OS Communications Server: IP Configuration Reference*.
- The OSA-Express Direct SNMP subagent is also shipped with z/OS CS but is supported by the zSeries OSA Support Group. The OSA-Express Direct SNMP subagent and the OSA MIB provided by the zSeries OSA Support Group can be used with Communications Server SNMP support to provide SNMP management data for some OSA adapters. For details regarding the OSA-Express Direct SNMP subagent and OSA MIB, see *zEnterprise 196, System z10, System z9 and eServer zSeries OSA-Express Customer's Guide and Reference*.

These subagents use the stack's IPv4 primary interface IP address when connecting to the SNMP agent. The IPv4 primary interface IP address is either the first IPv4 IP address specified in the HOME profile statement, or the IP address of the IPv4 interface specified on a PRIMARYINTERFACE profile statement. If the subagents cannot obtain the IPv4 primary interface IP address, they will use the IPv4 loopback IP address, 127.0.0.1, to connect to the agent. For information on using the IPv4 primary interface IP address and a community name to permit the subagents to connect to the SNMP agent, see "Provide community name information" on page 1336 or "Provide community-based and user-based security and notification destination information" on page 1338.

TCP/IP subagent configuration

There are two statements in the profile data set used to configure the TCP/IP subagent, the SACONFIG and ITRACE statements.

- SACONFIG

  Use the SACONFIG statement to configure the subagent. The SACONFIG parameters determine whether or not the subagent is automatically started at TCP/IP initialization, what port number to use to contact the agent, and other configuration values. For a detailed explanation of this statement, see *z/OS Communications Server: IP Configuration Reference*.

- ITRACE

  Use the ITRACE statement to determine what trace information, if any, should be recorded by the subagent. For a detailed explanation of this statement, see *z/OS Communications Server: IP Configuration Reference*.

Step 4: Configure the Open Systems Adapter support

The TCP/IP subagent can retrieve SNMP management data from the Open Systems Adapter Support Facility (OSA/SF) for several OSA adapters.

The OSA product also provides an SNMP subagent, the OSA-Express Direct subagent, that supports management data for OSA-Express adapters. The OSA-Express Direct subagent can be used with Communications Server SNMP support to retrieve the management data. You should use the OSA-Express Direct subagent for OSA management data, rather than the TCP/IP subagent, because the OSA-Express Direct subagent communicates directly with the OSA-Express adapters and does not require the OSA/SF and IOASNMP applications. For more information about the management data provided by the OSA-Express Direct subagent, see *zEnterprise 196, System z10, System z9 and eServer zSeries OSA-Express Customer's Guide and Reference*.

The TCP/IP subagent supports management data for the following OSA adapters:

- ATM management data is supported for any OSA-2 ATM or OSA-Express ATM155 adapters.
- Ethernet management data is supported for any OSA-Express Gigabit Ethernet or OSA-Express QDIO Fast Ethernet adapters.
- Tables of OSA-Express management data are supported for any OSA-Express Gigabit Ethernet, Fast Ethernet, or ATM155 adapters.

The TCP/IP subagent retrieves the data using the OSA/SF components IOAOSASF (OSA/SF application) and IOASNMP (OSA/SF socket application). For more information on these components, see "OSA/SF prerequisites" on page 1355. Specifying the SACONFIG profile statement, with the OSAENABLED and OSASF parameters, in the TCP/IP profile data set causes the TCP/IP subagent to try to connect to the OSA/SF socket application, IOASNMP, using the TCP protocol and the port number specified on the OSASF parameter. If the subagent connects successfully, the following message is issued:

```
EZZ3218I SNMP SUBAGENT: CONNECTED TO OSA/SF
```

Because of timing considerations, the TCP/IP subagent might not be able to connect to IOASNMP at initalization. If this occurs, the subagent will attempt to connect when the first request for OSA MIB data is received. Therefore, the EZZ3218I message might not always be issued during subagent initialization.

When retrieving management data from the OSA adapters, the TCP/IP subagent sends a request to IOASNMP for the data, passing the adapter's portname as an identifier. The portname is obtained from the DEVICE and LINK profile statements used to define the adapter to the TCP/IP stack. The IOASNMP socket application uses APPC to pass the request to the OSA/SF application. The OSA/SF application then retrieves the data from the adapter and returns it to IOASNMP. IOASNMP uses its TCP connection to the TCP/IP subagent to return the data to the subagent. If this configuration is active and either the IOASNMP application or the TCP/IP subagent terminates, the subagent will issue the following message:

```
EZZ3219I SNMP SUBAGENT: DISCONNECTED  FROM OSA/SF
```

To obtain the management data, the adapters must be defined to the TCP/IP stack where the subagent is active, through DEVICE and LINK statements in the TCP/IP profile.

- To retrieve ATM management data, the ATM adapter must be defined as an ATM device/link, even if it is configured for ATM LAN emulation mode and is therefore also defined to some TCP/IP instance as an LCS or MPCIPA device. For OSA-Express ATM155 adapters configured for QDIO LAN Emulation mode, you can use one of the adapter's logical port names on the PORTNAME parameter of the ATM DEVICE statement.
- To retrieve Ethernet management data, the OSA-Express adapter must be defined as an MPCIPA Ethernet link.
- To retrieve OSA-Express management data, the adapters must be defined as the following TCP/IP device/link types:
  - MPCIPA link for Gigabit Ethernet
  - MPCIPA or LCS Ethernet link for Fast Ethernet
  - ATM device/link for ATM155

If the port name is manually configured at the adapter, then management data can be retrieved from the adapter even if it is not active and not in use by any TCP/IP stack or by VTAM. If the port name is dynamically configured (e.g. MPCIPA links), then the adapter has to be active to some TCP/IP stack to retrieve the management data.

Current support consists of:

- Interface table from RFC2233 for ATM, LAN emulation links, AAL5 and ATM layer interfaces.
- ATM Channel table from the IBM MVS Enterprise-Specific MIB for OSA-2 ATM adapters.
- ATM Port and PVC tables from the IBM MVS Enterprise-Specific MIB for OSA-2 ATM and OSA-Express ATM155 adapters.
- ATM LAN Emulation tables from the IBM MVS Enterprise-Specific MIB for OSA-2 ATM and OSA-Express ATM155 adapters.
- atmInterfaceConfTable from RFC1695 for OSA-2 ATM and OSA-Express ATM155 adapters.
- IP over ATM tables from RFC2320 for OSA-2 ATM and OSA-Express ATM155 adapters.
- OSA-Express Channel and Performance tables from the IBM MVS Enterprise-Specific MIB for OSA-Express Gigabit Ethernet, Fast Ethernet, and ATM155 adapters. The performance MIB object values in the ibmMvsOsaExpChannelTable, and all of the MIB object values in the ibmMvsOsaExpPerfTable, are only available starting with zSeries processors where the adapters are, at least, at microcode level 1.31.

- OSA-Express Ethernet Port table from the IBM MVS Enterprise-Specific MIB for OSA-Express Gigabit Ethernet and Fast Ethernet adapters.
- OSA-Express Ethernet SNA table from the IBM MVS Enterprise-Specific MIB for OSA-Express Fast Ethernet adapters.
- dot3StatsTable from EtherLike-MIB in RFC2665 for OSA-Express Gigabit Ethernet and QDIO Fast Ethernet adapters.
- Asynchronous SNMP Trap generation for operational management:
  - ATM Permanent Virtual Circuit (PVC) creation - ibmMvsAtmOsasfAtmPvcCreate Trap (ATM OSA-2 adapter only).
  - ATM Permanent Virtual Circuit (PVC) deletion - ibmMvsAtmOsasfAtmPvcDelete Trap (ATM OSA-2 adapter only).
- Provide method for assigning an IP Address to the ATM Port.

  Use the **osnmp set** command against the ibmMvsAtmOsasfPortIpAddress MIB object to assign the IP Address.

OSA/SF prerequisites

The TCP/IP subagent provided by z/OS Communications Server will connect to OSA/SF to obtain management data. For a subagent to establish a connection to OSA/SF, two OSA/SF components must be started:

- IOAOSASF

  IOAOSASF is a sample JCL procedure that can be used to start the main OSA/SF address space. The sample has a job name of OSASF1.
- IOASNMP

  IOASNMP is a sample JCL procedure that starts the OSA/SF-provided z/OS UNIX socket application that interconnects the TCP/IP subagent with OSASF1.

These sample procedures and all entities that they call are provided with OSA/SF. For a detailed explanation of how to set up OSA/SF on your MVS system, see *zEnterprise 196, System z10, System z9 and eServer zSeries OSA-Express Customer's Guide and Reference*. The primary purpose of OSA/SF is to manage OSA Adapters. It has been extended to support OSA management via SNMP. An instance of IOAOSASF, IOASNMP, the TCP/IP stack, the TCP/IP subagent, and the SNMP agent must be started on every MVS image where OSA management support is needed.

The recommended startup order is:

1. Start IOAOSASF and wait until it completely initializes. IOAOSASF must be started before IOASNMP.
2. Include OSNMPD (the CS SNMP agent) and IOASNMP on the AUTOLOG profile statement for your TCP/IP stack. This ensures that they will be started by autolog processing when TCP/IP is started. For additional profile statement requirements, see "Required TCP/IP profile statements" on page 1356. Start the TCP/IP stack.

On an MVS image only a single instance of either IOAOSASF or IOASNMP can (or should) be started. An attempt to start multiple copies of IOAOSASF will be rejected. Starting multiple copies of IOASNMP will yield unpredictable results.

Ensure that OSA/SF is at Version 2 Release 1 level or higher with the OSA/SF APAR OW45237 applied.

Required TCP/IP profile statements

For a detailed description of the statements mentioned here, see *z/OS Communications Server: IP Configuration Reference*. The following TCP/IP profile statements must be updated for OSA management support:

- SACONFIG

  On the SACONFIG statement, OSA Management support must be enabled by specifying OSAENABLED. Omission of OSAENABLED when TCP/IP is started will result in no OSA management support. The SACONFIG statement controls the operation of the subagent that runs in a TCP/IP address space as a separate task.

  The OSASF parameter specifies which port IOASNMP should use to Listen for connections from subagents to OSA/SF. For an explanation of the usage of this parameter when starting multiple TCP/IP instances, see "Subagent connection to OSA/SF when there are multiple TCP/IP instances." It is recommended that the OSASF port be reserved by also specifying it on a PORT statement.

  For example:

  ```
  SACONFIG OSAENABLED OSASF 721
  ```

- PORT

  Prereserve the port to be used in communication with OSA/SF.

  For example:

  ```
  PORT
     721  TCP IOASNMP ; OSA/SF TCP/IP Communications
  ```

  In the above example since IOASNMP runs as a z/OS UNIX application the port could have been reserved for z/OS UNIX. Review the /etc/services file to insure that there are no port conflicts.

- DEVICE and LINK

  Provide ATM DEVICE and LINK statements for any OSA ATM adapter for which you want SNMP ATM management data. For example:

  ```
  DEVICE osaName ATM PORTNAME portname
  LINK linkName ATM osaName
  ```

  Provide DEVICE and LINK statements for any OSA-Express Ethernet adapter for which you want SNMP Ethernet management data. For example:

  ```
  DEVICE portname MPCIPA NONROUTER
  LINK linkName IPAQENET portname
  ```

Subagent connection to OSA/SF when there are multiple TCP/IP instances

When multiple z/OS Communications Server instances are active in the same MVS image, only one of the TCP/IP instances is connected to IOASNMP. For a TCP/IP instance to connect to IOASNMP, the OSASF parameter must be specified on the SACONFIG profile statement.

IOASNMP connects to a TCP/IP instance and acts as a server, receiving connections from those TCP/IP subagents where OSAENABLED was specified on the SACONFIG Profile statement. The result is that all these subagents connect through the same TCP/IP to IOASNMP in order to retrieve OSA information from OSA/SF. For a depiction of this process, see Figure 132 on page 1357.

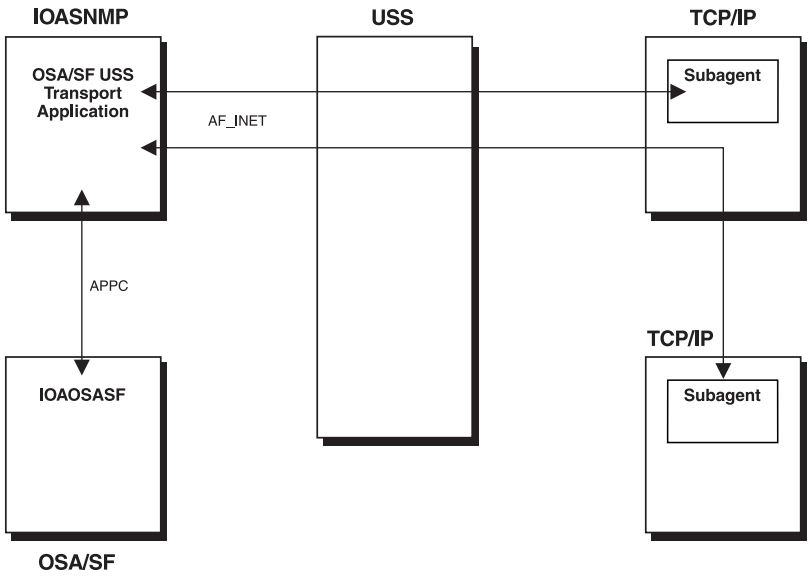

Figure 132. Subagent connection to OSA/SF

If IOASNMP loses its connection to TCP/IP it terminates and needs to be restarted.

If the currently connected TCP/IP terminates, IOASNMP will attempt to connect to another TCP/IP instance for which the OSASF parameter was specified on the SACONFIG Profile statement, using the port number specified for the OSASF parameter. The subagents will also attempt to reconnect to OSA/SF via IOASNMP using this same OSASF port number. For this reason it is recommended that the same OSASF port number be used on the SACONFIG statement of every TCP/IP instance where the OSASF parameter is specified.

Whenever a socket error occurs on the OSA/SF socket, the connected subagents will issue the following message:

```
EZZ3219I SNMP SUBAGENT: DISCONNECTED FROM OSA/SF
```

When the subagent connection is reestablished, the following message is issued:

```
EZZ3218I SNMP SUBAGENT: CONNECTED TO OSA/SF
```

Step 5: Configure the trap forwarder daemon

Most SNMPv1 agents forward traps to port 162. If a manager needs to listen for these traps, it has to bind to port 162 and listen for it. When a manager has already issued a bind it is impossible for another manager to listen for the same traps. The Trap Forwarder daemon eliminates this problem by listening for traps on port 162 and forwarding them to all the configured managers.

You can configure the Trap Forwarder daemon to receive a trap on a specified port and forward it to multiple other ports on the same host and on different hosts. This will allow multiple SNMP managers on z/OS to be able to receive all the traps sent to one port.

To configure the Trap Forwarder daemon, perform the following tasks:

1. Provide PROFILE.TCPIP statements.
2. Provide Trap Forwarder configuration.
3. Start the Trap Forwarder daemon (TRAPFWD).

Provide PROFILE.TCPIP statements

Add or update the following PORT configuration statements in *hlq*.PROFILE.TCPIP.

The default port used by the trap forwarder daemon to receive trap datagrams is UDP port 162. If you want to ensure that no other application uses this port, you must specify the following PORT statement:

```
PORT
  162 UDP TRAPFWD   ;  Trap Forwarder daemon
```

If the daemon will be started from the z/OS shell, reserve the port for z/OS UNIX by changing OMVS instead of TRAPFWD. Note that by doing so, the **snmp** command could make use of the port if it is started (with the trap option) before TRAPFWD is started.

Provide trap forwarder configuration information

The TRAPFWD.CONF file defines the configuration parameters for trapfwd daemon.

A sample of the TRAPFWD.CONF is shown below:

```
#
# A sample configuration file for trapfwd
#
# Syntax  : ip_address/host_name            port_number            option
#
#
9.67.113.79               1064           ADD_RECVFROM_INFO
myHost                    1066
myHost                    1067           ADD_RECVFROM_INFO
myHost                    1099
9.67.35.37                1064           ADD_RECVFROM_INFO
-                         1065
-                         1068           ADD_RECVFROM_INFO
12ab::2                   1069
```

For more information about the statement syntax, see *z/OS Communications Server: IP Configuration Reference*.

Starting and stopping the trap forwarder daemon

The Trap Forwarder daemon can be started from the z/OS UNIX shell or from the MVS console.

Starting the trap forwarder daemon from z/OS UNIX

This example starts the Trap Forwarder daemon on the standard port (port 162).

```
# trapfwd
```

This example starts the Trap Forwarder daemon on a particular port (port 5062).

```
# trapfwd -p 5062
```

Starting the trap forwarder daemon from an MVS console: Update cataloged procedure TRAPFWD by copying the sample in SEZAINST(EZASNTRA) to your system. See *z/OS Communications Server: IP Configuration Reference* the for more information about this cataloged procedure.

Stopping the trap forwarder daemon:

From MVS:

```
P TRAPFWD
```

If TRAPFWD was started from a cataloged procedure, procname is the member name of that procedure. If TRAPFWD was started from the z/OS shell, procname is useridX, where X is the sequence number set by the system. To determine the sequence number issue d omvs u=userid from the console. This will show the programs running under the user ID.

From UNIX:

```
kill < pid >
```

Issue the **kill** command to the process ID (PID) associated with TRAPFWD. To find the PID issue the **ps -ef** command from the z/OS shell.

Tracing: The MODIFY command can be used to display the existing tracing level and also to change the tracing level.

The following example sets the trace level of the Trap Forwarder Daemon to 1.

```
MODIFY TRAPFWD,TRACE,LEVEL=1
```

The following example displays the level of tracing set for the Trap Forwarder Daemon.

```
MODIFY TRAPFWD,TRACE,QUERY
```

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

Dynamically refreshing configuration: The MODIFY command can be used to dynamically refresh the configuration information. When this is done, the old configuration information is discarded completely. The configuration file is read again and the daemon is initialized.

The following example refreshes the configuration by reading the configuration file.

```
MODIFY TRAPFWD,REFRESH
```

See *z/OS Communications Server: IP Configuration Reference* for more information about syntax.

Chapter 26. Remote print server

Read "Understanding search orders of configuration information" on page 19. It covers important information about data set naming and search sequences.

The remote print server supports the line print daemon (LPD) and allows you to print on JES controlled printers from any host in your TCP/IP network that implements the line print client functions. These client functions are invoked with the LPR command. LPR is available as a TSO command, and the LPD server is implemented as a started z/OS task.

See *z/OS Communications Server: IP System Administrator's Commands* for information on starting and stopping the TCP/IP print server (LPD). When LPD is stopped by the MVS operator with the *P procname* command, LPD will terminate any TCP/IP connections currently transferring data. Before ending, LPD will finish spooling to JES any print jobs that it has received and is currently spooling. JES will handle these jobs after LPD ends.

This topic describes how to configure the LPD server. To operate the LPD server after it is running, see *z/OS Communications Server: IP Configuration Reference*.

The LPD server uses the Pascal socket API, so VMCF must be started for the server to successfully initialize. If VMCF is not started, message EZY1980E will be issued and the server will terminate.

Configuring the Remote Print Server

Steps to configure the Remote Print Server:

1. Specify AUTOLOG and PORT statements in PROFILE.TCPIP.
2. Update the LPD server cataloged procedure.
3. Update the LPD server configuration data set.
4. Create a banner page (optional).

For information about operating and controlling the LPD server, see *z/OS Communications Server: IP Configuration Reference*.

Step 1: Configuring PROFILE.TCPIP for LPD

If you want the LPD server started automatically when the TCPIP address space is started, include the name of the member containing the LPD server cataloged procedure in the AUTOLOG list in *hlq*.PROFILE.TCPIP. For example:

```
AUTOLOG
  LPSERVE
ENDAUTOLOG
```

To ensure that port TCP 515 is reserved for the LPD server, also add the name of the member containing the LPD cataloged procedure to the PORT statement in *hlq*.PROFILE.TCPIP. For example:

```
PORT
  515 TCP LPSERVE
```

See the *z/OS Communications Server: IP Configuration Reference* for more information about the AUTOLOG and PORT statements.

Step 2: Updating the LPD server cataloged procedure

Update the LPD server cataloged procedure to suit your local configuration by copying the sample to your system or recognized PROCLIB from SEZAINST(LPSPROC) and modifying the sample. Specify LPD parameters, and change the data set names as required. See "Specifying LPD server parameters" for more information on the LPD server parameters.

Specifying LPD server parameters

The system parameters required by the LPD server are passed by the PARM option on the EXEC statement of the LPD cataloged procedure. Update the following parameters as required.

LPDDATA='*data_set_name***'**
Specifies the fully qualified name of the data set containing the LPD configuration statements. This data set can be sequential or a member of a PDS.

LPDPRFX='PREFIX ***your_prefix***'
Specifies the high-level qualifier to be used for temporary data sets created by the LPD server. Include both the PREFIX keyword and your qualifier in the quoted string. The qualifier may be up to 26 characters. If it is blank, the default is the procedure name. The LPD task requires the authority to create and modify data sets with this prefix.

DIAG='*options***'**
Specifies any of the following diagnostic options in a quoted string of keywords separated by blanks. For example, `DIAG='VERSION TRACE'`

VERSION
Displays the version number.

TYPE Activates high-level trace facility in the LPD server. Significant events, such as the receipt of a job for printing, are recorded in the //SYSOUT DD data set specified in your LPD server cataloged procedure.

TRACE
Causes a detailed trace of activities within the LPD server to record in the //SYSOUT DD data set specified in your LPD server cataloged procedure. The detailed tracing can also be activated with the DEBUG statement in the LPD server configuration data set and with the TRACE command of the SMSG interface.

Note: The JCL PARM= statement has a limit of 100 characters.

Configuring LPDDATA

Use a DD card that requires the LPD configuration file to be in a data set.

```
//SYSLPDD  DD DISP=SHR,DSN=TCPIP.SEZAINST(LPDDATA)
```

Using this example, the DD card must be specified as SYSLPDD, but the data set name can be any valid data set name with a member specified up to 44 characters.

To use the DD card method, you must comment out or remove the LPDDATA= parameter from the PROC statement and remove the "&LPDDATA" PARM from the LPD EXEC statement.

Note: The search order for the configuration file is:

1. LPDDATA= on the PARM= statement
2. //SYSLPDD DD statement
3. *hlq*.LPD.CONFIG

If both the LPDDATA= statement on the PARM= statement and the //SYSLPDD DD statement are specified, the data set name specified on LPDDATA= is used.

The LPD server does not limit the number of print jobs it handles per connection. This can cause a memory abend to occur if too many print jobs are sent in one connection. Certain LPR clients, such as SUN UNIX, are set up to send multiple jobs in one connection. It is recommended that the LPD start procedure be started with a region size of 6M and the LPR client send no more than 50 print jobs in one connection.

Step 3: Updating the LPD server configuration data set

The LPD configuration data set defines the local, NJE, and remote services (printers and punches) used by the LPD server. To update the LPD server configuration data set, copy the sample provided in SEZAINST(LPDDATA) and modify it to suit your installation. See *z/OS Communications Server: IP Configuration Reference* for more details.

- To define a printer or punch:
  - Include a SERVICE statement with the appropriate parameters for each printer or punch your are defining.
  - Specify the type of service with the LOCAL, NJE, or REMOTE parameter in the SERVICE statement.
  - For local or NJE services, include any of the optional parameters to further define the service: EXIT, FAILEDJOB, FILTERS, LINESIZE, PAGESIZE, RACF, and SMTP.
  - For remote services, specify the destination printer and host. Any additional specifications are defined on the remote system and are not necessary in the SERVICE statement.
- To turn on LPD server tracing, include the optional DEBUG statement.
- To authorize users for the SMSG interface, include the optional OBEY statement.
- Printer names cannot contain an at sign (@).

Step 4: Creating a banner page (optional)

LPBANNER is the name of the default program that is provided in executable form in the SEZATCP data set. This program is specified on the EXIT parameter in the SERVICE statement. LPBANNER prints a separator page that contains, in large letters, a banner stating “LPD BANNER”, the user ID, the job name, and the job class. Field headings of HOST, USER, JOB, and CLASS appear in smaller letters.

The sample exit LPBANNER uses machine carriage control and is designed to be used with the SERVICE PRINTER LOCAL or SERVICE PRINTER NJE statements. To use this sample exit, both SERVICE statements require a printed LINESIZE of 78 or greater. Banner pages are usually not used with the SERVICE PUNCH or SERVICE RECFMU statements; however, if you want to have banner pages (headers) for the SERVICE PUNCH or SERVICE RECFMU devices, a user created banner exit is required.

You can either use the executable form or copy and modify the sample source provided in SEZAINST(EZAAE04S) and SEZAINST(EZAAE04T) to create a banner. If you are changing the source to create your own banner, assemble and link-edit these data sets as reentrant. You can modify and use the following JCL to do this. Changing the ENTRY and NAME to something other than LPBANNER will avoid possible maintenance problems in the future.

```
//ASMLNK JOB MSGLEVEL=(1,1),MSGCLASS=A,CLASS=A,REGION=1024K
//ASM1   EXEC PGM=ASMA90,PARM='OBJECT,XREF(FULL)'
//STEPLIB DD  DISP=SHR,DSN=HLA.OSV1R4.SASMMOD1
//*  ASSEMBLER H
//SYSLIB   DD DSN=tcpip_hlq.SEZACMAC,DISP=SHR
//         DD DSN=SYS1.MACLIB,DISP=SHR
//         DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1   DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=80
//SYSPRINT DD SYSOUT=A
//SYSLIN   DD DSN=&&OBJECT(EZAAE04S),DISP=(,PASS),UNIT=SYSDA,
//            SPACE=(CYL,(5,5,1)),DCB=BLKSIZE=400
//SYSIN    DD DSN=tcpip_hlq.SEZAINST(EZAAE04S),DISP=SHR
/*
//ASM2   EXEC PGM=ASMA90,PARM='OBJECT,NODECK,XREF'
//STEPLIB  DD  DISP=SHR,DSN=HLA.OSV1R4.SASMMOD1
//*  ASSEMBLER H
//SYSLIB   DD DSN=tcpip_hlq.SEZACMAC,DISP=SHR
//         DD DSN=SYS1.MACLIB,DISP=SHR
//         DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1   DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=80
//SYSPRINT DD SYSOUT=A
//SYSLIN   DD DSN=&&OBJECT(EZAAE04T),DISP=(OLD,PASS)
//SYSIN    DD DSN=tcpip_hlq.SEZAINST(EZAAE04T),DISP=SHR
/*
//LNK    EXEC PGM=IEWL,PARM='LIST,NCAL,RENT,LET'
//SYSPRINT DD SYSOUT=A
//SYSUT1   DD UNIT=SYSDA,SPACE=(CYL,(1,1))
//SYSLMOD  DD DSN=tcpip_hlq.SEZATCP,DISP=SHR
//AEZAMODS DD DSN=tcpip_hlq.AEZAMODS,DISP=SHR
//OBJECT   DD DSN=&&OBJECT,DISP=(OLD,DELETE)
//SYSLIN   DD *
  ORDER   EZBOECPR
  INCLUDE AEZAMODS(EZBOECPR)
  INCLUDE OBJECT(EZAAE04S)
  INCLUDE OBJECT(EZAAE04T)
  MODE    AMODE(24),RMODE(24)
  ENTRY   LPBANNER
  NAME    LPBANNER(R)
/*
```

Chapter 27. Remote procedure calls

This topic contains information to help you configure the following:

- PORTMAP
- UNIX PORTMAP
- rpcbind
- NCS

Restriction: PORTMAP, UNIX PORTMAP, and rpcbind cannot be run concurrently, because all three applications listen on the well known /etc/services sunrpc port of 111. You must determine which server will service your RPC applications.

For information about rpcbind configuration and setup in a multilevel secure environment, see "z/OS UNIX rpcbind server" on page 170.

Read "Understanding search orders of configuration information" on page 19. It covers important information about data set naming and search sequences.

Steps for configuring the PORTMAP address space

This topic describes how to configure the PORTMAP address space, which runs the Portmapper function.

Portmapper is the software that supplies client programs with the port numbers of server programs. Clients contact server programs by sending messages to port numbers where receiving processes receive the message. Because you make requests to the port number of a server rather than directly to a server program, client programs need a way to find the port number of the server programs they wish to call. Portmapper standardizes the way clients locate the port number of the server programs supported on a network.

Perform the following steps to configure PORTMAP:

1. Specify AUTOLOG and PORT statements in *hlq*.PROFILE.TCPIP.
2. Update the PORTMAP cataloged procedure.
3. Define the data set for well-known procedure names.

Step 1: Configuring PROFILE.TCPIP for PORTMAP

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP data set.

```
AUTOLOG
  PORTMAP
ENDAUTOLOG
```

Note: If your system is using the Network File System (NFS) server, you ***must*** start the PORTMAP address space. See *z/OS Network File System Guide and Reference* for more information.

To ensure that port UDP 111 and TCP 111 are reserved for the PORTMAP server, also add the name of the member containing the PORTMAP cataloged procedure to the PORT statement in *hlq*.PROFILE.TCPIP:

```
PORT
  111 UDP PORTMAP
  111 TCP PORTMAP
```

See the *z/OS Communications Server: IP Configuration Reference* for more information about the AUTOLOG and PORT statements.

Step 2: Updating the PORTMAP cataloged procedure

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(PORTPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See *z/OS Communications Server: IP Configuration Reference* for more details.

Step 3: Defining the data set for well-known procedure names

z/OS Communications Server includes a data set that contains a list of commonly used procedure names. This data set is used by the RPCINFO command to resolve remote program numbers into their equivalent program names.

To create the data set, copy SEZAINST(ETCRPC) to the default data set called *hlq*.ETC.RPC. If a user has a *user_id*.ETC.RPC data set defined, it takes precedence over the preceding data set.

Normally, you would not change this data set except to add a new application to the list. To add a new application, add a line that contains the following items:

- The *program_name* of the new application or procedure
- The *program_number* of the new application or procedure
- Any comments regarding the description of the program

The items are variable in format, each separated by a blank.

The SEZAINST(ETCRPC) data set contains the well-known procedure names. Following is the ETCRPC sample.

```
#  z/OS Communications Server
#  SMP/E distribution path: /usr/lpp/tcpip/samples/IBM/EZAOERPC
#  SMP/E distribution path: SEZAINST(EZAEB01X)

```

Starting the PORTMAP address space

If you did not include PORTMAP in the AUTOLOG statement, you can start PORTMAP with the START command. For example:

```
START PORTMAP
```

Steps for configuring the z/OS UNIX PORTMAP address space

This topic describes how to configure the z/OS UNIX PORTMAP address space, which runs the Portmapper function.

Perform the following steps to configure z/OS UNIX PORTMAP:

1. Specify PORT statements in *hlq*.PROFILE.TCPIP.
2. Update the PORTMAP cataloged procedure.

Step 1: Configuring PROFILE.TCPIP for UNIX PORTMAP

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP data set.

```
AUTOLOG
  PORTMAP JOBNAME PORTMAP1
ENDAUTOLOG
```

To ensure that port UDP 111 and TCP 111 are reserved for the z/OS UNIX PORTMAP server, add the z/OS UNIX PORTMAP server jobname to the PORT statement in *hlq*.PROFILE.TCPIP. If you use the sample cataloged procedure, PORTMAP, to start the z/OS UNIX PORTMAP server, the jobname is PORTMAP1:

```
PORT
  111 UDP PORTMAP1     ; Portmapper Server
  111 TCP PORTMAP1     ; Portmapper Server
```

See the *z/OS Communications Server: IP Configuration Reference* for more information about the PORT statement.

Step 2: Updating the PORTMAP cataloged procedure

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(OPORTPRC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See *z/OS Communications Server: IP Configuration Reference* for more details.

Starting the PORTMAP address space

There are two ways to start the portmapper as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

To start the portmapper from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue *oportmap &* to start the portmapper. For the authorization procedure, see *z/OS UNIX System Services Planning*.

You can also start PORTMAP as a started task with the START command as follows:

```
START PORTMAP
```

Note: If your system is using the Network File System (NFS) server, see *z/OS Network File System Guide and Reference* for more information.

Steps for configuring the rpcbind address space

The rpcbind software supplies client programs with the universal addresses of RPC server programs. RPC server applications do not have well known port numbers. Instead, they obtain an ephemeral port number, create a universal address, and register that address with rpcbind. Clients contact server programs by obtaining the server's universal address from rpcbind and sending messages to the server's universal address.

The z/OS rpcbind server supports the portmapper binding protocol (RPC Binding Protocol Version 2) as well as other RPC binding protocols. This means you can run rpcbind instead of portmapper. Portmapper and rpcbind cannot be run at the same time, because they both listen on /etc/services sunrpc port 111.

Perform the following steps to configure the rpcbind address space.

1. Configure the PROFILE.TCPIP data set for rpcbind.
2. Configure security server (or RACF equivalent) items.
3. Update the RPCBIND cataloged procedure.
4. Update the /etc/services file.
5. Configure SYS1.PARMLIB for rpcbind.

Step 1: Configuring the PROFILE.TCPIP data set for rpcbind

If you want the rpcbind server to start automatically when the TCPIP address space is started, include rpcbind in the AUTOLOG statement in the PROFILE.TCPIP data set.

```
AUTOLOG
  RPCBIND JOBNAME RPCBIND1
ENDAUTOLOG
```

To ensure that port UDP 111 and TCP 111 is reserved for the rpcbind server, add the rpcbind server job name to the PORT statement in the PROFILE.TCPIP data set. If you use the sample cataloged procedure, RPCBIND, to start the rpcbind server, the job name is RPCBIND1.

```
PORT
  111 UDP RPCBIND1     ; rpcbind server
  111 TCP RPCBIND1     ; rpcbind server
```

If you start the rpcbind server from the z/OS UNIX shell, the job name is OMVS.

```
PORT
  111 UDP OMVS         ; rpcbind server OMVS
  111 TCP OMVS         ; rpcbind server OMVS
```

For more information about the PORT statement, see *z/OS Communications Server: IP Configuration Reference*.

Step 2: Configuring security server (or RACF equivalent) items

The RPCBIND cataloged procedure assumes that the procedure has the authority to run as a started task. To ensure that the RPCBIND procedure has the proper security server access, enter the following commands as shown in SEZAINST(EZARACF):

```
ADDUSER RPCBIND DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
RDEFINE STARTED RPCBIND.* STDATA(USER(RPCBIND))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

You can define the SAF resource profile EZB.RPCBIND.*sysname*.*rpcbindname*.REGISTRY in the SERVAUTH class to control which users can register or deregister applications with rpcbind. You can use wildcards. For example, if you use wildcard values for *sysname* and *rpcbindname*, the profile name is as follows:

```
EZB.RPCBIND.*.*.REGISTRY
```

In this example, suppose the MVS system name is MVS000 and the RPCBIND catalogued procedure is used to start the rpcbind server. This procedure uses the job name RPCBIND. RPCBIND is fewer than 8 characters, so the *rpcbindname* is RPCBIND1, and the profile name is as follows:

```
EZB.RPCBIND.MVS000.RPCBIND1.REGISTRY
```

The profile EZB.RPCBIND.*sysname*.*rpcbindname*.REGISTRY is optional. If it is not defined, all users can register and deregister applications with rpcbind. If the profile is defined, only users granted at least READ access to this resource profile can register or deregister applications with rpcbind.

In this example, if your SAF security product is RACF and you want only the RPC server TRUESERV running under user ID TRUESERV to be able to register and

deregister applications with rpcbind, you can use the following commands to define the profile EZB.RPCBIND.*.*.REGISTRY in the SERVAUTH class and grant TRUESERV read access to the profile:

```
RDEFINE SERVAUTH EZB.RPCBIND.*.*.REGISTRY UACC(NONE)
PERMIT EZB.RPCBIND.*.*.REGISTRY ID(TRUESERV) ACCESS(READ) CLASS(SERVAUTH)
```

Requirements for a multilevel secure environment:

- The profile EZB.RPCBIND.*sysname*.*rpcbindname*.REGISTRY is mandatory, and you must grant user IDs associated with trusted RPC servers at least READ access to this profile. For more information about running rpcbind in a multilevel secure environment, see "z/OS UNIX rpcbind server" on page 170.
- If the SAF FACILITY class resource profile BPX.POE is defined, and your installation directs target assistance calls to rpcbind, you must grant the user ID assigned to rpcbind at least READ access to this profile. For more information on target assistance, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Tips:

- The target assistance RPCs PMAPPROC_CALLIT, RPCBPROC_CALLIT, RPCBPROC_BCAST, and RPCBPROC_INDIRECT are defined in RFC 1833 (*Binding Protocols for ONC RPC Version 2*).
- The RPC library routines clnt_broadcast and pmap_rmtcall() issue a target assistance request on behalf of the caller.
- The rpcinfo utility issues a target assistance call when it is invoked with the **-b** option.

Guideline: If RPCBIND is the user ID assigned to the rpcbind server, you can use the following command to grant the user ID READ access to the profile:

```
PERMIT   BPX.POE CLASS(FACILITY) ID(RPCBIND) ACCESS(READ)
```

Step 3: Updating the RPCBIND cataloged procedure

Update the RPCBIND cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(RPCBIND) to your system or recognized PROCLIB, and modifying it as necessary. Change the data set names as required. For further information, see "Starting the rpcbind address space" on page 1371. A copy of RPCBIND is also available in *z/OS Communications Server: IP Configuration Reference*.

Step 4: Updating the /etc/services file

Update /etc/services to ensure that the sunrpc service is reserved for TCP and UDP port 111:

```
sunrpc 111/tcp
sunrpc 111/udp
```

Restriction: If you change the sunrpc port, rpcinfo on that host will not be able to contact the rpcbind server.

Step 5: Configure SYS1.PARMLIB for rpcbind

The rpcbind server uses semaphore sets and shared memory segments. Inspect your BPXPRM*xx* member in SYS1.PARMLIB and verify that the following statements are configured such that rpcbind will be able to obtain three shared memory segments of one page each, and three semaphore sets:

```
IPCSHMMPAGES
IPCSHMNSEGS
IPCSEMNIDS
IPCSEMNSEMS
```

For more information about these SYS1.PARMLIB statements, see *z/OS MVS Initialization and Tuning Reference*.

Tip: You can issue the operator command **d omvs,o** to display these values.

Starting the rpcbind address space

There are two ways to start rpcbind as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

It cannot be started from TSO.

To start rpcbind from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue **rpcbind** to start rpcbind. For information about assigning superuser attributes, see *z/OS UNIX System Services Planning*.

You can also start rpcbind as a started task from the MVS console with the START command, as follows:

```
START RPCBIND
```

You can specify the following options when starting rpcbind:

- Specify **-d** to have rpcbind send trace information to the daemon facility of syslogd.
  - -df sends flow information.
  - -dl sends log information of all RPC procedures called.
  - -dx sends XDR information.
- The **-i** option enables you to specify the z/OS UNIX file system directory to which the pid file is written. The pid file name is always rpcbind.pid. If **-i** is not specified, the rpcbind's process ID is written to /etc/rpcbind.pid.

  Restriction: The directory path name must be an absolute path name. That is, it must begin with the forward slash (/) character, as shown in the following example:

  ```
  rpcbind -i /tmp
  ```
- The **-n** option enables you to direct rpcbind to run in a non-swappable environment. A process might need to run as non-swappable to ensure that it is available during periods of high CPU usage. However, a non-swappable process might convert real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing rpcbind to run in a non-swappable state can reduce your installation's future ability to reconfigure storage.

  If you do specify the **-n** option, ensure that the user ID associated with rpcbind has at least READ access to the resource profile BPX.STOR.SWAP in the FACILITY class. The default is to start rpcbind as swappable.
- The **-s** option specifies the number of statistics entries per binding protocol that rpcbind will maintain. Valid values are in the range 113 – 500. Statistics maintained by the rpcbind server are used to reply to the RPCBPROC_GETSTAT request. For more information on statistics maintained by the rpcbind server, see RFC 1833.

Result: Rpcbind calculates the number of pages needed to store statistics for the value specified, and obtains that number of pages of shared memory for statistics. Rpcbind rounds up the number of statistics entries it tracks to fully use the shared memory.

Tip: Rpcbind does not start unless it can obtain sufficient shared memory to maintain statistics for the number of entries you specify. You configure the number of pages of shared memory available to z/OS with the IPCSSHMMPAGES parameter in the BPXPRM*xx* member of SYS1.PARMLIB.

- To display help information, specify the **-?** option.

Tip: If your system is using the Network File System (NFS) server, see *z/OS Network File System Guide and Reference* for more information about initialization attributes for the z/OS client and Network File System operation.

Restriction: Portmapper and rpcbind cannot be run at the same time, as they both listen on /etc/services sunrpc port 111.

Steps for configuring the NCS interface

This topic describes how to configure the Network Computing System (NCS).

NCS is the Remote Procedure Call (RPC) implementation of Apollo's Network Computing Architecture (NCA**).

NCS includes:
1. RPC run-time library
2. Location broker
3. Network Interface Definition Language (NIDL) compiler

The RPC run-time library and the location broker provide runtime support. Together these two elements make up the Network Computing Kernel (NCK) which includes all the software necessary to run a distributed application. The NIDL compiler is a tool for developing NCS-based applications.

In order to execute NCS applications in an MVS environment, you must start a local location broker (LLBD). One of the hosts in your TCP/IP network must also start the global location broker (GLBD). Both the LLBD and the NRGLBD maintain information about active NCS server applications.

Understanding the LLBD server

The LLBD manages the LLB database which stores information for the NCS-based servers running on this host.

Your host must run LLBD if you want to support the location broker forwarding function or allow remote access to the LLB database. The LLBD function must be started on the host before any other NCS-based servers are started and before the NRGLBD is started.

The LLB database is stored in the data set ADM@SRV.LLB@LL.DATABASE, which is not created until an entry is registered with the LLBD. This data set can be administered using the lb@admin tool.

Understanding the NRGLBD server

The NRGLBD manages the NCS global location broker (GLB) database. The GLB helps clients locate servers on a network or internet.

There are two versions of the GLB daemon: replicated GLBD and NRGLBD. The replicated GLBD is only available on Apollo, SunOS, and Ultrix systems. For other systems, such as IBM, only the NRGLBD is available. The advantage of replicated GLBD over NRGLBD is that the GLBD can be run at the same time on several network hosts, providing greater availability in the event that one of the hosts running GLBD fails or if there is a partial network failure.

You cannot use the NRGLBD on your system if:
- The replicated version of GLBD can run on some other host in your network
- Another host in your network is already running NRGLBD

The GLB database is stored in a data set ADM@SRV.LLB@LG.DATABASE. This data set is not created until an entry is registered with the NRGLBD.

The record structure for the LLBD and the NRGLBD databases is identical.

Perform the following steps to configure NCS:

1. Specify AUTOLOG and PORT statements in *hlq*.PROFILE.TCPIP.
2. Update the NRGLBD cataloged procedure in SEZAINST(NRGLBD).
3. Update the LLBD cataloged procedure in SEZAINST(LLBD).

For more information about NCS, see *Network Computing System Reference Manual*.

Step 1: Configuring PROFILE.TCPIP for NCS

If you want LLBD and NRGLBD to start automatically when the TCPIP address space is started, then you should include the names of the members containing the LLBD and NRGLBD cataloged procedures in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP data set.

The LLBD must be running before you start NRGLBD. Therefore, you must put LLBD before NRGLBD in the AUTOLOG statement.

```
AUTOLOG
  LLBD
  NRGLBD
ENDAUTOLOG
```

To ensure that port UDP 135 is reserved for the LLBD server, add the name of the member containing the LLBD cataloged procedure to the PORT statement in the *hlq*.PROFILE.TCPIP data set.

```
PORT
  135 UDP LLBD
```

Note: z/OS UNIX DCE also uses port 135 and therefore cannot be used concurrently with NCS.

See the *z/OS Communications Server: IP Configuration Reference* for more information about the AUTOLOG and PORT statements.

Step 2: Updating the NRGLBD cataloged procedure

Update the NRGLBD cataloged procedure by copying the sample provided in SEZAINST(NRGLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in *z/OS Communications Server: IP Configuration Reference* for more details.

Step 3: Updating the LLBD cataloged procedure

Update the LLBD cataloged procedure by copying the sample provided in SEZAINST(LLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in *z/OS Communications Server: IP Configuration Reference* for more information.

Chapter 28. Mail on z/OS

This topic describes how to configure the Simple Mail Transfer Protocol (SMTP) server, the Communications Server SMTP (CSSMTP) application, z/OS UNIX sendmail, and popper. To determine the appropriate server or application that you should use, consider the following:

- Use CSSMTP if you want to forward mail from your NJE network or from local applications that write mail to a JES spool file, using the existing SMTP batch interface to forward the mail to other gateway servers.

  CSSMTP provides the easiest and simplest solution for this purpose, and if you currently use the SMTP server (SMTPD) for this purpose only, you should consider replacing SMTPD with CSSMTP.

  For more information about CSSMTP, see "Configuring the CSSMTP application."
- Consider using both SMTPD and CSSMTP if you need to receive mail from the SMTP network into your NJE network or for local TSO users that use the TSO RECEIVE command interface to access their mail.

  You must continue to use SMTPD for receiving mail from the SMTP network. If you also need to send mail from those same users, you can use CSSMTP to send that mail from JES. CSSMTP can run concurrently with SMTPD.

  For more information about SMTPD, see "Configuring the SMTP server (SMTPD)" on page 1392.
- Use z/OS UNIX sendmail if you need to receive or send mail from local z/OS UNIX shell users, or from remote POP/SMTP clients that use your z/OS system as a mail server.

  Sendmail can run concurrently with CSSMTP, SMTPD, or both.

  For more information about sendmail, see "Configuring z/OS UNIX sendmail and popper" on page 1413.

Configuring the CSSMTP application

Communications Server Simple Mail Transfer Protocol (CSSMTP) is a mail-forwarding SMTP client application. CSSMTP processes data sets containing mail messages on the spool file and forwards them to a target message transfer agent (MTA) without resolving each recipient. If you currently use MVS batch jobs to have the SMTP server (SMTPD) send bulk mail that does not typically require a reply to the originator, you can use CSSMTP to process this mail. CSSMTP can improve the performance, scalability, and availability of the client function of SMTPD, but it does not act as a listening MTA server like SMTPD. CSSMTP can coexist with SMTPD, and multiple instances of CSSMTP can run on a single host. Figure 133 on page 1376 shows how CSSMTP fits into a network.

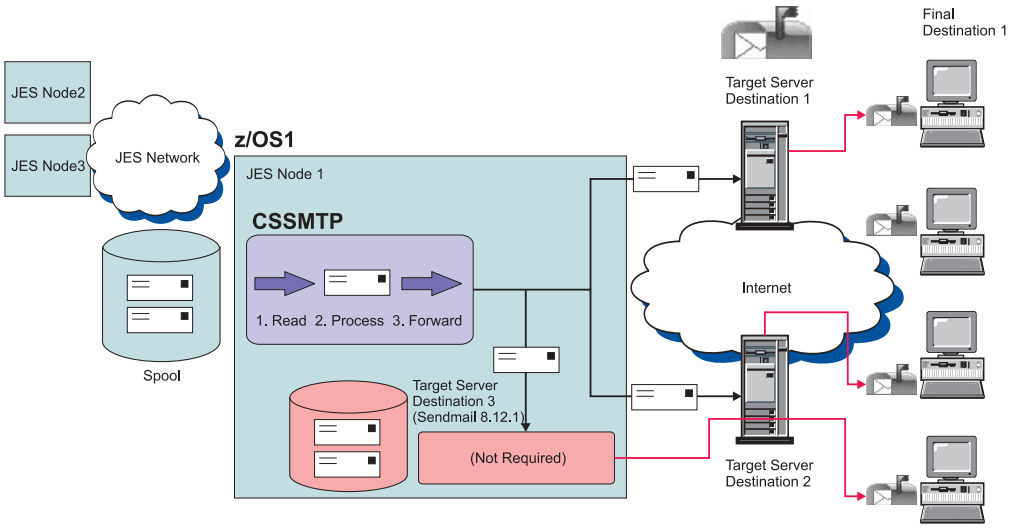

Figure 133. CSSMTP forwards mail messages from spool to the network

CSSMTP implements RFC 2821 and RFC 2822 for interacting with server MTAs, and supports additional RFCs for message size (RFC 1870) and security (RFC 3207). CSSMTP is not a fully capable MTA and functions as an outbound forwarder, sending mail messages from the JES spool data set to the Internet. As the mail messages are read from the spool file, CSSMTP functions like a TCP/IP SMTP client and interacts with one or more configured target servers. When processing mail messages from the spool file, CSSMTP does not resolve mail message recipients, but simply transfers mail messages to one or more configured, next-hop servers (fully capable MTAs) that might or might not be the final destination.

CSSMTP provides the following:

- Checkpoint capabilities. If CSSMTP must be restarted, it does not have to reprocess the entire spool file, which reduces duplicate mail that is received by message recipients.
- A retry capability for up to 2 hours. This capability is intended to compensate for short-term relay server outages
- Multiple security capabilities. For details, see "Security for CSSMTP" on page 1384.
- SMF recording of CSSMTP events, see "Steps for configuring SMF records for CSSMTP (optional)" on page 1388.

As stated in RFC 2821, SMTP clients that transfer all traffic, regardless of the target domain names associated with the individual mail messages, or that do not maintain queues for retrying mail message transmissions that initially cannot be completed, might otherwise conform to this specification but are not considered fully capable. CSSMTP does not implement all aspects of RFC 2821.

If you are moving from SMTPD to CSSMTP, see "Differences between CSSMTP and SMTPD" on page 1389.

Terms and concepts

The following terms and concepts are used in this information:

Backpressure
CSSMTP stops processing the JES spool file when mail cannot be sent to

the target because the connection to a target server is down or unresponsive. CSSMTP resumes processing the JES spool file when a target server connection becomes active.

Bad spool file
A bad spool file is a JES spool file that cannot be processed as the result of security, configuration, syntax, readability, or delivery issues. The action taken by CSSMTP is subject to the setting of the BadSpoolDisp statement. For more information about the BadSpoolDisp statement, see *z/OS Communications Server: IP Configuration Reference*.

Checkpointing
If checkpointing is enabled using the CHKPOINT DD statement in the CSSMTP started procedure and there are partially processed spool files on the spool when restarting, CSSMTP attempts to send only the mail from these spool files that was not previously sent, which reduces the duplicate mail that is received by recipients. If CSSMTP is started cold using the **-f** option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPOINT DD statement in the CSSMTP started procedure and starting CSSMTP with the **-f** start option, see *z/OS Communications Server: IP Configuration Reference*.

Dead letter
A dead letter is created and stored for the following reasons:

- An undeliverable mail notification cannot be returned to the originator
- The original mail message was undeliverable, but did not specify an originator
- An error report cannot be delivered to the mail administrators

To ensure that dead letters are stored, configure Store on the DeadLetterAction parameter of the Undeliverable statement. For information about the Undeliverable statement, see *z/OS Communications Server: IP Configuration Reference*.

For examples of customizing the configuration to handle undeliverable mail, see "Customizing the CSSMTP configuration file to handle undeliverable mail" on page 1382.

ESMTP
Extended Simple Mail Transfer Protocol

Long retry
A state for mail that was unable to be sent to all recipients because one or more target servers replied with a retry reply code. The mail might be able to be sent and is retried again after a delay. If all retries are exhausted, the mail is marked as undeliverable. For information about using the RetryLimit statement to configure the retry limits, see *z/OS Communications Server: IP Configuration Reference*.

Tip: Because CSSMTP is a mail forwarder, the likelihood of receiving delivery errors from an MTA is very low. These errors are most likely to be received when the MTA is also the home mail server for the mail recipients, and the MTA reports errors that are related to the mailboxes of the recipients on the MTA, such as mailbox full, recipient not known, and so on.

Mail administrator
The mail administrator is a special user ID for mailing systems, to which CSSMTP delivers error reports for problems detected while processing a spool file from the JES spool data set. For information about using the

MailAdministrator statement to configure up to four mail administrator addresses, see *z/OS Communications Server: IP Configuration Reference*.

Message content
The headers and the structured body of a mail message. A separate Multipurpose Internet Mail Extensions (MIME) specification provides the definitions for structured bodies.

MTA Message transfer agent

SMTP Simple Mail Transfer Protocol

SMTP command
A command sent from the client to the SMTP server that lets the server know what information is being sent. For example, MAIL FROM: is a command.

SMTP reply
The acknowledgement, positive or negative, sent from an SMTP server. Replies are in US ASCII (ISO8859-1).

SMTP server
A network application implementing the SMTP protocol that accepts mail messages from SMTP clients.

Target server
A target server is the resolved or configured IP address from a TargetServer statement. The first four target servers are used by CSSMTP. For information about using the TargetServer statement to configure a target server, see *z/OS Communications Server: IP Configuration Reference*.

Undeliverable mail
Mail messages that cannot be delivered. CSSMTP processes and tries to send all mail messages in the spool file. Sometimes, one or more of these mail messages might be undeliverable. Examples of what causes undeliverable mail include the following:

- A problem with the mail message itself, such as the message size
- A problem with the recipient record (RCPT TO:), such as an unknown mailbox
- A mail message requires a secure connection and none of the target servers support the STARTTLS SMTP command
- Security problems
- A networking problem, such as being unable to reach a target host that has the capabilities that are needed for the mail message

For examples of customizing the configuration to handle undeliverable mail, see "Customizing the CSSMTP configuration file to handle undeliverable mail" on page 1382.

Undeliverable mail notification
CSSMTP creates an undeliverable mail notification when the ReturntoMailFrom parameter is set to YES on the Undeliverable statement and the mail message cannot be delivered. This notification contains the reply from the target server, describing the reason that the mail message was undeliverable and the text of the original mail message. If the undeliverable mail notification cannot be sent immediately, it is not retried and is subject to the setting of the DeadLetterAction parameter of the Undeliverable statement.

For examples of customizing the configuration to handle undeliverable mail, see "Customizing the CSSMTP configuration file to handle undeliverable mail" on page 1382.

Setting up CSSMTP

To set up CSSMTP to process and forward your mail, you must do the following:

- Configure and start CSSMTP.

  See "Steps for configuring and starting CSSMTP."
- Create mail on the JES spool data set for CSSMTP.

  See "Steps for creating mail on the JES spool data set for CSSMTP" on page 1380.

Steps for configuring and starting CSSMTP

This topic provides the minimum information that you need to configure and start CSSMTP.

Perform the following steps to configure and start CSSMTP:

1. Create a new data set member in your procedure library for the CSSMTP JCL.

   A sample job is in SEZAINST(CSSMTP).
2. Define explicit authority for all user IDs that you want to be able to start CSSMTP.

   See "Steps for granting authority to start CSSMTP" on page 1383.
3. Customize the CSSMTP configuration file and set up at least one valid target server IP address using the TargetServer statement.

   A sample CSSMTP configuration file is included in member CSSMTPCF in SEZAINST. A target server is defined as the IP address that is resolved from or configured on the TargetServer statement. For information about using the TargetServer statement to configure a target server, see *z/OS Communications Server: IP Configuration Reference*. For details about other configuration statements used by CSSMTP, see *z/OS Communications Server: IP Configuration Reference*. For information about handling undeliverable mail, see "Customizing the CSSMTP configuration file to handle undeliverable mail" on page 1382.

   CSSMTP configuration statements are processed during the initialization of CSSMTP or when you issue the MODIFY *procname*,REFRESH command.
4. Set up the resolver search order.

   Use the default search order unless there are special circumstances that require you to use unique parameters. For example, if the resolver has parameters that are used only when the resolver is called by CSSMTP, you need to define those unique parameters. Define the unique parameters in a data set that is specified on the SYSTCPD DD statement in the CSSMTP procedure JCL. For more information about resolvers and resolver configuration files, see Chapter 14, "The resolver," on page 731.
5. Optionally, set up additional security for CSSMTP.

   See "Security for CSSMTP" on page 1384.
6. Optionally, allocate and define a Virtual Storage Access Method (VSAM) linear data set for the checkpoint function.

   A sample job is in SEZAINST(CSSMTPVL).
7. Set up the timezone using the TZ environment variable.

If you do not set up the timezone, the timezone is not shown in the `Received` header line, which is used to indicate that CSSMTP has picked up a mail message. The default time value is used if the DATE header is not specified in the mail message.

8. Start CSSMTP by issuing the following command, where *csproc* is the CSSMTP procedure member name:

   ```
   START csproc
   ```

You know you are done when: Initialization is complete and you have successfully connected to the specified target server for processing mail, as indicated by the following messages:

```
EZD1802I  csproc INITIALIZATION COMPLETE FOR  extWrtName
EZD1821I  csproc ABLE TO USE TARGET SERVER  ipAddress
```

Steps for creating mail on the JES spool data set for CSSMTP

This topic provides the minimum information that you need to create mail that can be processed and forwarded by CSSMTP. For details about creating mail using CSSMTP commands, see *z/OS Communications Server: IP User's Guide and Commands*.

Before you begin: You need to know the external writer name of the CSSMTP application that you want to process your mail data set. If the external writer name is not configured for CSSMTP using the ExtWrtName statement, then the default is the job name. For information about configuring the external writer name using the ExtWrtName statement, see *z/OS Communications Server: IP Configuration Reference*.

Perform the following steps to create mail on the JES spool data set for CSSMTP:

1. Set up JES so that CSSMTP can create, read, write, and purge data from the JES spool data set.

   See "Steps for initial setup for CSSMTP" on page 1381.

2. Set up the mail to conform to the standardized syntax for text messages that are sent across networks.

   The standard syntax for SMTP commands supported by CSSMTP is described in RFC 821 and RFC 2821. The standard syntax for mail message content supported by CSSMTP is described in RFC 822 and RFC 2822. Mail messages have an envelope and contents. Envelopes contain all necessary information to accomplish transmission and delivery of the mail message content. The fields in the envelope are in a standard format.

3. Configure the code page.

   The spool file must be in a supported EBCDIC code page. Mail is written in an EBCDIC code page recognized and translated by iconv to US ASCII (ISO8859-1) before sending to the target server. The default code page is IBM 1047. For information about configuring the code page using the Translate statement, see *z/OS Communications Server: IP Configuration Reference*.

4. Set up the mail in one of the following formats:

   - A flat file generated using the IEBGENER utility or batch jobs that write to the SYSOUT data set

     For information about using the IEBGENER utility to copy a mail file to a JES SYSOUT data set, see *z/OS Communications Server: IP User's Guide and Commands*.

- Netdata generated from SMTPNOTE or from TSO xmit

  For information about using the SMTPNOTE command to compose a single mail message to one or more recipients and about using the TSO TRANSMIT (XMIT) command to send a mail file, see *z/OS Communications Server: IP User's Guide and Commands*.

You must copy and customize the SMTPNOTE CLIST on every system where users can send mail with the SMTPNOTE command. For more information, see "Steps for customizing the SMTPNOTE CLIST (optional)."

You know you are done when: Mail is on the JES spool data set ready to be processed by CSSMTP.

Steps for initial setup for CSSMTP:

Before you begin:

Perform the following steps to set up JES:

1. Set up JES2 or JES3 initialization parameters so that CSSMTP can interface with JES utilities to create, read, write, and purge data from the JES spool data set.

   For information about JES2 initialization, see *z/OS JES2 Initialization and Tuning Guide*. For information about JES3 initialization, see *z/OS JES3 Initialization and Tuning Guide*. For information about JES RACF authorization, see *z/OS Security Server RACF Security Administrator's Guide*.
2. Verify that JES exit programs do not interfere with the function of CSSMTP.

   For JES2 exit and exit routine association, see *z/OS JES2 Initialization and Tuning Reference*. For JES3, if you are using the IATUX18 exit, see *z/OS JES3 Customization*.
3. Set up security authorization for the CSSMTP started task name in your definitions of authorized users. If you are using RACF for security, see *z/OS Security Server RACF Security Administrator's Guide* for information about RACF controls for the spool file.
4. Set up CSSMTP for warm starts by configuring the CHKPOINT DD statement.

   Checkpointing enables CSSMTP to recognize partially processed spool files, so that CSSMTP does not reprocess the entire spool file when restarting. This reduces the duplicate mail messages that are received by mail message recipients. Warm starts work only when restarting CSSMTP with the same job name and external writer name. If CSSMTP is started cold using the **-f** option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPOINT DD statement in the CSSMTP started procedure and starting CSSMTP, see *z/OS Communications Server: IP Configuration Reference*.

Steps for customizing the SMTPNOTE CLIST (optional): Perform these steps for every system from which mail can be sent using the SMTPNOTE command.

Before you begin: If the ExtWrtName statement is specified in the CSSMTP configuration file, you should change the configured SMTPJOB value in the SMTPNOTE CLIST to match the ExtWrtName name of CSSMTP. If the ExtWrtName statement is not specified, you should customize the SMTPJOB name to match the CSSMTP job name. The SMTPJOB name must not be defined as a node name to JES and cannot begin with the characters R, RM, or RMT, because SMTPNOTE uses TSO XMIT to transmit the mail to CSSMTP.

Perform the following steps to customize the SMTPNOTE CLIST:

1. Copy SEZAINST(SMTPNOTE) into the system CLIST data set.
2. Customize the variables in the SMTPNOTE CLIST, including the SMTPJOB variable so that it uses the CSSMTP job name. DOMAIN should also be set when using CSSMTP. For more information, see "Step 3: Customize the SMTPNOTE CLIST and modify parmlib data sets" on page 1394.

Customizing the CSSMTP configuration file to handle undeliverable mail

CSSMTP provides configuration options to indicate how it handles undeliverable mail messages. You can configure CSSMTP to send individual undeliverable mail notifications or not to send them. You can also configure CSSMTP to create a report describing errors that were found while processing mail messages; this report can be created on the spool or sent to the configured mail administrators.

The following examples describe the configuration options for handling undeliverable mail. For more information about the BadSpoolDisp statement, the Undeliverable statement, the MailAdministrator statement, and the Report statement, see *z/OS Communications Server: IP Configuration Reference*.

- Example 1 — Configuring CSSMTP to not return an undeliverable mail notification to the originator and to hold the original spool file on the JES spool data set:

  ```
  BadSpoolDisp       Hold
  Report             Admin
  MailAdministrator  myuserId@ibm.us.com
  Undeliverable
  {
    ReturnToMailFrom No
  }
  ```

  To configure the application to not send an undeliverable mail notification to the originator, you need to set the ReturnToMailFrom value to No. This example might be useful if the mail messages do not specify an originator, or if the spool file is for sending bulk mail that does not typically require a reply to the originator. This example has optionally configured that a report be sent to the specified mail administrator.

  Tips:

  – The mail administrator can use the received report to determine which mail messages were undeliverable in the original spool file.
  – When the examination of this JES spool file is complete, the mail administrator should delete the JES spool file, which is now in a hold state.

  Results:

  – CSSMTP tries to send all mail messages, and if any of the mail is undeliverable, CSSMTP does not create and send an undeliverable mail notification.
  – Because the BadSpoolDisp statement is set to Hold, CSSMTP does not delete the JES spool file.

- Example 2 — Configure CSSMTP to send an undeliverable mail notification to the originator, and to hold the original spool file on the JES spool data set if necessary:

  ```
  BadSpoolDisp       Hold
  Report             None
  Undeliverable
  {
  ```

```
  ReturnToMailFrom     Yes
  DeadLetterAction     Store
  DeadLetterDirectory  /var/cssmtp/myDir/
}
```

This example is useful if the originator of the mail messages needs to be informed that the messages cannot be delivered. If you determine that it is not necessary to inform the originator of failed deliveries, set the ReturnToMailFrom value to No. No report is created in this example.

Tip: When spool files contain many mail messages, this configuration should be used with caution because a failure can cause many individual undeliverable mail notifications to be maintained in storage while trying to return them to the originator.

Results:

- CSSMTP builds an undeliverable mail notification and attempts to notify the originator of the mail message failure.
- Because the ReturnToMailFrom value is Yes, if the original spool file contains no errors other than undeliverable mail errors, CSSMTP always deletes the spool file even when the BadSpoolDisp value is set to Hold.
- If the original spool file contains both undeliverable mail errors and syntax errors, CSSMTP holds the spool file because the BadSpoolDisp value is set to Hold.
- If the undeliverable mail notification cannot be returned to the originator of the mail message, then this undeliverable mail notification becomes a dead letter. The action taken by CSSMTP is based on the value configured on the DeadLetterAction parameter. In this example, because the DeadLetterAction value is set to Store, CSSMTP stores the dead letters in the /var/cssmtp/myDir directory:

  ```
  /var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541437.1U
  /var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541999.1U
  ```

- Because None is specified on the Report statement, the log must be inspected for messages about any problems found in the JES spool file.

Steps for granting authority to start CSSMTP

Perform the following steps to grant authority to a user ID to start CSSMTP:

1. Ensure that the OPERCMDS class is active and RACLISTed, and that RACLIST processing is enabled.
2. Define the OPERCMDS class profile using a security product like RACF.
3. Grant CSSMTP access to the OPERCMDS class and then refresh the OPERCMDS class.

Depending on how you start CSSMTP, some RACF profiles that restrict who can issue the START, CANCEL, MODIFY, or STOP operator commands are as follows:

```
MVS.START.STC.CSSMTP.*
MVS.START.STC.CSSMTP

MVS.CANCEL.STC.CSSMTP.*
MVS.CANCEL.STC.CSSMTP

MVS.MODIFY.STC.CSSMTP.*
MVS.MODIFY.STC.CSSMTP

MVS.STOP.STC.CSSMTP.*
MVS.STOP.STC.CSSMTP
```

For more information about protecting operator commands, see *z/OS MVS Planning: Operations*.

Security for CSSMTP

Consider the following additional security measures for CSSMTP:

- For spool files from NJE nodes, the user ID associated with the spool file must be defined by SAF. For more information about the protection of SYSOUT data sets, see the following topics:
  - Protecting Data Sets on Spools in *z/OS Security Server RACF Security Administrator's Guide*
  - Authorizing SYSOUT in *z/OS Security Server RACF Security Administrator's Guide*
  - Authorizing Network Jobs and SYSOUT (NJE) in *z/OS Security Server RACF Security Administrator's Guide*
  - Authorizing SYSOUT in *z/OS JES2 Initialization and Tuning Guide*
  - Understanding default userids in *z/OS JES2 Initialization and Tuning Guide*
  - Using RACF to Provide Security in *z/OS JES3 Initialization and Tuning Guide*
  - Understanding Default User IDs in *z/OS JES3 Initialization and Tuning Guide*
- If your installation protects access to the JESSPOOL class of resources, provide ALTER access to the CSSMTP user ID so that it can read and delete spool files. An example JESSPOOL definition follows:

```
//CSSMTP   EXEC PGM=IKJEFT01
//SYSTSPRT DD  SYSOUT=*
//* The PERMIT for CLASS(JESSPOOL) is needed only if it has already
//*   been activated.
//SYSTSIN  DD  *
    SETROPTS CLASSACT(STARTED)
    SETROPTS RACLIST(STARTED)
    SETROPTS GENERIC(STARTED)
    ADDUSER  CSSMTP  DFLTGRP(OMVSGRP) OMVS(UID(nn) HOME('/'))           -
             NOPASSWORD
    RDEFINE  STARTED CSSMTP.* STDATA(USER(CSSMTP))
    RDEFINE  JESSPOOL  localnodeid.** UACC(READ)
    PERMIT   localnodeid.**                                             -
             CLASS(JESSPOOL) ID(CSSMTP) ACCESS(ALTER)
    SETROPTS GENERIC(JESSPOOL) REFRESH
    SETROPTS RACLIST(STARTED) REFRESH
    SETROPTS GENERIC(STARTED) REFRESH
```

- When CSSMTP is defined with a nonzero UID value, Delete Operator Message (DOM) messages are prefixed with message BPXM023I. To remove the prefix, you must authorize the CSSMTP procedure user ID to use the UNIX System Services console service. You can authorize CSSMTP to use the console service by entering the following commands:

```
RDEFINE FACILITY BPX.CONSOLE UACC(NONE)
PERMIT BPX.CONSOLE -
CLASS(FACILITY) ID(CSSMTP) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

- You can control whether CSSMTP reads and processes the spool files created by specific users by creating one or more resource profiles in the SERVAUTH class.

  The format of the SERVAUTH profile name is EZB.CSSMTP.*sysname.writername.originJESnode*, where *sysname* is the system name defined in the sysplex, *writername* is the CSSMTP configured external writer name, and *originJESnode* is the JES node that originated the spool file. If this profile is created with UACC(NONE), then only user IDs permitted to the resource are able to have spool files processed by CSSMTP.

For examples of the resource profile definitions, see the EZARACF sample in data set SEZAINST. For information about configuring the external writer name using the ExtWrtName statement, see *z/OS Communications Server: IP Configuration Reference*.

Tips:

– You can specify a wildcard on segments of the profile name, as shown in the following example:

```
RDEFINE  SERVAUTH EZB.CSSMTP.sysname.writername.originJESnode          -
    UACC(NONE)
 PERMIT EZB.CSSMTP.sysname.writername.originJESnode                    -
    CLASS(SERVAUTH) ID(userid) ACCESS(READ)

 PERMIT EZB.CSSMTP.sysname.writername.*                                -
    CLASS(SERVAUTH) ID(userid) ACCESS(READ)

 SETROPTS GENERIC(SERVAUTH) REFRESH
 SETROPTS RACLIST(SERVAUTH) REFRESH
```

– You can define multiple profiles. For example, if this CSSMTP instance processes spool files from local jobs and from remote systems, you can define a profile for the local system and for each JES node that originates spool files. The spool file is matched to the most specific RACF profile, and then the user ID associated with the spool file is validated against that profile.

Result: If the profile is active with UACC(NONE), then when the spool file is received on the JES spool data set, CSSMTP checks to determine whether a profile is defined for the originating node or for any originating node (*), and then checks whether the user ID associated with the job that created the spool file is permitted to the profile:

– If the user ID is permitted, the spool file is processed by CSSMTP.

– If the user ID is not permitted, the spool file is considered to be a bad spool file and is subject to the action specified by the BadSpoolDisp statement. For more information about the BadSpoolDisp statement, see *z/OS Communications Server: IP Configuration Reference*.

If the profile is not defined, then the spool file is processed as if the user ID is permitted.

- You can write a CSSMTP user exit or use the existing SMTPD user exit to inspect mail before it is sent to a target server.

  For example, you can create an exit to check the MAIL FROM: string on outbound mail. The mail originator, recipients, and other information can be inspected by the exit, and the entire JES job or a single mail message can be discarded.

  You can control the user exit that is used with the UserExit statement:

  – If you want to use a user exit that you have written for CSSMTP, then specify Version3 on the UserExit statement. You need to use this version if you want to use both RFC 821 and RFC 2821 commands to read and process from the JES spool data set. For more information about the CSSMTP exit, see *z/OS Communications Server: IP Configuration Reference*.

  – If you want to continue using your SMTPD user exit and use only RFC821 commands, then specify Version2 on the UserExit statement. For more information about using the SMTP server exits, see *z/OS Communications Server: IP Configuration Reference*.

  For more information about the UserExit statement, see *z/OS Communications Server: IP Configuration Reference*.

- You can enable the SMTP server and client to use Transport Layer Security (TLS) to provide private, authenticated communication over the Internet using RFC

3207, *SMTP Service Extension for Secure SMTP over Transport Layer Security*. For more information, see "Steps for using Transport Layer Security for CSSMTP."

Steps for using Transport Layer Security for CSSMTP

Perform the following steps to use Transport Layer Security (TLS) for CSSMTP:

1. Set up secure mail using the YES option on the Secure parameter of the TargetServer statement, the STARTTLS command in the JES batch job, or both.

   Table 67 shows whether TLS is required between CSSMTP and a target server based on various JES batch job and CSSMTP configuration combinations.

   Table 67. JES batch job and CSSMTP configuration combinations for secure mail

STARTTLS command?	Secure parameter value	TLS required?
Yes	YES	Yes
No	YES	Yes
Yes	NO	Yes
No	NO	No

   If secure communication is required according to Table 67 and no available target servers support TLS (as indicated by server capabilities in response to the EHLO command), the mail message fails and is not delivered.

   For information about the TargetServer statement, see *z/OS Communications Server: IP Configuration Reference*. For information about the STARTTLS command, see *z/OS Communications Server: IP User's Guide and Commands*.

2. See the following simple example to get started with TLS. For more information about TLS, see Chapter 22, "Application Transparent Transport Layer Security data protection," on page 1193.

   In this example, assume the following characteristics:

   - The mail contains sensitive data, and you want CSSMTP to communicate with only TLS protocols.
   - CSSMTP is using port 25 to communicate with a target server on another platform.
   - There is only one TCP/IP stack over which mail is delivered, referred to as the client stack.

   To set up TLS for this sample environment, do the following:

   a. Create the key ring.

      The client key ring needs the root certification used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see Appendix B, "TLS/SSL security," on page 1461. For more information about managing key rings and certificates with RACF and the RACDCERT command, see *z/OS Security Server RACF Security Administrator's Guide*. For more information about managing key rings and certificates with gskkyman, see *z/OS Cryptographic Services System SSL Programming*.

   b. Configure CSSMTP to require secure communication. Configure the TargetServer statement with the Secure parameter set to YES, which specifies that TLS protocols are always required. For information about the TargetServer statement, see *z/OS Communications Server: IP Configuration Reference*.

   c. Configure the client system to use TLS with AT-TLS policies as follows:

1) Specify TTLS on the TCPCONFIG statement in the TCP/IP profile for the client stack. For information about the TCPCONFIG statement, see *z/OS Communications Server: IP Configuration Reference*.
2) Block the ability of applications to open a socket before AT-TLS policy is loaded into the TCP/IP stack by setting up EZB.INITSTACK.*sysname.tcpname* for the client stack.
3) Create a main Policy Agent configuration file containing a TcpImage statement for the client stack, and create a TcpImage policy file for the client stack. For more information about AT-TLS policy statements, see *z/OS Communications Server: IP Configuration Reference*.
4) Add a TTLSConfig statement to each TcpImage policy file to identify the TTLSConfig policy file location:

   ```
   TTLSConfig  clientPath
   ```

5) Add the AT-TLS policy statements to the *clientPath* file:

   ```
   TTLSRule                          CSSMTPRule
   {
      RemotePortRange                25
      Direction                      Outbound
      TTLSGroupActionRef             CSSMTPGroup
      TTLSEnvironmentActionRef       CSSMTPEnvironment
   }
   TTLSGroupAction                   CSSMTPGroup
   {
      TTLSEnabled                    On
   }
   TTLSEnvironmentAction             CSSMTPEnvironment
   {
      HandshakeRole Client
      TTLSKeyRingParms
      {
         Keyring                     client_key_ring
      }
      TTLSEnvironmentAdvancedParms
      {
         ApplicationControlled       On
      }
   }
   ```

   Tip: You can use the IBM Configuration Assistant for z/OS Communications Server to generate the AT-TLS Policy Agent files. For information about the configuration assistant, see "Option 1: Use the IBM Configuration Assistant for z/OS Communications Server" on page 1195.

You know you are done when: CSSMTP can successfully deliver mail to a target server using secure connections. If SECURE YES is configured and CSSMTP is able to successfully negotiate and establish a TLS session, the following message is displayed:

```
EZD1821I  csproc ABLE TO USE TARGET SERVER  ipAddress
```

Restriction: To use the STARTTLS command with a target server, the target server must have a certificate that can be validated by the AT-TLS component of z/OS Communications Server as configured by Policy Agent. This certificate can be a self-signed certificate or a certificate that can be validated by a known certificate authority. If the certificate of the server cannot be validated, secure communication with the server fails and mail that requires security cannot be delivered to that server.

Steps for configuring SMF records for CSSMTP (optional)

CSSMTP can write System Management Facilities (SMF) records for the following:

- When the configuration has been initialized or modified by a MODIFY REFRESH command, a MODIFY LOG,LEVEL command, or a MODIFY USEREXIT command. A CSSMTP application configuration record (CONFIG subtype 48) is written.
- At the end of a connection with a target server, a CSSMTP application connection record (CONNECT subtype 49) is written.
- At the end of the processing for each mail message, a CSSMTP application mail message record (MAIL subtype 50) is written.
- At the end of the processing of a spool file when all the mail messages have been completed, a CSSMTP application spool file record (SPOOL subtype 51) is written.
- When statistical information about the CSSMTP processing at the SMF intervals is required, a CSSMTP application statistical record (STATS subtype 52) is written.

Perform the following steps to write SMF records to both the MVS SMF data sets and the real-time SMF NMI. Writing SMF records to the MVS SMF data sets and writing SMF records to the real-time SMF NMI are two independent functions and are controlled by different configuration parameters.

1. Add a SMF119 statement to the CSSMTP configuration file. This configuration parameter controls which SMF record types are written to the MVS SMF data sets. For example:

   ```
   SMF119
    {
    CONFIG YES
    SPOOL YES
    MAIL NO
    CONNECT YES
    STATS YES
    }
   ```

   In this example, the CONFIG, SPOOL, CONNECT and STATS records will be written to MVS SMF data sets and not the MAIL record.

2. Restart the CSSMTP task or issue a MODIFY REFRESH command to dynamically update CSSMTP with the new SMF119 statement values.

3. Update the TCPIP profile NETMONITOR statement to forward all of the CSSMTP SMF records associated with the CONFIG, SPOOL, CONNECT and STATS types to an application using the real-time SMF NMI, SYSTCPSM. Note that these record types are both connection oriented and non-oriented (see 5 on page 1389). See *z/OS Communications Server: IP Programmer's Guide and Reference* for more information about SYSTCPSM.

   ```
   NETMONITOR SMFSERVICE CSSMTP
   ```

   For the descriptions of the SMF records see *z/OS Communications Server: IP Programmer's Guide and Reference*.

4. Update the TCPIP profile NETMONITOR statement to forward all the CSSMTP SMF records associated with the MAIL type to an application using the real-time SMF NMI, SYSTCPSM. See *z/OS Communications Server: IP Programmer's Guide and Reference* for more information about SYSTCPSM.

   ```
   NETMONITOR SMFSERVICE CSMail
   ```

5. Special considerations for CSSMTP application and NETMONITOR in a CINET environment:
   - The CSSMTP application can be started with the **-p** parameter to set stack affinity. This enables that all of the SMF records will be written to the real-time SMF NMI associated with the stack whose name was specified on the **-p** parameter. This forces connection oriented SMF records (CONNECT) and non-connection oriented SMF records (CONFIG, SPOOL, MAIL and STATS) to go to the same stack. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of the stack name to match the name specified on the **-p** parameter.
   - If the CSSMTP application is started without the **-p** parameter and multiple stacks are active, then a network management application can not determine the stack that records will be written to. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of all stacks, so that network management applications can obtain all the records. The network management application will not get redundant records. In this case CSSMTP writes the records to the first stack with an active SMFService application and with the appropriate SMFSERVICE CSMAIL or CSSMTP parameter set.

Monitoring CSSMTP

You can use the following MODIFY commands to monitor CSSMTP:

- MODIFY DISPLAY,CONFig

  Displays the current configuration values.
- MODIFY DISPLAY,IPList

  Displays the current set of target servers to which mail can be sent that are configured or resolved from the TargetServer statement.
- MODIFY DISPLAY,SPoolstatus

  Helps you determine how mail is being processed off the JES spool file.
- MODIFY DISPLAY,TARgets

  Helps you monitor the mail being sent to target servers to determine whether mail is being delivered, is being placed in undeliverable states, or is being retried through long retry queues. This command also helps you determine the list of target servers, their attributes, and the number of mail messages that a target server is accepting.

For information about the MODIFY command for CSSMTP, see *z/OS Communications Server: IP System Administrator's Commands*.

Differences between CSSMTP and SMTPD

If you are currently using Communications Server SMTPD on z/OS, you should consider using CSSMTP. CSSMTP has been designed to support z/OS users of SMTPD that create mail on the JES spool data set using batch jobs or that use SMTPNOTE for delivery to the Internet. The mail messages you send today using SMTPD can probably be sent with CSSMTP. However, as shown in Table 68 on page 1390, CSSMTP does have differences from SMTPD, and might not be able to accommodate everyone. Some of the primary differences that require migration consideration are as follows:

- CSSMTP does not provide SMTP listener support; it cannot be used to receive mail to z/OS for delivery to TSO users. You must continue to use SMTPD for this kind of support or consider using sendmail for delivering mail to mailboxes defined in the z/OS UNIX file system.

- CSSMTP delivers mail only to systems that have TCP/IP host names. If you are using a local TSO user ID on the POSTMASTER statement for your SMTPD server, then the local TSO user ID must be changed to an email address with the format *userid@host.domain* on the MailAdministrator statement for CSSMTP. For information about the MailAdministrator statement, see *z/OS Communications Server: IP Configuration Reference*.
- CSSMTP does not perform DNS lookups to determine a target server for each recipient. CSSMTP requires a connection to an SMTP or ESMTP server that receives the mail and handles next-hop delivery. Typically, the target server is located at a remote destination, but could also be a local instance of sendmail.
- If mail that CSSMTP sends to the target server becomes undeliverable, CSSMTP is not able to receive the undeliverable mail notification because CSSMTP is not a server. The originator (that is, MAIL FROM) of mail messages should be reachable from the target server.
- CSSMTP does not store mail to DASD. CSSMTP processes mail directly from the JES spool data set and sends the mail to the target server. If mail cannot be delivered immediately, it is held for only a short period of time, defined by the RetryLimit statement. If the mail cannot be delivered by the end of any configured retry limit, then the mail becomes undeliverable.
- CSSMTP does not support source routing, such as the <@host1,@host2:userid@host3> or <NJEuserid%NJEhost> formats. For example, in the address string @host1,@host2,...,@hostn:user_id@host_name, the @host1,@host2,...,@hostn portion of the address is ignored and user_id@host_name is used as the recipient value. If you are using source routing, you might want to change it to be an email address with the format *userid@domain* (*mailbox*). Otherwise, the mail might not be delivered.

Table 68. Differences between CSSMTP and SMTPD

Function	CSSMTP	SMTPD
Managing the JES spool file	Uses bad spool file or error report. For information about the BadSpoolDisp, Undeliverable, and Report statements, see *z/OS Communications Server: IP Configuration Reference*.	Uses DASD to store mail
Code page translation	Yes; uses iconv support for the EBCDIC code page for the JES spool file. For information about using the Translate statement, see *z/OS Communications Server: IP Configuration Reference*.	Yes; user-defined translate tables are configured in SMTPD
Modify RFC 822 headers or the body of the mail	No, except for code pages for converting from EBCDIC to ASCII, and for appending a RECEIVED line header to the beginning of the RFC 822 headers to indicate that CSSMTP has picked up the mail message.	Yes
Supports SMTP server function (for example, receive mail)	No, CSSMTP is a mail-forwarding SMTP client application and is not a fully capable MTA.	Yes
Deliver to local TSO user	No; if this function is required, use SMTPD to provide access to a local TSO mailbox.	Yes

Table 68. Differences between CSSMTP and SMTPD (continued)

Function	CSSMTP	SMTPD
Undeliverable mail	The undeliverable mail notification can either be sent back to the originator or deleted. An error report for undeliverable mail can be generated for SYSOUT or sent to the mail administrator. For information about the Undeliverable and Report statements, see *z/OS Communications Server: IP Configuration Reference*.	Send back to originator
Dead letter mail	The dead letter mail can either be deleted or written to a z/OS UNIX file system directory. For information about the DeadLetterAction parameter on the Undeliverable statement, see *z/OS Communications Server: IP Configuration Reference*.	No configuration parameters to support deadletter processing
Monitoring mail processing	MODIFY commands	SMSG
Requires VMCF and TNF subsystems	No	Yes; SMTPD is a Pascal application
Security	Uses security product authorization profile to provide security. See "Security for CSSMTP" on page 1384	Uses the RESTRICT and SECURE statements
Rewrite the path name in command	No; The batch job needs to use a correct mail address format, such as *userid@host.domain*.	Yes
Addition of a message-id field when none appears	Yes	No
Source routing support, such as the *@host1,@host2:userid@host3* or *NJEuserid%NJEhost* formats	No; CSSMTP removes source routes from the path. CSSMTP does not support source routing and does not generate these addressing formats.	Yes
Send mail to local mail administrator	No; CSSMTP internally generates a report that can be delivered to a mail administrator, but the mail administrator address must be in the form (*userid@host.domain*).	Yes; supports the local TSO or remote (NJE) user IDs as a mail administrator
Supports the SMTP commands EXPN, QUEU, HELP, NOOP, TICK, VERB, and VRFY	No; for commands supported, see *z/OS Communications Server: IP User's Guide and Commands*.	Yes
Resolver	z/OS UNIX search order for resolver configuration files. Uses system resolver.	Native MVS search order for resolver configuration files. Does not use system resolver.
Checkpoint	Yes; for information about using the CHKPOINT DD statement in the CSSMTP started procedure and starting CSSMTP, see *z/OS Communications Server: IP Configuration Reference*.	No
IPv6 support	Yes	No
SMF support	Yes	No

Configuring the SMTP server (SMTPD)

Before you configure...

Read "Understanding search orders of configuration information" on page 19. It covers important information about data set naming and search sequences.

Note: Before configuring the SMTP server, it is assumed that the necessary SYS1.PARMLIB changes have been made. Consult the Program Directory for current information about the storage estimates for this version. The Program Directory also contains information about customization of certain SYS1.PARMLIB members, which must be completed before the initial program load (IPL) for the MVS image.

The SMTP server uses the Pascal socket API, so VMCF must be started for the server to successfully initialize. If VMCF is not started, message EZY1980E will be issued and the server will terminate.

If you have specified PROFILE NOINTERCOM in your TSO user ID's profile, then there are some SMTP server messages that you will not receive.

Checklist for working within the SMTP environment

1. SMTP needs to interface with JES utilities to create, read, write and purge data from the JES spool. JES exit programs might interfere with SMTP functioning properly.
2. JES initialization parameters must be set up correctly so mail can be sent to SMTP and so that local mail can be placed on the JES spool for local users.
3. Because SMTP needs authority to create, read, write, and purge data on the JES spool, any security programs that protect JES spool access must have the user ID or group ID that is associated with the SMTP started task name in their definitions of authorized users. If your security product is RACF, you can control the association of a user ID or group ID to a started task name by the STARTED class. For more information about RACF controls for the JES spool, see *z/OS Security Server RACF Security Administrator's Guide*.
4. DASD management is important to have SMTP run properly, it is recommended that SMTP have its own dedicated volumes. The MAILFILEVOLUME statement may be used to specify a particular volume where newly allocated SMTP data sets reside. See *z/OS Communications Server: IP Configuration Reference* for more information on this parameter.
5. SMTP is a heavy user of data set I/O functions. It creates data sets for every piece of mail it processes. There are two data sets associated with each piece of mail:
   a. SMTPhlq.*.ADDRBLOK (control file)
   b. SMTPhlq.*.NOTE (message content)

   The SMTP high level qualifier (SMTPhlq) is configured in the SMTP configuration data set using the MAILFILEDSPREFIX statement. When SMTP is executing, SMTP must have exclusive access to the data sets it has created to work properly.

   To avoid contention, applications that manage DASD should only be run when SMTP is not active, or exclude the SMTP data sets or the volumes on which they reside from their processing. If contention occurs, EZA5335E will be displayed before the SMTP server terminates. Also, the SMTP high level qualifier can be used to exclude the SMTP data sets if necessary.

6. SMTP requires that the ASCII LineFeed character (x'0A') be translated to an EBCDIC LineFeed (x'25'). The translation table used by SMTP must have this translation. For information regarding customizing translation tables and for the search order used by SMTP to locate the translation table, see *z/OS Communications Server: IP Configuration Reference*.

Configuration process

Steps to configure SMTP:

1. Verify TCP/IP profile statements in the TCP/IP profile data set.
2. Update the SMTP cataloged procedure SEZAINST(SMTPPROC).
3. Customize the SMTPNOTE CLIST and modify parmlib members.
4. Customize the SMTP mail headers (optional).
5. Set up a TCP-to-NJE mail gateway (optional).
6. Specify configuration statements in the SMTP configuration data set.
7. Create an SMTP security table (optional).
8. Enable SMTP domain name resolution.
9. Enable sending messages to SMTP users and users on an IP Network.
10. Optionally, design SMTP exit to inspect and filter unwanted mail (*spam*).
11. Set up automation to monitor how much mail is queued.

Step 1: Verify TCP/IP profile statements in the TCP/IP profile data set

Consider specifying the following TCP/IP profile statements.

AUTOLOG: If you want the SMTP server to start automatically when the TCPIP address space is started, include the name of the member that contains the SMTP cataloged procedure in the AUTOLOG statement of the *hlq*.PROFILE.TCPIP data set.

```
AUTOLOG
  SMTP
ENDAUTOLOG
```

PORT: To ensure that port TCP 25 is reserved for SMTP, verify that the name of the member that contains the SMTP cataloged procedure has been added to the PORT statement in *hlq*.PROFILE.TCPIP.

```
PORT
  25 TCP SMTP
```

Other TCP/IP profile considerations: The SMTP server uses the Pascal API MonQuery function to obtain the IPv4 IP addresses defined for the TCP/IP stack. The total number of IPv4 IP addresses that can be defined for the TCP/IP stack is limited to 255 IP addresses. This limit of 255 IP addresses applies to all IPv4 IP addresses, including loopback and dynamic VIPA.

For more information about TCP/IP profile statements, see *z/OS Communications Server: IP Configuration Reference*.

Step 2: Update the SMTP cataloged procedure

Update the SMTP cataloged procedure by copying the sample in SEZAINST(SMTPPROC) to your system or recognized PROCLIB. Specify SMTP parameters, and change the data set as required to suit your local configuration. See *z/OS Communications Server: IP Configuration Reference* for more detailed information about the procedure.

Note: SMTP does not support z/OS UNIX files.

Step 3: Customize the SMTPNOTE CLIST and modify parmlib data sets

You must copy and customize the SMTPNOTE CLIST on every system where users will be able to send mail with the SMTPNOTE command. This includes TCP/IP nodes and each NJE node that sends mail through SMTP on a remote gateway node. SMTPNOTE uses the TSO transmit (XMIT) command to interface with SMTP.

Copy SEZAINST(SMTPNOTE) into the system CLIST data set. Since the SEZAINST data set is in a fixed format, the SMTPNOTE member may be truncated if your system CLIST library is not in a fixed format.

You should customize the following variables in the SMTPNOTE CLIST:

DDNAME
The DDNAME that SMTPNOTE will use to allocate the input data set. The allocation is done to allow shared access to the data set. The default value is set to EZBSMTPN and should only be changed if this value will cause a conflict on your system.

HOSTNAME
The name of the system on which this CLIST is installed. Typically, the name is the NJE node name of this system. The NJE node name of the system is the value of the NAME parameter on the NODE(nn) statement in the JES2PARM member of parmlib.

SMTPNODE
The NJE node on which the SMTP server runs. Typically, HOSTNAME and SMTPNODE have the same value. When SMTPNODE is used on an NJE network in conjunction with a TCP-to-NJE gateway, the value of this parameter is the NJE node name of that gateway.

SMTPJOB
The name of the address space in which SMTP runs at SMTPNODE. Usually this is SMTP. The SMTPJOB name must not be defined as a node name to JES and cannot begin with the characters R, RM, or RMT, since SMTPNOTE uses TSO XMIT to transmit the note to the SMTP address space.

TEMPDSN
The name of the temporary data set used to store the contents of the note being created. This can be any arbitrary data set name that ends with the low-level qualifier, TEXT. Do not use a fully qualified name. If you do not fully qualify the name (no quotes), the data set name will be prefixed by the *userid*. If you enclose the name in single quotes, several users can use this temporary data set.

TIMEZONE
The time zone for your system. This will appear in the "Date:" stamp of the RFC 822 header generated by SMTPNOTE. See RFC 822 for valid time zone formats. SMTPNOTE does not check the validity of the character string configured. If SYSTZ is configured, SMTPNOTE gets the TIMEZONE value from the MVS system using the local TIME/DATE offset in the communication vector table (CVT) associated with SMTPNOTE. This value is then converted to a string format of a plus sign (+) or a minus sign (-) followed by 4 digits (for example, *-HHMM*). The local TIME/DATE offset is controlled by the system administrator that sets the MVS system

time/date and timezone parameters. For more information about the CLOCK*xx* parmlib member, see *z/OS MVS Initialization and Tuning Reference*. For more information about the MVS SET CLOCK=*hh.mm.ss* or SET TIMEZONE={W|E}.*hh.mm* commands, see *z/OS MVS System Commands*. For information about accessing RFCs, see Appendix G, "Related protocol specifications," on page 1555.

Note: SMTPNOTE does not alter any existing date/time and timezone headers in the mail.

ATSIGN
Some foreign languages need to use a different character to represent the @ symbol. This input symbol is a single-byte representation of the @ symbol in their national language code page.

DOMAIN
Some SMTP message transfer agents (MTAs) need a fully qualified name as an email address for the originator of the mail. If DOMAIN is set, then this string is appended to the HOSTNAME variable string provided in this CLIST, and the resulting fully qualified name string is *hostname.domain*. The resulting string is later used by the CLIST to create the SMTP MAIL FROM: command and the RFC 822 From: header in the mail message. The CLIST does not check validity of the content of the string. This variable should be set when sending mail to CSSMTP.

You should also modify the following parmlib members:

IEFSSNxx
When the SMTP server is running in the same host (or system) as the SMTPNOTE CLIST, the IEFSSNxx member can be modified in one of the following two ways:

- The following lines may be included:

```
TNF,MVPTSSI
VMCF,MVPXSSI, nodename
```

  where *nodename* is the NJE node name. The NJE node name, *nodename*, must be the same as the *hostname* and the *smtpnode* that are defined in the SMTPNOTE CLIST.

- If you are using restartable VMCF, you must make changes to IEFSSxx members in the SYS1.PARMLIB data set.

  For introductory information on restartable VMCF, see "Step 3: Configure VMCF and TNF" on page 103. For the MVS system changes required for restartable VMCF, see the TCP/IP for MVS Program Directory. For information on VMCF commands, see *z/OS Communications Server: IP Diagnosis Guide*.

  Note: You should define the SystemName in the IEFSSNxx parmlib member to be the same as your JES2 or JES3 (NJE) nodename. This is required for correct delivery of SMTP mail. For example, if the following line is coded in your SMTPNOTE CLIST:

```
SMTPNODE P390
```

  you need to code NAME=P390 in your IEFSSNxx parmlib member. As an alternative, instead of using the IEFSSNxx parmlib member to specify the JES node, you can use the keyword NJENODENAME within your SMTP configuration to a valid NJE node. For more information, see NJENODENAME.

IKJTSOxx
The TRANSREC statement must contain the correct nodename, or the NODESMF parameter can be coded as NODESMF((*,*)). For more information on the TRANSREC statement, see *z/OS MVS Initialization and Tuning Reference*.

Step 4: Customize the SMTP mail headers (Optional)

Electronic mail has a standardized syntax for text messages that are sent across networks. The standard syntax is described in RFC 822. Messages have an envelope and contents. Envelopes contain all necessary information to accomplish transmission and delivery of the message content. The fields within the envelope are in a standard format.

In most cases, the IBM-supplied mail header defaults are adequate. To understand the IBM-supplied mail header defaults, see "Default SMTP rules" on page 1402. If it is necessary for you to change them, you can use the REWRITE822HEADER statement in the SMTP configuration data set to control the way SMTP performs a rewrite of the RFC 822 mail headers. Mail headers are passed from the local system, or NJE network, to the TCP network. Mail headers passing from the TCP network to the local system or NJE network are not affected. Only the addresses under certain RFC 822 header fields can be subject to the header rewriting rules.

The header fields affected by the REWRITE822HEADER statement are:

Field **Description**

From The identity of the person sending the message.

Resent-From
Indicates the person that forwarded the message.

Reply-To
Provides a mechanism for indicating any mailboxes to which responses are to be sent.

Resent-Reply-To
Indicates the person to whom you should forward the reply.

Return-Path
This field is added by the mail transport service at the time of final delivery. It contains definitive information about the address and route back to the originator of the message.

Sender
The authenticated identity of the agent that sent the message. An agent can be a person, system, or process.

Resent-Sender
The authenticated identity of the agent that has resent the message.

To Contains the identity of the primary recipient of the message.

Cc Contains the identity of the secondary (informational) recipients of the message.

Bcc Contains the identity of additional recipients of the message. The contents of this field are not included in copies sent to the primary and secondary recipients of the message but are included in the author's copy.

The SMTP rules data set: You can override the default rules for header addresses by creating an SMTP rules data set. This allows you to customize the address transformations to the needs of a particular site. If you are customizing SMTP mail headers, this task is required.

The SMTP rules data set is pointed to by the //SMTPRULE DD statement in the SMTP cataloged procedure. The SMTP rules data set consists of:

Field definition
Contains the names of all header fields whose addresses are to be rewritten.

Rules definition
Contains the rewrite rules for the header fields.

Statement syntax: In creating the SMTP rules data set you must use the following syntax conventions:

- The data set statements are free-format. Tokens can be separated by an arbitrary number of spaces, and statements can span an arbitrary number of lines. However, you must end every statement with a semicolon (;).
- A character string appearing within single quotation marks ('...') is not case-sensitive. For example, 'abc' represents 'abc', 'Abc', 'ABC', and so forth.
- A character string appearing within double quotation marks ("...") is case-sensitive. For example, "abc" only represents "abc". It does not represent "Abc", "ABC", and so forth.

  Special characters, such as @ and % are treated the same whether enclosed by single quotation marks or double quotation marks.
- Double-hyphens ("--") are used to begin a comment. The comment extends to the end of the line.

The components of the SMTP rules data set are described in "Format of the field definition section" and "Format of the rule definition section" on page 1399.

Format of the field definition section: The field definition section is the first section in any SMTP rules data set. It defines any applicable alias fields, and it is introduced by the following heading:

```
Field Definition Section
```

This section allows similar fields to be grouped under an alias or common name. This name, or alias, is used to represent the field list. You can define an arbitrary number of aliases representing a set of field lists.

An alias name can be any alphanumeric sequence of characters that is not a predefined keyword within the SMTP rules (see the following). However, the alias name `DefaultFields` is treated specially by the SMTP configuration interpreter. If `DefaultFields` is defined, and if a rule is written that does not specify an associated field alias, the rules interpreter assumes that `DefaultFields` is the associated field alias.

The alias definition within this section is of the following form:

```
alias_name = alias_definition; optional comment
```

where *alias_name* is the name of the alias and *alias_definition* is an expression describing which fields are to be grouped under this alias. This expression can be as simple as a single field name. For example:

```
MyAlias = 'To';
```

The aliases can be a list or set of field names. The field names ***To, From, Cc***, and ***Bcc***, in the following example are part of a set of field names referenced by the alias MyAlias.

```
MyAlias = 'To' 'From' 'Cc' 'Bcc' ; -- first list of fields
```

You can combine field names and previously defined aliases to create a new alias. In the following example, the set of field names defined as MyAlias and the field names in the new alias YourAlias are combined to form a third set. The new alias TheirAlias is the union of both aliases and contains the fields of MyAlias and YourAlias.

```
MyAlias    = 'To' 'From' 'Cc' 'Bcc';
YourAlias  = 'Errors-To' 'Warnings-To';
TheirAlias =  MyAlias YourAlias;
```

In the previous example, TheirAlias is an alias that represents the following fields:

```
TheirAlias:  'To' 'From' 'Cc' 'Bcc' 'Errors-To' 'Warnings-To'
```

You can perform the following operations on set members of the alias to create a subset of the initial alias:

- Union operations
- Difference operations
- Intersection operations

Union and difference operations: Certain field names can be added to or omitted from a new alias of field names by using a minus sign to omit set members and an optional plus sign to include another field name. In the mathematics of sets, when you add together 2 or more sets, they form a union. When set members are omitted, the remaining set is created by the difference operation. In the following example HerAlias and HisAlias are defined. The alias HisAlias is created from the union of TheirAlias, HerAlias, and the omission of Warning-To and Bcc from the sets:

```
HerAlias   = 'Reply-To' 'Sender';
HisAlias   = TheirAlias - 'Warnings-To' - 'Bcc' + HerAlias;
```

In the previous example, HisAlias is an alias that represents the following fields:

```
HisAlias:  'To' 'From' 'Cc' 'Errors-To' 'Reply-To' 'Sender'
```

Intersection operations: A field definition can include an intersection operation. When the intersection operation is applied to two field expressions, the resulting set contains the fields common to both. In the following example, MyAlias and YourAlias are defined. The alias OurAlias is created from the intersection of MyAlias and YourAlias. The asterisk (*) is the intersection operator.

```
MyAlias    = 'Bcc' 'Cc' 'From' 'Reply-To';
YourAlias  = 'Resent-From' 'Cc' 'Sender' 'To' 'Bcc';
OurAlias   = MyAlias * YourAlias; -- the intersection
```

In the previous example, OurAlias represents the following fields:

```
OurAlias:  'Bcc' 'Cc'
```

In the following complex example TheirAlias is created from the intersection of YourAlias with the sum of MyAlias plus Resent-From:

```
TheirAlias = (MyAlias + 'Resent-From') * YourAlias;
```

In the previous example, TheirAlias represents the following fields:

```
TheirAlias: 'Bcc' 'Cc' 'Resent-From'
```

The parentheses within the definition of TheirAlias perform the same functions as in algebra. Field expressions are evaluated from left to right, but the intersection operation has greater priority than union and difference operations. If parentheses were not used in the definition of TheirAlias, the result would be:

```
TheirAlias: 'Bcc' 'Cc' 'From' 'Reply-To' 'Resent-From'
```

Format of the rule definition section: The rule definition section is the next section in any SMTP RULES data set. It contains the header rewriting rules that define the intended address transformations, and it is introduced by the following heading:

```
Rule Definition Section
```

The basic form of a rewrite rule is:

```
alias :before-address-pattern  => after-address-pattern;
```

where the alias name *alias* is an optional name representing the fields for which the rule is applicable. If the alias name *alias* : is omitted from this part of the rules, then DefaultFields is assumed.

The sequence of tokens that define how a particular type of address is to be recognized is the *before-address-pattern* portion of the rules definition. The sequence of tokens that define how the address is to appear after the address has been rewritten is the *after-address-pattern* portion of the rules definition. The following example is the rule for converting host names:

```
A '@' NJEHostName => A '@' TCPHostName; -- convert host names
```

In the previous example, A '@' NJEHostName is the *before-address-pattern* portion of this rule, and A '@' TCPHostName is the *after-address-pattern* portion. This rule specifies that the address to be rewritten has an arbitrary local name (A), an at sign (@), and the NJE host name (NJEHostName) of the current site. The rule also specifies that the rewritten address must contain the same arbitrary local name (A), an at sign, and the current site's TCP host name TCPHostName.

SMTP rules syntax conventions: Use the following syntax convention when writing SMTP rules:

- Some keywords have special meaning to the rules interpreter. For example, NJEHostName keyword means the NJE host name of the present system, and TCPHostName keyword means the TCP host name of the present system. For more information about valid keywords see "Predefined keywords within the SMTP rules" on page 1401. Some keywords, such as TCPHostName, have single values. Other keywords, such as AltTCPHostName and AnyDomainName, can have many possible values. To avoid ambiguity, any keyword that can have multiple values, and is used in the *after-address-pattern* of a given rule, must appear exactly once within the *before-address-pattern* of that rule. The following rule example shows a valid syntax:

  ```
  A '@' AltTCPHostName '.' AltTCPHostName =>
     A '%' TCPHostName '@' TCPHostName;
  ```

  The following two rules have incorrect syntax because the first keyword AltTCPHostName must be rewritten to a keyword with specific values. The AltTCPHostName is attempting to be rewritten to the same AltTCPHostName but with unknown values, which is not valid.

```
A '@' AltTCPHostName '.' AltTCPHostName =>
   A '%' AltTCPHostName '@' TCPHostName;

A '@' TCPHostName => A '@' AltTCPHostName;
```

Any rule whose *before-address-pattern* includes a keyword that has a null value is ignored during the header rewriting. Thus, if there is no `AltNJEDomain` defined in the system configuration data set, no rule that includes `AltNJEDomain` in the *before-address-pattern* is considered during the header rewriting.

- Alphanumeric identifiers that are not within single or double quotation marks, and that are not predefined keywords, are considered wildcards in the rule statement. Wildcards represent an arbitrary (non-null) sequence of characters. The identifier `A`, in the previous rule example, is a wildcard. Thus, if `host` were the NJE host name for the current site, and if `tcphost` were the TCP host name for the current site, the previous rule example recognizes `abc@host` and `d@host` as candidates for address rewriting, and rewrites them as `abc@tcphost` and `d@tcphost` respectively. To avoid ambiguity, within the *before-address-pattern* of a given rule, no two wildcards are allowed in a row, and the same wildcard cannot be used more than once. The following rules have valid syntax:

  ```
  A '@' B TCPHostName      => A '%' B '@' TCPHostName;
  A '%' B '@' NJEHostName => A B '@' TCPHostName;
  ```

  The following rules have incorrect syntax because the first rule has 2 wildcards in a row `A` and `B`. The second rule has the same wildcard `A` repeated:

  ```
  A B '@' TCPHostName      => A A '%' B '@' TCPHostName;
  A '%' A '@' NJEHostName => A '@' TCPHostName;
  ```

- A character string appearing within single or double quotation marks tells the rules interpreter where a particular string is to appear within a header address. In the previous rule example, the `'@'` string in the *before-address-pattern* tells the rules interpreter that an at-sign (@) must appear between the arbitrary character string and the NJE host name. The `'@'` string in the *after-address-pattern* tells the rules interpreter that the address must be rewritten so an at-sign appears between the arbitrary string and the TCP host name. As previously mentioned, single quotation marks denote strings that are not case-sensitive, and double quotation marks denote case-sensitive strings.
- The character sequence `"=>"`, with no spaces between the characters, separates the *before-address-pattern* from the *after-address-pattern*.
- The order in which the rules are specified is important; the first rule encountered whose *before-address-pattern* matches the current address is the rule to dictate the address transformation. Once a matching rule has been found for an address, no other rule is considered.

In addition to the rules themselves, there is the capability for some simple logic to decide at system configuration time which rules within the data set should become active. These conditions are specified in the form of an IF-THEN-ELSE statement, as shown in the following example:

```
IF cond THEN
   statement list
ELSE
   statement list
ENDIF
```

A statement list can consist of any number of rules or nested IF statements, or both. Each IF statement, regardless of whether it is nested, must be ended by an ENDIF keyword. As with IF statements in other programming languages, the ELSE clause is optional.

There are only two conditions recognized by an IF statement:
1. IF *predefined keyword* = '*character string*' THEN ... ENDIF
2. IF *predefined keyword* CONTAINS '*character string*' THEN ... ENDIF

The conditional operators = and CONTAINS can be prefixed by the word NOT to invert the conditions.

The *predefined keyword* must be a keyword that resolves to a single value at system configuration time. The character string in the first condition can be null. A character string cannot span more than one line.

The following example shows the use of IF statements.

```
IF NJEDomain = '' THEN
   A '@' AnyNJEHostName => A '%' AnyNJEHostName '@' TCPHostName;
ELSE
   A '@' NJEHostName '.' NJEDomain    => A '@' TCPHostName;
   A '@' NJEHostName '.' AltNJEDomain => A '@' TCPHostName;
   IF NJEDomain CONTAINS '.' THEN
      A '@' AnyNJEHostName                   =>
         A '@' AnyNJEHostName '.' NJEDomain;
      A '@' AnyNJEHostName '.' NJEDomain    =>
         A '@' AnyNJEHostName '.' NJEDomain;
      A '@' AnyNJEHostName '.' AltNJEDomain =>
         A '@' AnyNJEHostName '.' NJEDomain;
   ELSE
      A '@' AnyNJEHostName                    =>
         A '%' AnyNJEHostName '.' NJEDomain '@' TCPHostName;
      A '@' AnyNJEHostName '.' NJEDomain    =>
         A '%' AnyNJEHostName '.' NJEDomain '@' TCPHostName;
      A '@' AnyNJEHostName '.' AltNJEDomain =>
         A '%' AnyNJEHostName '.' NJEDomain '@' TCPHostName;
   ENDIF
ENDIF
```

Predefined keywords within the SMTP rules: The following predefined keywords can be used to define the header rewriting rules:

AltNJEDomain
Matches the alternative domain name of the NJE network as defined by the ALTNJEDOMAIN statement in the SMTP configuration data set.

AltTCPHostName
Matches any alternative TCP host name of the system, as defined by ALTTCPHOSTNAME statements in the SMTP configuration data set.

AnyDomainName
Matches any fully qualified domain name. Any host name with a period (.) is considered to be a fully qualified domain name.

AnyNJEHostName
Matches any (unqualified) NJE host name defined in the SMTPNJE.HOSTINFO data set.

NJEDomain
Matches the domain name of the NJE network as defined by the NJEDOMAIN statement in the SMTP configuration data set.

NJEHostName
Matches the NJE host name of the system.

SecureNickAddr
Matches an address of the form *NJE_user_id@NJE_node_id*, where *NJE_user_id*, and *NJE_node_id* are defined with a nickname in the SMTP security data set.

Note: This only matches user and node IDs that are defined with nicknames.

When SecureNickAddr is specified in the *before-address-pattern* of a rule, SMTP automatically associates the keyword SecureNickName with the corresponding nickname. This allows SecureNickName to be specified in the *after-address-pattern*.

SecureNickName
Matches a nickname defined in the SMTP security data set. When SecureNickName is specified in the *before-address-pattern* of a rule, SMTP automatically associates the keyword SecureNickAddr with the corresponding *NJE_user_id@NJE_node_id*. This allows SecureNickAddr to be specified in the *after-address-pattern*.

ShortTCPHostName
Matches the first portion of the TCP host name of the system, as defined by the HOSTNAME statement in the TCPIP.DATA data set. For example, if the TCP host name was `mvs1.acme.com`, the value of ShortTCPHostName is `mvs1`.

TCPHostName
Matches the TCP host name of the system as defined by the concatenation of the HOSTNAME and DOMAINORIGIN statements in the TCPIP.DATA data set.

TCPHostNameDomain
Matches the domain portion of the TCP host name of the system as defined by the DOMAINORIGIN statement in the TCPIP.DATA data set. For example, if the TCP host name was `mvs1.acme.com`, the value of TCPHostNameDomain is `acme.com`.

The predefined keywords can consist of any combination of uppercase and lowercase characters; the rules interpreter does not distinguish between them.

The secure keywords are only valid when SMTP is configured to be a secure gateway.

Default SMTP rules: If the //SMTPRULE DD statement is not found, SMTP uses a default set of rules. The default set used depends on whether SMTP is configured as a secure gateway.

SMTP nonsecure gateway configuration defaults: If SMTP is not configured as a secure gateway, SMTP uses the following defaults:

```
FIELD DEFINITION SECTION
DEFAULTFIELDS = 'BCC' 'CC' 'FROM' 'REPLY-TO' 'RESENT-FROM'
                'RESENT-REPLY-TO' 'RESENT-SENDER' 'RETURN-PATH'
                'SENDER' 'TO';

RULE DEFINITION SECTION

A '@' NJEHOSTNAME => A '@' TCPHOSTNAME;

IF NJEDOMAIN = '' THEN
   A '@' ANYNJEHOSTNAME => A '%' ANYNJEHOSTNAME '@' TCPHOSTNAME;
```

```
ELSE
   A '@' NJEHOSTNAME '.' NJEDOMAIN    => A '@' TCPHOSTNAME;
   A '@' NJEHOSTNAME '.' ALTNJEDOMAIN => A '@' TCPHOSTNAME;
   IF NJEDOMAIN CONTAINS '.' THEN
      A '@' ANYNJEHOSTNAME                 =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
      A '@' ANYNJEHOSTNAME '.' NJEDOMAIN    =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
      A '@' ANYNJEHOSTNAME '.' ALTNJEDOMAIN =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
    ELSE
       A '@' ANYNJEHOSTNAME                  =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
       A '@' ANYNJEHOSTNAME '.' NJEDOMAIN    =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
       A '@' ANYNJEHOSTNAME '.' ALTNJEDOMAIN =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
    ENDIF
 ENDIF

A '@' TCPHOSTNAME       => A '@' TCPHOSTNAME;
A '@' SHORTTCPHOSTNAME  => A '@' TCPHOSTNAME;
A '@' ALTTCPHOSTNAME    => A '@' TCPHOSTNAME;
A '@' ANYDOMAINNAME     => A '@' ANYDOMAINNAME;
A '@' B                 => A '@' B '.' TCPHOSTNAMEDOMAIN;
```

SMTP secure gateway configuration defaults: If SMTP is configured as a secure gateway, SMTP uses the following defaults:

```
FIELD DEFINITION SECTION
DEFAULTFIELDS = 'BCC' 'CC' 'FROM' 'REPLY-TO' 'RESENT-FROM'
                'RESENT-REPLY-TO' 'RESENT-SENDER' 'RETURN-PATH'
                'SENDER' 'TO';

RULE DEFINITION SECTION

SECURENICKADDR    => SECURENICKNAME '@' TCPHOSTNAME;
A '@' NJEHOSTNAME => A '@' TCPHOSTNAME;

IF NJEDOMAIN NOT = '' THEN
   SECURENICKADDR '.' NJEDOMAIN    => SECURENICKNAME '@' TCPHOSTNAME;
   SECURENICKADDR '.' ALTNJEDOMAIN => SECURENICKNAME '@' TCPHOSTNAME;
   A '@' NJEHOSTNAME '.' NJEDOMAIN    => A '@' TCPHOSTNAME;
   A '@' NJEHOSTNAME '.' ALTNJEDOMAIN => A '@' TCPHOSTNAME;
   IF NJEDOMAIN CONTAINS '.' THEN
      A '@' ANYNJEHOSTNAME                 =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
      A '@' ANYNJEHOSTNAME '.' NJEDOMAIN    =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
      A '@' ANYNJEHOSTNAME '.' ALTNJEDOMAIN =>
         A '@' ANYNJEHOSTNAME '.' NJEDOMAIN;
    ELSE
       A '@' ANYNJEHOSTNAME                  =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
       A '@' ANYNJEHOSTNAME '.' NJEDOMAIN    =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
       A '@' ANYNJEHOSTNAME '.' ALTNJEDOMAIN =>
          A '%' ANYNJEHOSTNAME '.' NJEDOMAIN '@' TCPHOSTNAME;
    ENDIF
 ENDIF
 A '@' TCPHOSTNAME       => A '@' TCPHOSTNAME;
 A '@' SHORTTCPHOSTTNAME => A '@' TCPHOSTNAME;
 A '@' ALTTCPHOSTNAME    => A '@' TCPHOSTNAME;
 A '@' ANYDOMAINNAME     => A '@' ANYDOMAINNAME;
 A '@' B                 => A '@' B '.' TCPHOSTNAMEDOMAIN;
```

Examples of header rewrite rules: The following examples show how the header rewriting rules affect an SMTP mail header. The example site is not a secure gateway and is configured as follows:

```
TCPHostName      = mvs1.acme.com
ShortTCPHostName = mvs1
AltTCPHostName   = seeds.acme.com
NJEHostName     = mvs1
NJEDomain       = acmenet
AltNJEDomain    = centralnet
```

Note that the above keywords are configured according to the definitions found in "Predefined keywords within the SMTP rules" on page 1401 (for example, from TCPIP.DATA). In addition, assume that the following are known to be other NJE hosts:

```
bird
iron
```

Then the following header:

```
From: abc@mvs1 (Brendan Beeper)
To: Jenny Bird <def@bird>
Cc: ghi@iron.acmenet, j@mvs1,
 k@seeds.acme.com,
 Mailing List <owner@acmenet>,
 lmno@iron.centralnet
Subject: New Ore
```

is rewritten by the default header rewriting rules as:

```
From: abc@mvs1.acme.com (Brendan Beeper)
To: Jenny Bird <def%bird.acmenet@mvs1.acme.com>
Cc: ghi%iron.acmenet@mvs1.acme.com, j@mvs1.acme.com,
 k@mvs1.acme.com,
 Mailing List <owner%acmenet@mvs.acme.com>,
 lmno%iron.acmenet@mvs1.acme.com
Subject: New Ore
```

The next example deviates from the defaults listed in "Default SMTP rules" on page 1402. On the configuration for nonsecure gateways, if you change the rule before the 2 ENDIFs to:

```
A '@' AnyNJEHostName '.' AltNJEDomain =>
   '<@' TCPHostName ':' A '@' AnyNJEHostName '.' NJEDomain '>';
```

then the last address in the Cc: field within our header is rewritten as:

```
Cc: <@mvs1.acme.com:lmno@iron.acmenet>
```

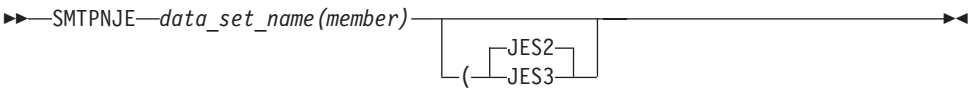
Note: Do not make the change shown in the previous example; it is intended only as a demonstration of the capabilities of the pattern-matching language.

Step 5: Set up a TCP-to-NJE mail gateway (Optional)

You can configure the SMTP server to run as a mail gateway between TCP network users and users located on a NJE network attached to the local host. This way NJE users can send mail or data sets to users on TCP hosts using SMTPNOTE. See *z/OS Communications Server: IP User's Guide and Commands* for more information about SMTPNOTE. For JES2, see *z/OS JES2 Initialization and Tuning Guide* and *z/OS JES2 Initialization and Tuning Reference*. For JES3, see *z/OS JES3 Initialization and Tuning Guide* and *z/OS JES3 Initialization and Tuning Reference*.

Follow these steps to set up your TCP-to-NJE mail gateway:

1. Add the GATEWAY statement to the SMTP configuration data set. Add other related statements, such as ALTDOMAIN, NJECLASS, NJEDOMAIN, and NJEFORMAT, as required by your configuration.
2. Issue the SMTPNJE command.



data_set_name(member)
The name of the input data set for SMTPNJE. It specifies the initialization data set of the JES2 or JES3 subsystem that is scanned for NJE nodes by SMTPNJE. The data set name is the same name as defined on ddname HASPPARM in your JES2 procedure or in the JES3IN ddname in your JES3 procedure.

member is the JES2PARM member that contains the NODE and DESTID entries for your installation.

(Required delimiter.

JES2 or JES3
Denotes whether the initialization data set being pointed to is for JES2 or JES3. If omitted, the default is JES2. For JES2, the SMTPNJE program scans for the keywords NODE and DESTID from which it extracts the information. For JES3, the keyword scanned for is NJERMT.

The SMTPNJE program creates the NJE host table data set called *user_id*.SMTPNJE.HOSTINFO. You can rename this data set and include the name of the data set on the SMTPNJE DD statement in the SMTP cataloged procedure. The //SMTPNJE DD statement is required.

3. Install the SMTP server (along with the TCPIP address space) on the gateway node. Use the GATEWAY, NJEDOMAIN, and NJEFORMAT statements in the configuration data set. Optionally, you can use either the RESTRICT or the SECURE statements to limit which users can use the gateway.

Step 6: Specify configuration statements in SMTP configuration data set

Copy the member SEZAINST(SMTPCONF) to your own SMTP configuration data set and modify it for your site using the SMTP configuration statements.

Note: If the SMTP configuration data set is a sequential data set, you cannot edit the data set while SMTP is running. If the data set is a PDS member, it can be edited while SMTP is running.

Summary of SMTP configuration statements: The SMTP configuration statements are summarized in Table 69.

Note: See *z/OS Communications Server: IP Configuration Reference* for more information about these statements.

Table 69. Summary of SMTP configuration statements

Statement	Description
ALTNJEDOMAIN	Specifies an alternative domain name of the NJE network, if SMTP is running as a mail gateway.
ALTTCPHOSTNAME	Specifies an additional host name for the local host. Mail received for this host name is accepted and delivered locally.

Table 69. Summary of SMTP configuration statements (continued)

Statement	Description
ATSIGN	Enables SMTP to replace the @ symbol used in addressing strings.
BADSPOOLFILEID	Specifies the user ID on the local system where SMTP transfers unreadable spool files and looping mail.
CHECKSPOOLSIZE	Enables SMTP to check the size of the JES spool file prior to writing the data to the hlq.TEMP.NOTE file.
DBCS	Specifies that DBCS code conversion be performed on the mail.
DEBUG	Records all SMTP commands and replies.
DELETEBADSPOOLFILE	Permits SMTP to delete the spool file from the JES spool that would cause an ABENDS001 when accessed by SMTP.
DISALLOWCMD	Enables the SMTP server to discontinue support for certain specified SMTP commands.
EXITDIRECTION	Enables SMTP to call the SMTP exit provided by the customer for data coming from the JES spool.
FINISHOPEN	Specifies the SMTP wait time for connection.
GATEWAY	Specifies operation of SMTP as a gateway.
INACTIVE	Specifies the SMTP wait time before closing an inactive connection.
INBOUNDOPENLIMIT	Specifies a limit on the maximum number of simultaneous TCP connections over which the SMTP server will receive mail.
IPMAILERADDRESS	Specifies the IP address of an SMTP server that can resolve network addresses of unknown hosts.
IPMAILERNAME	Enables SMTP to forward non-local mail to the specified IP mailer name.
LISTENONADDRESS	Allows you to restrict which IP address is used to receive and send mail on a multihomed system.
LOCALCLASS	Specifies the spool data set class for local mail delivery.
LOCALFORMAT	Specifies the spool data set format for local host mail delivery.
LOG	Directs SMTP to log all SMTP traffic.
MAILER	Specifies the address of the batch SMTP server that receives mail.
MAILFILEDSPREFIX	Specifies the prefix to add to mail data sets.
MAILFILESUNIT	Specifies the unit where SMTP mail data sets reside.
MAILFILEVOLUME	Specifies the volume where newly allocated SMTP data sets reside.
MAXMAILBYTES	Specifies the maximum size of mail that is accepted over a TCP connection.
MAXMSGSENT	Enables control of the SMTP client code by limiting the number of messages sent on a single TCP/IP connection.
NJECLASS	Specifies the spool data set class for mail delivered on an NJE network.
NJEDOMAIN	Specifies the domain name of the NJE network if SMTP functions as a gateway.
NJEFORMAT	Specifies the spool data set format for mail delivered on the NJE network.
NJENODENAME	Specifies the node name of the local JES2 or JES3 node for mail delivered on the NJE network.
NOLOG	Turns off the logging of mail transactions.
NOSOURCEROUTE	Enables SMTP to *not* generate source routing addressing strings on certain RFC 821 SMTP commands.
OUTBOUNDOPENLIMIT	Specifies a limit on the maximum number of simultaneous TCP connections over which SMTP actively delivers mail.

Table 69. Summary of SMTP configuration statements (continued)

Statement	Description
PORT	Specifies an alternative port number for the SMTP server during testing.
POSTMASTER	Specifies the address (or addresses) for mail addressed to the postmaster at the local host.
RCPTREPLY452	Enables SMTP to handle reply code 452 differently for the RCPT command.
RCPTRESPONSEDELAY	Specifies how long the SMTP server delays responding to the RCPT commands.
REMOTEPORT	Specifies the remote port to which the SMTP client connects.
RESOLVERRETRYINT	Specifies the number of minutes SMTP waits between attempts to resolve domain names.
RESOLVERUSAGE	Specifies whether SMTP will send queries to the domain name servers if they are configured in the TCPIP.DATA file.
RESTRICT	Specifies addresses of users who are not allowed to use SMTP mail services.
RETRYAGE	Specifies the number of days after which mail is returned as undeliverable.
RETRYINT	Specifies the number of minutes between attempts to send mail to an inactive TCP host.
REWRITE822HEADER	Prevents SMTP from rewriting RFC 822 headers with source routing.
SECURE	Specifies that SMTP operates as a secure mail gateway between TCP network sites and NJE network sites.
SMSGAUTHLIST	Specifies the addresses of users authorized to issue privileged SMTP SMSG commands.
SPOOLPOLLINTERVAL	Specifies the interval for SMTP to check the spool for incoming batch data sets.
STOPONRENF	Enables control of the SMTP server such that if a RENAME failure occurs on a data set associated with the batch connection (257), the SMTP server terminates normally.
TEMPERRORRETRIES	Specifies the number of times SMTP tries to redeliver mail to a host with a temporary problem.
TIMEZONE	Sets the printable name of the local time zone.
WARNINGAGE	Specifies the number of days after which a copy of the mail is returned to the sender, indicating that the mail has so far been undeliverable and that SMTP will continue to retry delivery for RETRYAGE days.

Sample SMTP configuration data set (SMTPCONF): The sample SMTP Configuration data set can be found in SEZAINST(SMTPCONF). See *z/OS Communications Server: IP Configuration Reference* for more information on configuration data set parameters.

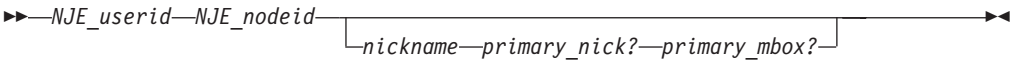
Step 7: Create an SMTP security table (Optional)

If you want to set up a secure TCP-to-NJE gateway, you need to:

- Include the SECURE statement in the SMTP configuration data set.
- Create a security data set that contains a list of NJE users who are authorized to use the gateway.
- Create a mailfiledsprefix.SECURITY.MEMO data set. The contents data set are sent to unauthorized NJE users whose mail is rejected. See "Rejected mail examples" on page 1409 for sample contents of this data set. This data set must be defined as LRECL=255 and RECFM=VB. It will be dynamically allocated by SMTP when needed.

The SMTP security data set is pointed to by //SECTABLE DD statement. The security table data set must be allocated with LRECL=255 and RECFM=VB. Records whose first nonblank character is an asterisk (*) are treated as comments and are ignored.

Use the following format when creating the list of NJE users:



NJE_userid
The NJE user ID of the authorized user.

NJE_nodeid
The NJE node ID of the authorized user.

nickname
The name by which this user is known on the TCP side of the gateway. This name must not contain any special characters, such as < > ( ) [ ] \ . , ; : @ and ".

primary_nick?
Either Y or N. If Y is specified, then mail addressed to *nickname*`@smtp-gateway` is automatically forwarded to *NJE_userid* `at` *NJE_nodeid*. Each nickname can have only one *primary_nick?* record set to Y.

primary_mbox?
Either Y or N. If Y is specified, then mail from *NJE_userid* `at` *NJE_nodeid* is converted to *nickname*`@smtp-gateway` before it is sent to the TCP recipient. Each *NJE_userid*, *NJE_nodeid* pair can only have one *primary_mbox?* record.

SMTP security data set examples: The following example shows an SMTP security data set:

```
*  Records for Jane Doe, within IBM
JDOE   ALMADEN
JDOE   AUSTIN
*  Records for John Smith, within IBM
SMITH  RALEIGH   JOHNNY  Y  N
SMITH  YORKTOWN  JOHNNY  N  Y
SMITH  DALLAS    JOHNNY  N  N
SMITH  RALEIGH   JSMITH  Y  Y
```

For example, mail sent from the following NJE network addresses through the SMTP gateway is rewritten to the following TCP network addresses. Assume the host name of the gateway is `SMTP-GATEWAY.IBM.COM`.

```
NJE Address              TCP Address
-------------------------------------------------------------------------

JDOE  at ALMADEN         JDOE%ALMADEN@SMTP-GATEWAY.IBM.COM
JDOE  at AUSTIN          JDOE%AUSTIN@SMTP-GATEWAY.IBM.COM
SMITH at RALEIGH         JSMITH@SMTP-GATEWAY.IBM.COM
SMITH at YORKTOWN        JOHNNY@SMTP-GATEWAY.IBM.COM
SMITH at DALLAS          JOHNNY%DALLAS@SMTP-GATEWAY.IBM.COM
```

Mail sent from the TCP network to the following TCP network addresses is forwarded to the following NJE network addresses. Assume the host name of the gateway is `SMTP-GATEWAY.IBM.COM`.

```
TCP Address                              NJE Address
-------------------------------------------------------------------------
```

```
JDOE%ALMADEN@SMTP-GATEWAY.IBM.COM          JDOE  at ALMADEN
JDOE%AUSTIN@SMTP-GATEWAY.IBM.COM           JDOE  at AUSTIN
JSMITH@SMTP-GATEWAY.IBM.COM                SMITH at RALEIGH
JOHNNY@SMTP-GATEWAY.IBM.COM                SMITH at RALEIGH
SMITH%DALLAS@SMTP-GATEWAY.IBM.COM          SMITH at DALLAS
```

Rejected mail examples: SMTP rejects mail to or from an unauthorized NJE user. If the mail is from the TCP network, SMTP rejects the RCPT TO command with the error:

```
550 User is not a registered gateway user
```

If the mail is from the NJE network, SMTP rejects the MAIL FROM command with the error:

```
550 User is not a registered gateway user
```

and includes the *mailfiledsprefix*.SECURITY.MEMO data set as an explanation.

The following example shows a sample *mailfiledsprefix*.SECURITY.MEMO data set:

```
The mail you sent to this SMTP gateway cannot be delivered because
you are not a registered user of this gateway.  Contact your local
administrator for instructions on how to be authorized to use this
SMTP gateway.
```

The following is an example of rejected mail that was sent to an unregistered NJE user:

```
Date: Fri, 5 Jul 91 10:55:59 EST
From: SMTP@MVS1.ACME.COM
To: DANIEL@MVS1
Subject: Undeliverable Mail

MVS1.ACME.COM unable to deliver following mail to recipient(s):
    <MATT@SMTP-GATEWAY.IBM.COM>
MVS1.ACME.COM received negative reply from host:
    SMTP-GATEWAY
550 User 'MATT@SMTP-GATEWAY' is not a registered gateway user

           ** Text of Mail follows **
Date: Fri, 5 Jul 91 10:55:56 EDT
From: <DANIEL@MVS1.ACME.COM>
To:   <MATT@SMTP-GATEWAY.IBM.COM>
Subject:  Lunch
Matt,

Do you have time to meet for lunch next week?  I want to discuss the
shipment of ACME iron birdseed.
Daniel
```

The following is an example of rejected mail that was sent from an unregistered NJE user:

```
Date: Fri, 5 Jul 91 11:35:18 EST
From: <SMTP@SMTP-GATEWAY.IBM.COM>
To: <MATT@SMTP-GATEWAY.IBM.COM>
Subject: Undeliverable Mail
Unable to deliver mail to some/all recipients.
050 MAIL FROM:<MATT@SMTP-GATEWAY.IBM.COM>
550-User 'MATT@SMTP-GATEWAY' is not a registered gateway user.
550-
550-The mail you sent to this SMTP gateway cannot be delivered because
550-you are not a registered user of this gateway.  Contact your local
550-administrator for instructions on how to be authorized to use this
550 SMTP gateway.
```

```
          ** Text of Mail follows **
HELO SMTP-GATEWAY.IBM.COM
MAIL FROM:<MATT@SMTP-GATEWAY.IBM.COM>
RCPT TO:<DANIEL@MVS1.ACME.COM>
DATA
Date: Fri, 5 Jul 91 11:34:17 EST
From: <MATT@SMTP-GATEWAY.IBM.COM>
To:   <DANIEL@MVS1.ACME.COM>
Subject:  Awaiting your message
Daniel,
When are you going to contact me about the iron birdseed and giant
electromagnet that I ordered?  I would like to meet with you soon.
Matt

 .
QUIT
```

Step 8: Enable SMTP domain name resolution

The SMTP server's RESOLVERUSAGE statement indicates if domain name resolution is to be used or not. If name resolution is not desired, RESOLVERUSAGE NO should be specified. See “Step 9: Enable sending of non-local messages to other mail servers” on page 1411.

If the RESOLVERUSAGE statement is not specified or is specified as RESOLVERUSAGE YES, the SMTP server will resolve domain names. Resolver TCPIP.DATA statements must be configured before you can use domain name resolution for SMTP. For a description of how TCPIP.DATA statements can be specified, see Chapter 14, “The resolver,” on page 731.

For more information on the SMTP RESOLVERUSAGE statement and the TCPIP.DATA resolver statements, see *z/OS Communications Server: IP Configuration Reference*.

To use a domain name server, configure the TCPIP.DATA data set with the IP address of one or more name servers. If the TCPIP.DATA data set does not point to any name servers, the local site tables are used by SMTP. However, if the SMTP server is configured to use name servers, SMTP does not use the site tables.

To determine which DSN the SMTP server is using, look for message number EZA5231I in the output data set specified by the OUTPUT statement in SEZAINST(SMTPPROC).

When SMTP uses a domain name server, it asks the domain name server for the MX records for the host to which it is trying to connect. If SMTP does not find MX records for a host, it delivers mail only to the primary host listed in the A records. The MX and A records are coded in the domain name server database.

The basic idea behind MX records is to send the mail as close as possible to the final destination. The destination host may currently be inactive, for example, because it is in another time zone. SMTP needs a synchronous connection to deliver the mail, but due to the different time zones, two systems might never be active at the same time and would never be able to exchange mail.

Using MX records would allow the SMTP server to deliver the mail to an alternate host if the first one is unavailable. SMTP tries to deliver mail to the host with the lowest MX record count. If the host is not currently available, it tries the host with the next lowest count.

For example, if SMTP wants to send mail to USER@BASKET, it checks the name server for MX records and finds the following:

```
MVS20  BASKET  A
       BASKET  MX  0    MVS20
       BASKET  MX  5    MVS18
       BASKET  MX  10   VMQ
```

SMTP delivers the mail to the BASKET with the lowest count on its MX record. If `MVS20` is unable to receive the mail, SMTP then tries to deliver it to `MVS18`. If `MVS18` cannot receive the mail, it tries `VMQ`. If none of the hosts can receive the mail, SMTP stores the mail and queues it for later delivery, at which time the process repeats.

For more information about how to add MX records to your name server, consult RFC 974, "Mail Routing and the Domain System."

To receive a detailed trace on how SMTP is resolving a particular host name, you can issue the SMSG SMTP TRACE command at the console or use a SYSTCPT DD statement in the SMTP cataloged procedure. You can also add the TRACE RESOLVER statement when configuring the TCPIP.DATA data set, but this will also trace the name resolution for all the other applications using the name server. To prevent the console log from becoming too large, only use the TRACE RESOLVER statement for debugging.

If changes to the domain name server requires you to resolve already queued mail again, use the SMSG SMTP EXPIRE command as described in the *z/OS Communications Server: IP User's Guide and Commands*. You can also query operating statistics, such as mail delivery queues of the SMTP server, by using the SMSG SMTP command. This and other administrative tasks are discussed in more detail in the *z/OS Communications Server: IP User's Guide and Commands*.

Step 9: Enable sending of non-local messages to other mail servers

Non-local mail is mail that must go through a Mail Transfer Agent (MTA) to get to another host. SMTP supports the following configuration statements to assist in forwarding non-local mail:

- IPMAILERNAME, for non-local mail destined for SMTP servers in the IP network using a hostname
- IPMAILERADDRESS, for non-local mail destined for SMTP servers in the IP network using a static IP address
- MAILER, for non-local mail destined for SMTP servers in the NJE network using the JES spool

Restriction: You cannot use the IPMAILERNAME statement, the IPMAILERADDRESS statement, or the MAILER statement with the UNKNOWN option simultaneously.

For more information regarding these configuration statements, see *z/OS Communications Server: IP Configuration Reference*.

The SMTP server can be configured to send all your non-local TCP/IP SMTP mail to a specified mail server, or mail relay. You might need to do this if you have installed a firewall. One way to accomplish this is by using IPMAILERADDRESS, making both of the following changes to your *hlq*.SMTP.CONFIG data set:

1. Inhibit SMTP from attempting to resolve non-local hostnames by specifying the following statement in your SMTP.CONFIG data set:

```
RESOLVERUSAGE NO
```

2. Update the SMTP.CONFIG file to redirect mail to a specific server using the IPMAILERADDRESS statement:

   ```
   IPMAILERADDRESS ip_address
   ```

   where ip_address is address of the mail server that can perform the hostname resolution.

Step 10: Design SMTP exit to inspect and filter unwanted mail (optional)

The SMTP exit facility allows an installation to better control the volume of unwanted mail (spam) that is entering the installation. SMTP makes use of the Dynamic Exit Facility (CSVDYNEX macro) provided by MVS. See *z/OS MVS Programming: Authorized Assembler Services Guide* for more information. The exit is provided by the customer to implement policies that they deem workable. Based on user-defined (and implemented) criteria, individual mail items may be rejected before they consume other resources. SMTPEXIT is provided as a programming guide to aid in the implementation of the local policies. It can be found in SEZAINST. This exit must be REENTRANT and AMODE 31, in an authorized library. In using the SMTP exit a name token (EZBTCPIPSMTPEXIT) needs to be established in SYS1.PARMLIB(PROGxx).

If a user program is enabled, message EZA5549I is generated in the SMTP output data set when the SMTPPROC program is started. This message indicates a user exit is active.

This exit can be replaced dynamically without stopping the SMTPPROC program. The procedure for doing this follows:

1. Issue a "SMSG *smtpprocname* STOPEXIT" TSO command. The TSO user ID must be in the authorized list for SMTPPROC to issue this command. This will cause SMTP to issue the termination call to the exit and then set a flag so that the exit will not be called anymore. Processing of mail will continue as if there is no exit.
2. Remove the exit via the SETPROG EXIT operator command or by updating SYS1.PARMLIB(PROGxx) and issuing the refresh console command. Example of updating SYS1.PARMLIB follows:
   a. Include the following in SYS1.PARMLIB(PROGxx):

      ```
      EXIT DELETE EXITNAME(EZBTCPIPSMTPEXIT) MODNAME(MYEXIT) FORCE(YES)
      ```

   b. At the MVS console issue SET PROG=xx.
3. Replace with the desired new exit by adding the exit via the SETPROG EXIT operator command or by updating SYS1.PARMLIB(PROGxx). Example of updating SYS1.PARMLIB follows:
   a. In SYS1.PARMLIB(PROGxx) have this line:

      ```
      EXIT ADD EXITNAME(EZBTCPIPSMTPEXIT) MODNAME(NEWEXIT)
      ```

   b. At the MVS console issue SET PROG=xx.
4. Issue a "SMSG *smtpprocname* STARTEXIT" TSO command. This will cause SMTP to issue the initialization call to the exit. A flag is then set so the exit will be called from then on for new mail connections. Processing of new mail will continue with the exit being called. The first smtp command to be seen by a reinstated exit will be HELO. The exit will not be called in the middle of a currently processing exchange.

In designing the SMTP exit some of the following design points need to be considered. It should be noted that a remote SMTP application will be connected to the local SMTP while this exit is running. If too much time is spent in the exit, timeout situations may occur and the remote SMTP application may terminate the connection and then go into retry logic. This will seriously affect the performance of the mail system. The exit must be coded as efficiently as possible and all efforts should be taken to avoid excessive processing or waiting, e.g. I/O operations and DNS resolver calls, while within the exit. Efforts to reject mail may be more efficient if extensive scanning of the data portion of the message can be avoided. The exit may allow processing to continue or reject the entire message and does not have the ability to reject individual segments of a message. The message contents cannot be changed in any way by the exit. The exit may accept a message at any point and disable further exit calls for that message. Only commands that are currently implemented by the SMTP program will be passed to the exit program. RFC 2505 and RFC 2635 should be read and understood before undertaking such a coding effort. Multiple connections can occur simultaneously and the exit must take precautions to keep any desired state information on a connection basis. More information on SMTP commands and standards are documented in RFCs 821 and 822.

The SMTP server can be allowed to call the SMTP exit program to interrogate data coming from the JES spool as well as the inbound TCP/IP connections.

See *z/OS Communications Server: IP Configuration Reference* for more detailed information.

Step 11: Set up automation to monitor how much mail is queued

You can use automation to monitor how much mail is queued in SMTP. To retrieve the number of mail messages currently queued for SMTP, your automation tool can issue the command MODIFY *smtpprocname*,SMSG,NUMQUEUE. You can set up automation to generate an alert for SMTP if the number of mail messages queued is larger than what you would expect for your system. You can also set up automation to issue the command MODIFY *smtpprocname*,SMSG,QUEUE to display a list of mail queued on the various SMTP mail processing queues. For more information about the MODIFY SMSG command, see *z/OS Communications Server: IP System Administrator's Commands*.

Configuring z/OS UNIX sendmail and popper

The following is intended to provide the administrator with specific information on how to configure sendmail on the z/OS platform. Before using this information, become familiar with the industry-accepted publication for sendmail, *sendmail* by O'Reilly & Associates, Inc. (ISBN 1-56592-839-3). That publication is known throughout the industry as simply the *bat book*, and this information consistently refers to the *bat book* for further information.

The *bat book* supports sendmail version 8.12. For new features supported in sendmail 8.12.1, this information refers to documents that come from sendmail resources. The most noteworthy document is *Sendmail Installation and Operation Guide*. You can find this document on the web, http://www.sendmail.org/~ca/email/doc8.12/op.html, and it is also shipped in /usr/lpp/tcpip/samples/sendmail/sendmail.ps.

Sendmail 8.12.1 has been developed with two main topics in mind, enhanced security mail filters and IPv6 support. Associated topics like Transport Layer Security (TLS), mail filters (Milter) and IPv6 are explained.

If sendmail is to be used in a multilevel secure environment, for more details concerning sendmail configuration and setup, see “z/OS UNIX sendmail” on page 173.

Additional information about sendmail can also be found in documents from the sample directory that were received during the port of sendmail 8.12.1 from the http://www.sendmail.org Web site. The *Sendmail Installation and Operation Guide* document (/usr/lpp/tcpip/samples/sendmail/sendmail.ps), for instance, is the generic guide from http://www.sendmail.org, which might be helpful as a more thorough guide in a slightly different format. The README.m4 document gives more details for building a configuration file using the m4 preprocessor.

Information is also provided on how to configure popper on the z/OS platform. The popper function requires very little configuration. For more information on the protocol used by this UNIX application, see RFC 1939.

Overview

The simple mail architecture in which sendmail and popper fit includes a mail user agent (MUA), a mail transfer agent (MTA), and a mail delivery agent (MDA). An MUA is client software that a user invokes directly to send and receive e-mail. Examples of MUAs include Eudora, Netscape Navigator, pine and elm. An MTA is software that actually routes messages from a sender's system to the receiver's system. sendmail is an MTA. It is worth noting, however, that sendmail relies on other programs to implement non-SMTP based transport (for example, UUCP-based transport as well as local delivery to a user's mail spool file). An MDA is server software that delivers received mail to a user's MUA. Popper is an example of an MDA using the POP3 protocol.

At the sender's end of the mail delivery process, the sender's MUA transmits the message to be delivered to sendmail, as shown in Figure 134.

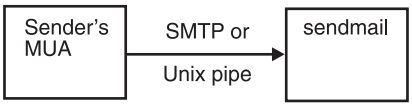


Figure 134. Sender MUA transmits the message to sendmail

This can occur in one of two ways. If the MUA is running on the local host, the message can be transmitted by executing a copy of sendmail and transmitting the message to the standard input of that process via a UNIX pipe.

Alternatively (and more commonly), a copy of sendmail will be running as a daemon, and the MUA (running on either the local host, or on a remote host) will open an SMTP connection to the sendmail daemon, transmitting the message to be delivered via that SMTP connection. In this case, sendmail is acting as an SMTP server, while the MUA is acting as an SMTP client.

In the next step, for each recipient address, sendmail transmits the message to some other SMTP server, to route the message to its final destination at the recipient's site. This is shown in Figure 135 on page 1415.

Figure 135. sendmail transmits the message to an intermediate SMTP server

The receiving SMTP server, in this case, might be a local hub that handles all mail at the sender's site, a remote hub handling all mail at the recipient's site, or an SMTP server at the recipient's host system.

In the next step, sendmail acts as an SMTP client, initiating an SMTP connection with some SMTP server, and then transmitting the message to be delivered to that server, via the SMTP connection.

At the receiver's end of the mail delivery process, a sendmail daemon receives the message from some SMTP client, as shown in Figure 136.

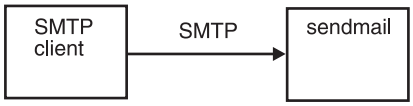

Figure 136. A sendmail daemon receives the message from an SMTP client

The sendmail daemon, acting as an SMTP server, accepts an incoming SMTP connection, and receives a message to be delivered over that SMTP connection. (This is identical to receipt of a message from an MUA, over an SMTP connection.)

Upon receiving the message, sendmail delivers it to the local recipient by appending the message to the recipient's mail spool file. To do this, sendmail requires a local mailer program, as depicted in Figure 137.

Figure 137. sendmail delivers the message to the local recipient

In this step, sendmail executes a specified local mailer program, such as /usr/lib/tsmail, and transmits the message to be delivered to that mailer through a UNIX pipe. The mailer program appends the message to the recipient's mail spool file. With this sendmail's role in delivery of mail is completed.

For the recipient to now read the received message, an MUA must be used. Depending upon the MUA, this may or may not require an additional MDA, such as popper. If the receiver's MUA has direct access to the mail spool file, the MUA may retrieve the mail directly from the spool file, as depicted in Figure 138.

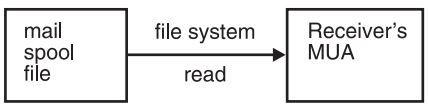

Figure 138. Receiver's MUA has direct access to the mail spool file

Alternatively (and more commonly), the MUA will establish a POP3 connection with a popper daemon, and retrieve the message over that connection. This is

shown in Figure 139.

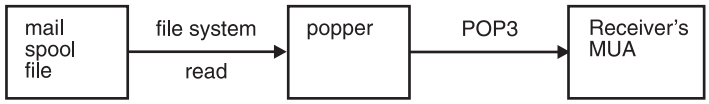

Figure 139. Receiver's MUA retrieves the message over a POP3 connection with a popper daemon

The popper daemon will also allow the receiver's MUA to manage the mail spool file, by allowing it to specify whether and which message should be deleted.

For security issues, sendmail has supported RFC 2487 (*SMTP Service Extension for Secure SMTP over TLS*) to provide private, authenticated communication over the Internet, as shown in Figure 140. z/OS UNIX sendmail uses System SSL instead of Open SSL.

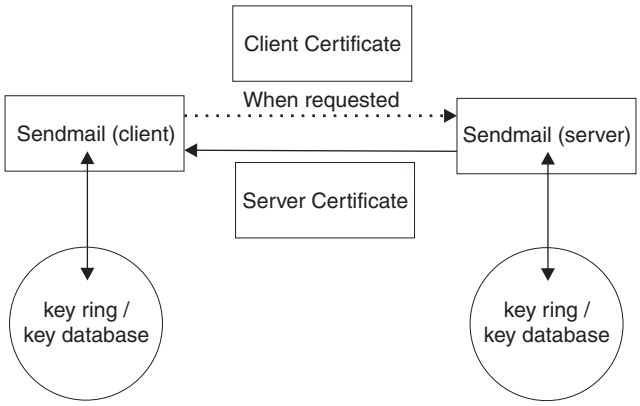

Figure 140. Using a certificate to establish a secure connection

Also, when sendmail receives mail, a mail filter provides an interface for third-party software to validate and modify messages as they pass through the mail transport system. Filters can process messages' connection information, envelope protocol elements, headers, and body contents, and modify a message's recipients, headers, and body. The MTA configuration file specifies which filters are to be applied, and in what order, allowing you to combine multiple independently-developed filters. Mail filters are separate daemons that can be run remotely or locally. How a mail filter works is shown in Figure 141.

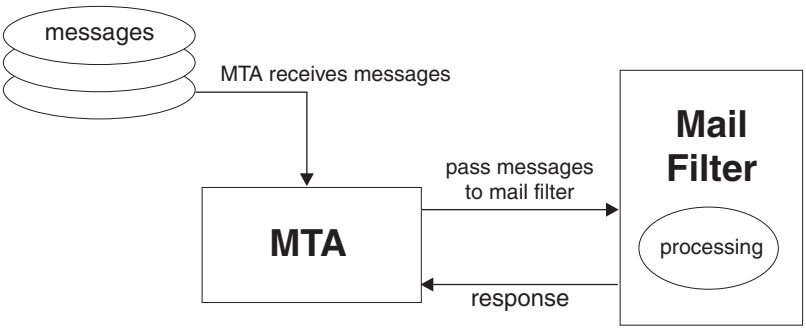

Figure 141. Mail filter processing

The sendmail samples directory

Much of the sendmail samples directory is dedicated to the automated creation of the configuration file. The /usr/lpp/tcpip/samples/sendmail/cf directory contains a sample.mc file and the subsequent sample.cf configuration file that was created by running the m4 macro preprocessor on the sample.mc file. If the /usr/lpp/tcpip/samples/sendmail directory is examined, the following directory structure can be found:

```
cd /usr/lpp/tcpip/samples/sendmail

README.m4       TRACEFLAGS      feature         mailer          sh
README.milter   TUNING          hack            milter          siteconfig
RELEASE_NOTES   cf              inetd.conf.pop  ostype
SECURITY        domain          m4              sendmail.ps
```

README.m4
Contains all the latest information regarding this latest version of sendmail from the *www.sendmail.org* site.

README.milter
This README file describes the steps needed to compile and run a filter, through reference to a sample filter that is attached at the end of this file.

RELEASE_NOTES
The sendmail release notes.

SECURITY
Gives some security-related hints on how to configure and run sendmail.

TRACEFLAGS
Describes the different trace flags used with the **-d** option.

TUNING
If the default configuration of sendmail does not achieve the required performance, several configuration options can be changed to increase performance. However, before those options are changed, it is necessary to understand why performance is not as good as desired. This file describes the performance implications of sendmail.

cf
Both site-dependent and site-independent descriptions of hosts. Files ending in **.mc** (Master Configuration) are the input descriptions. The output is in the corresponding **.cf** file. The general structure of these files is described "Creating the configuration file" on page 1419.

domain
Site-dependent subdomain descriptions. These are tied to the way your organization wants to do addressing. These descriptions are referenced using the DOMAIN *m4* macro in the **.mc** file.

feature
Definitions of specific features that some particular host in your site might want. These are referenced using the FEATURE *m4* macro. An example feature is `use_cw_file`, which tells z/OS UNIX sendmail to read an `/etc/mail/local-host-names` file on startup to find the set of local names.

hack
Local hacks, referenced using the HACK *m4* macro. This code should be used only during the transition from Berkeley.EDU names to .CS.Berkeley.EDU names.

inetd.conf.pop
The inetd changes needed to run popper.

m4
Site-independent *m4(1)* include files that have information common to all configuration files. Think of this as a "#include directory.

mailer
Definitions of mailers, referenced using the MAILER *m4* macro. The mailer types that are known in this distribution are fax, local, smtp, uucp, and usenet. For example, to include support for the UUCP-based mailers, use MAILER(uucp).

milter A directory containing a sample mail filter.

ostype Definitions describing various operating system environments (such as the location of support files). These are referenced using the OSTYPE *m4* macro.

sendmail.ps
This is a postscript file of the *Sendmail Installation and Operation Guide* provided by *www.sendmail.org* in this version of sendmail.

sh
Shell files used by the *m4* build process.

siteconfig
Local UUCP connectivity information. These normally contain lists of site information, for example:

- SITE(contessa)
- SITE(hoptoad)
- SITE(nkainc)
- SITE(well)

These are referenced using the SITECONFIG macro:

```
SITECONFIG(site.config.file, name_of_site,X)
```

where *X* is the macro or class name to use. It can be U (indicating locally connected hosts) or one of W, X, or Y for up to three remote UUCP hubs. This directory has been supplanted by the mailer table feature. Any new configurations should use that feature to do UUCP (and other) routing.

Steps for configuring z/OS UNIX sendmail

Before you begin: You need to know how to configure standard UNIX sendmail items, such as mailing lists and ~/.forward files. Only z/OS UNIX specific items are covered in this information. The *bat book* contains information on all the configurable options that can be included in the master configuration (.mc) file.

Perform the following steps to configure sendmail for z/OS UNIX:

1. Creating the configuration file

   _____

2. Creating the z/OS-specific file

   _____

3. Using sendmail databases

   _____

4. Configuring an IPv6 daemon and relay client (optional)

   _____

5. Configuring TLS support (optional)

   _____

6. Configuring Security Server (RACF or equivalent) items

   _____

7. Setting up a Milter (optional)

   _____

8. Creating the Message Submission Program (MSP) file submit.cf

   _____

9. Running sendmail as a daemon

   _____

You know you are done when you can send and, optionally receive mail. The easiest way to send mail is using the following UNIX command:

```
date | sendmail -v <user@host>
```

The **-v** option displays verbose error messages if any errors occur. After sending mail from another host, use the mailx UNIX command to receive mail.

Creating the configuration file

To make it easier to test sendmail, you can simply copy the /usr/lpp/tcpip/samples/sendmail/cf/sample.cf file as /etc/mail/sendmail.cf and use the copy. Later, when you are more familiar with creating your own configuration file, creating your own sendmail.cf file is recommended. However, this sample will suffice for a simple client configuration.

The basic steps to create the configuration file are:

1. Retrieving the m4 preprocessor.
2. Creating the *.mc* file.
3. Building the configuration file.

Retrieving the m4 preprocessor: Retrieve the m4 macro preprocessor from the z/OS Toys and Tools Web page at http://www.ibm.com/servers/eserver/zseries/zos/unix/tools/.

The m4 macro preprocessor can be given input that will generate a z/OS UNIX sendmail configuration file. It takes as input a user-defined master configuration source file (.mc file) that can define mail delivery mechanisms using files provided in the sample directory. For more information on the .mc file, see “Creating the .mc file.”

The m4 preprocessor is downloaded as m4.bin.pax.Z. To *unpax* the file, issue the following command:

```
pax -rzf m4.bin.pax.Z
```

The m4 preprocessor is created in ./bin/m4.

Creating the .mc file: The process of building a z/OS UNIX sendmail configuration file begins by creating a file of m4 statements. The suffix for this file is *.mc*.

The minimal mc file: Every **.mc** file must contain minimal information. This file defines the mail delivery mechanisms understood at this site, how to access them, how to forward e-mail to remote mail systems, and a number of tuning parameters. The following table shows which items are required and also which items are recommended. It is recommended that the starting point for these items be as shown in the sample.mc file, and an investigation of all the m4 techniques that are available to customize the .mc file for your mail server is encouraged (see the *bat book*).

Table 70. Required and recommended m4 items

Item	Bat book reference	Required or recommended	Description
OSTYPE()	4.2.2.1	Required	Support for your operating system
MAILER()	4.2.2.2	Required	Necessary delivery agent
DOMAIN()	4.2.2.3	Recommended	Common domain wide information
FEATURE()	4.2.2.4	Recommended	Solutions to special needs
confBIND_OPTS	N/A	Recommended	Add for IPv6 errors on name servers

Example files can be found in the `/usr/lpp/tcpip/samples/sendmail` directory. The *cf* directory contains an example of an **.mc** file. Of special interest are the files that begin with *generic*. These can serve as template statements in developing customized **.mc** files. The following is an example of a simple **.mc** file.

```
divert (-1)
divert(0) dnl
VERSIONID(`z/OS sample configuration 2002/09/20')
OSTYPE(zOS)dnl
DOMAIN(generic)dnl
MAILER(local)dnl
MAILER(smtp)dnl
```

Following is a description of these common *m4* items. For more information on these items, see the *bat book.*

divert

- (-1) Ignore the lines following.
- (0) Stop diverting and output immediately.

VERSIONID

Used to insert an identifier into each **.mc** and **.m4** file that will become your header.

OSTYPE()

- Support for operating system (the only ostype provided in the `/usr/lpp/tcpip/samples/sendmail/ostype` directory is zOS.m4).
- Required.

MAILER()

- Necessary delivery agent.
- Required.
- Known values include:
  - fax
  - local
  - smtp
  - uucp

– usenet

DOMAIN()
Common domain wide information.

FEATURE()
Solution to special needs.

RELAY_DOMAIN()
Defines hosts and domain names for which the sendmail server should allow mail to be relayed. By default, the sendmail server does not allow relayed mail. If the sendmail client uses the submit.cf file and uses FEATURE(`msp'), the sendmail server should be configured to allow this relayed mail.

Building the configuration file: To build the configuration file, go to the directory containing m4/cf.m4 and issue the following command:

```
m4  ../m4/cf.m4 yourmcfile.mc > yourcffile.cf
```

where *yourmcfile* is the name of your .mc file and *yourcffile* is the name you want to give your .cf file.

The `../m4/cf.m4` specifies the master prototype configuration file `cf.m4` in the `m4` directory of the samples/sendmail directory. This is the path to the samples/sendmail directory structure from the location of your m4 executable file. This can also be specified in your .mc file using *include* as follows:

```
include(`/usr/lpp/tcpip/samples/sendmail/m4/cf.m4')
```

Assuming that the m4 preprocessor is downloaded to /tmp/bin/m4 and that the master configuration (.mc) files are in /tmp/sendmail.mc and /tmp/submit.mc, the following commands will produce the configuration files:

```
$ cd /usr/lpp/tcpip/samples/sendmail/cf
$ /tmp/bin/m4 ../m4/cf.m4 /tmp/sendmail.mc > /etc/mail/sendmail.cf
$ /tmp/bin/m4 ../m4/cf.m4 /tmp/submit.mc > /etc/mail/submit.cf
```

Creating the z/OS-specific file

The purpose of the z/OS-specific file is to specify z/OS unique options. A sample file is in /usr/lpp/tcpip/samples/sendmail/cf/zOS.cf and can be copied to /etc/mail/zOS.cf with the installation information. The actual location of the file can be set by the confZOS_FILE m4 parameter. It is assumed that the administrator received the following information from the security administrator.

KeyfilePath
Directory path for the key ring files and password stash files.

ServerKeyFile
Name of the key database file or RACF key ring, used when sendmail acts as the server. If a key database is specified, it must be an existing z/OS UNIX file. If a RACF key ring is specified, it must be an existing key ring and the current user ID must have READ access to the IRR.DIGTCERT.LISTRING and IRR.DIGTCERT.LIST resources in the FACILITY class.

ClientKeyFile
Name of the key database file or RACF key ring, used when sendmail acts as the client. If a key database is specified, it must be an existing z/OS UNIX file. If a RACF key ring is specified, it must be an existing key ring

and the current user ID must have READ access to the IRR.DIGTCERT.LISTRING and IRR.DIGTCERT.LIST resources in the FACILITY class.

ServerPWFile
Name of the file that contains the password for the key database file, used when sendmail acts as the server. It must not be given a value when a RACF key ring is specified in ServerKeyfile.

ClientPWFile
Name of the file that contains the password for the key database file, used when sendmail acts as the client. It must not be given a value when a RACF key ring is specified in ClientKeyfile.

CipherLevel
Specifies the list of SSLV3, TLSV1.0, or TLSV1.1 ciphers in the order of usage preference. If it is not set, it takes on the default SSLV3 cipher specs. The default cipher spec list when Security Level 3 FMID JCPT321 is installed is "05040A0306090201". If Security Level 3 FMID JCPT321 is not installed, the default cipher spec list is "0306090201".

GskTraceFile
Specifies the file to receive SSL Trace information, used to debug problems using the sendmail TLS interface. The GSK_TRACE_FILE environmental variable is set to the value specified. For a discussion of concerns when obtaining a System SSL trace, see *z/OS Cryptographic Services System SSL Programming*. Ensure that the file is writable by the UID that sendmail will execute under. Be aware that sensitive information might be written to this file, and use a percent sign (%) to substitute the PID into the file name and avoid multiple tasks writing to (and over) the same file. To create a readable copy of the trace information, use the System SSL gsktrace command, which takes the trace file name as input and writes readable trace output to standard output.

z/OS sendmail also supports querying for certificate revocation lists (CRLs) if an LDAP server is specified.

LdapServer
Support LDAP for X.500 certificate verification.

LdapUser
LDAP user ID to support X.500 certificate verification.

LdapPw
LDAP password to support X.500 certificate verification.

LdapPort
Port number to be used to connect to the LDAP server.

Using sendmail databases

The aliases database is the only database included in every configuration. If you want to use other databases, you need to add the database to sendmail configuration. For more information on databases, see /usr/lpp/tcpip/samples/sendmail/README.m4.

Configuration option: During the process of building the configuration file, the following defines and features are used to configure support for the optional databases, as well as some import files:

RELAY_DOMAIN_FILE(`path')
This option specifies the file that contains the list of hosts, domains, and addresses that mail can be relayed to.

FEATURE(`use_ct_file'[, `path'])
This feature adds trusted usernames from the files to the class variable t. If the path is not provided, the default for sendmail 8.12 is /etc/mail/trusted-users.

FEATURE(`use_cw_file'[, `path'])
This feature adds hostname aliases from the file to the class variable w. If the path is not provided, sendmail 8.12 uses /etc/mail/local-host-names as the default.

Three basic files: The following three databases are disk files used to load sendmail.cf class variables:

trusted-users file
The default path of this file is /etc/mail/trusted-users. It adds usernames, to the list of users that are trusted to send mail under another user's name, to the class variable t in the configuration file. By default, the class variable t contains the names daemon, root, and uucp.

relay-domains file
Sendmail copies data written in this file to the class variable R. This enables relaying in the domains of the /etc/mail/relay-domains file.

local-host-names file
This file is used when systems use the sendmail server as a mailbox server to hold their mail. By using class variable w in the configuration file, the mail to the system listed in /etc/mail/local-host-names will be accepted as a local delivery.

Aliases database: Aliasing is the process of converting one recipient name into another; a generic name (such as root) into a real user name; or one name into a list of names (that is, a mailing list). Define the location of your aliases file using define(`ALIAS_FILE',`path') in your sendmail.mc file. For example:

```
define(`ALIAS_FILE',`/etc/mail/aliases')
```

For sendmail to work, aliases are required for MAILER-DAEMON and postmaster. Every aliases file must include these required aliases.

The alias for postmaster must expand to the name of a real user, based on the requirement that every site has to be able to accept mail addressed to a user named postmaster. Unless a site has real user account named postmaster, an alias is required in the aliases file. The postmaster receives mail about mail problems sent by mail-related programs and by users that are having trouble sending mail.

When mail is bounced (returned because it could not be delivered), it is sent from MAILER-DAEMON but it is shown as being the original sender who sent the mail. This alias is defined because users often inadvertently reply to the bounced mail.

Following is an example of an aliases file. Lines that begin with # are comments. Empty lines are ignored. For more information on the different forms of aliases, see the *bat book.*

```
# Alias for mailer daemon
MAILER-DAEMON:IBMUSER

# Following alias is required by the new mail protocol, RFC 822
```

```
postmaster:IBMUSER

# Alias to handle mail to msgs and news
nobody: /dev/null
```

Note: After the aliases file is created and before the sendmail daemon is brought up for the first time, the aliases file must be loaded by running sendmail using the *newaliases* command or with the *-bi* command-line switch.

Restriction: The section "USING LDAP FOR ALIASES, MAPS, AND CLASSES", as documented in /usr/lpp/tcpip/samples/sendmail/README.m4, is not supported on z/OS.

Configuring an IPv6 daemon and relay client (optional)

Depending on your system's environment, select one of the following sendmail configuration statements.

To listen on IPv4 interfaces only, use the following:

```
DAEMON_OPTIONS(`Name=MTA-v4, Family=inet')
```

To listen on both IPv4 and IPv6 interfaces, use the following:

```
DAEMON_OPTIONS(`Name=MTA-v6, Family=inet6')
```

To set a restriction for outgoing connections on a particular family, use ClientPortOptions in the configuration file. For example, the following indicates that sendmail will be a relay client for the IPv6 family.

```
CLIENT_OPTIONS(Family=inet6);
```

Note: If the following message is shown in the log file when invoking the sendmail daemon, check that your system supports IPv6. If your system has no IPv6 capability, sendmail will fail to start the daemon.

```
opendaemonsocket: daemon MTA-v6: can't create server SMTP socket"
opendaemonsocket: daemon MTA-v6: problem creating SMTP socket"
```

Configuring TLS support (optional)

See *Sendmail Installation and Operation Guide* (/usr/lpp/tcpip/samples/sendmail/sendmail.ps). Note that z/OS sendmail does not use OpenSSL, but instead uses the Security Server SSL interface. Therefore, a flag confZOS_FILE is defined to indicate where this information is set. The default location is /etc/mail/zOS.cf. A sample zOS.cf file is shipped in /usr/lpp/tcpip/samples/sendmail/cf/zOS.cf. For more information on the SSL fields used in the zOS.cf file, see *z/OS Cryptographic Services System SSL Programming*. For an explanation of the fields within the zOS.cf file, see "Creating the z/OS-specific file" on page 1421.

Configuring Security Server (RACF or equivalent) items

Sendmail assumes user IDs are used when running, and these user IDs must be defined to execute sendmail correctly. The commands to define the sendmail user IDs are defined in SEZAINST(EZARACF). The commands are:

```
ADDGROUP SMMSPGRP OMVS(GID(25))
ADDGROUP SNDMGRP OMVS(GID(26))
ADDUSER MAILNULL DFLTGRP(SNDMGRP)  NOPASSWORD OMVS(UID(26) HOME('/'))
ADDUSER SENDMAIL DFLTGRP(SNDMGRP)  NOPASSWORD OMVS(UID(0) HOME('/'))
ADDUSER SMMSP    DFLTGRP(SMMSPGRP) NOPASSWORD OMVS(UID(25) HOME('/'))
RDEFINE STARTED  SENDMAIL.* STDATA(USER(SENDMAIL))
SETROPTS RACLIST(STARTED) REFRESH
```

The queue directories must have the proper read and write permission for UID 25 and 26 respectively.

In addition, there are security concerns for programs that change user ID without prompting for a password. Program control is the Security Server facility used to manage programs that change user IDs without prompting for a password. By having an installation use program control, applications not permitted to the facility are not allowed to change user IDs without prompting for a password. The commands are:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(SENDMAIL) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

For more information on Security Server commands used to allow sendmail access to the program control facility, see SEZAINST(EZARACF). For complete information on the program control facility, see *z/OS Security Server RACF Security Administrator's Guide*.

When /usr/sbin/sendmail begins execution as a started task, or as a Mail Transmission Agent (MTA) daemon from the UNIX shell, it starts with the UID defined for the started task or the shell. It immediately does a setuid() to the confRUN_AS_USER (sendmail uid 0) to listen on port 25 and do other setup tasks. Then, when it begins processing mail, it does a setuid() to the confDEF_USER_ID (mailnull uid 26).

In addition, when using /bin/sendmail to create mail as a Mail User Agent (MUA), the Mail Submission Agent (MSA) configuration file /etc/mail/submit.cf is used. This file must exist in a program control environment. If it does not exist, EZZ9895I is issued when sendmail does a setuid() to the confRUN_AS_USER (smmsp uid 25) to do all the mail processing. With program control, an installation must have a /etc/mail/submit.cf, which can be a copy of /usr/lpp/tcpip/samples/sendmail/cf/submit.cf. /bin/sendmail must be owned by the UID confRUN_AS_USER (smmsp uid 25), and must have the Set UID and Set GID bits set. Assuming that the default UID of 25 is used, the following commands can be used to run /bin/sendmail in a program control environment:

```
chown 25:25 /bin/sendmail
chmod 6755  /bin/sendmail
```

Rule: The chown command must be issued before the chmod command, since chown turns off the Set UID and Set GID bits. To verify this has been set, issue the following command:

```
ls -l /usr/lpp/tcpip/bin/sendmail
```

The output will be as follows:

```
-rwsr-sr-x   1 SMMSP    SMMSPGRP ...  /usr/lpp/tcpip/bin/sendmail
```

It is important to have sendmail.cf and submit.cf files to isolate tasks done by the sendmail daemon MTA and the sendmail user MUA. Also, the queue directories must have the appropriate permission bits. The default directories used by the MTA and the MSA are /var/spool/mqueue and /var/spool/clientmqueue. If these directories are not correct for your system, use the QUEUE_DIR and MSP_QUEUE_DIR flags. Ensure that the permissions for the queue directories are set up for the user IDs defined.

Setting up a Milter (optional)

To describe where filters are located, you need to add reference to the filters in the sendmail configuration file (sendmail.cf). Filters declaration in the sendmail configuration file are made in the following form:

```
X name field =value |*
```

Filters are specified with a key letter (X for external), and *name* is the name of the filter (used internally only). The *field=value* pairs, or *equates*, define attributes of the filter.

The fields and their values are:

Socket

The socket specification is in one of the following forms:

```
S = inet: port @ host | [IP address]
S = inet6: port @ host | [IP address]
S = local: path
```

The first two describe an IPv4 (inet) and IPv6 (inet6) socket listening on a certain port at a given host or IP address. The final form describes a named socket on the file system at the given path.

Flags Special flags for a filter are:

```
F=R           Reject connection if filter unavailable
F=T             Temporary fail connection if filter unavailable
```

Timeouts

To override the default timeouts used by sendmail when talking to the filters, use T = *timeout*, where *timeout* includes four fields as follows:

```
C        Timeout for connecting to a filter (if 0, use system timeout)
S        Timeout for sending information from the MTA to a filter
R        Timeout for reading reply from the filter
E        Overall timeout between sending end-of-message to filter and
         waiting for the final acknowledgment
```

The separator between each timeout field is a semicolon (;). The default timeout values, if not set in the configuration file, are as follows, where *s* is seconds and *m* is minutes:

```
T=C:5m;S:10s;R:10s;E:5m
```

A comma (,) separates equates. Following are some example filters:

```
Xfilter1, S=local:/var/run/f1.sock, F=R
Xfilter2, S=inet6:999@localhost, F=T, T=C:10m;S:1s;R:1s;E:5m
Xfilter3, S=inet:3333@localhost
```

Assuming the filters are stored in /var/spool/milter, the following commands would start the above three mail filters. Note that S= is replaced by **-p**, and the flags are dropped.

```
/var/spool/milter/filter1 -p local:/var/run/f1.sock &
/var/spool/milter/filter2 -p inet6:999@localhost &
/var/spool/milter/filter3 -p inet:3333@localhost &
```

Which filters are invoked, and their sequencing, is handled by the InputMailFilters option as follows, where *fnamex* are the names of the filters:

```
O InputMailFilters=fname1, fname2, fname3
```

If InputMailFilters is not defined, no filters are used. However, there is a special case. Since sendmail can run multiple daemons, you can assign different filters to different daemons. For example:

```
O DaemonPortOptions=Port=6666,Name=mmta,I=filter
.
.
.
Xfilter, S=inet:3333@localhost
```

DaemonPortOptions is used to define multiple clients and daemons, and the I field is used to assign a specific filter to the daemon. If a daemon is assigned a specific filter, it connects to that filter only. In the previous example, the daemon using port 6666 connects to the filter defined by [Xfilter, S=inet:3333@localhost]. If a daemon is not assigned a specific filter, it connects to filters defined by [InputMailFilters].

There are two suboptions for Milter:

LogLevel
: Log level for input mail filter actions, the default is LogLevel

Macros
: Specifies list of macros to transmit to filters

The macros option has the following suboptions, which specify the list of macros to transmit to milters after a certain event has occurred. By default, the lists of macros are empty.

Option After this event

Connect
: Session connection start

Helo HELO command

Envfrom
: MAIL FROM command

Envrcpt
: RCPT TO command

Following are some examples:

```
O Milter.LogLevel=12
O Milter.macros.connect=j, _, {daemon_name}
```

These filters can easily be configured in your mc file using the following commands:

```
MAIL_FILTER(`name', `equates')
INPUT_MAIL_FILTER(`name', `equates')
```

The first command, MAIL_FILTER(), simply defines a filter with the given name and equates. For example:

```
MAIL_FILTER(`archive', `S=local:/var/run/archivesock, F=R')
```

This creates the following equivalent sendmail.cf entry:

```
Xarchive, S=local:/var/run/archivesock, F=R
```

The INPUT_MAIL_FILTER() command performs the same actions as MAIL_FILTER, but also populates the m4 variable `confINPUT_MAIL_FILTERS' with the name of the filter such that the filter will actually be called by sendmail. For example:

```
INPUT_MAIL_FILTER(`archive', `S=local:/var/run/archivesock, F=R')
INPUT_MAIL_FILTER(`spamcheck', `S=inet:2525@localhost, F=T')
```

The two commands above are equivalent to the following three commands:

```
MAIL_FILTER(`archive', `S=local:/var/run/archivesock, F=R')
MAIL_FILTER(`spamcheck', `S=inet:2525@localhost, F=T')
define(`confINPUT_MAIL_FILTERS', `archive, spamcheck')
```

In general, INPUT_MAIL_FILTER() should be used, unless you need to define more filters than you want to use for `confINPUT_MAIL_FILTERS'. Note that setting `confINPUT_MAIL_FILTERS' after any INPUT_MAIL_FILTER() commands clears the list created by the prior INPUT_MAIL_FILTER() commands.

The following table shows M4 variables:

Table 71. M4 variables

M4 variable	Configuration variable	Description
confINPUT_MAIL_FILTERS	InputMailFilters	A list of filters, separated by commas, that determines which filters are contacted for incoming SMTP messages, as well as the invocation sequence. If none are set, no filters are contacted.
confMILTER_LOG_LEVEL	Milter.LogLevel	Log level for input mail filter actions. The default is LogLevel.
confMILTER_MACROS_CONNECT	Milter.macros.connect	Macros to transmit to milters when a session connection starts. The default is [j, _, {daemon_name}, {if_name}, {if_addr}].
confMILTER_MACROS_HELO	Milter.macros.helo	Macros to transmit to milters after HELO command. The default is [{tls_version}, {cipher}, {cipher_bits}, {cert_subject}, {cert_issuer}].
confMILTER_MACROS_ENVFROM	Milter.macros.envfrom	Macros to transmit to milters MAIL FROM command. The default is [i, {auth_type}, {auth_authen}, {auth_ssf}, {auth_author}, {mail_mailer}, {mail_host}, {mail_addr}].
confMILTER_MACROS_ENVRCPT	Milter.macros.envrcpt	Macros to transmit to milters after RCPT TO command. The default is [{rcpt_mailer}, {rcpt_host}, {rcpt_addr}].

For instructions on how to compile and link a mail filter program, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

Creating the Message Submission Program file submit.cf

Sendmail needs to run as root for several reasons. The Message Submission Program (MSP) configuration file submit.cf eliminates the need for sendmail to run as root to write e-mail that is submitted from the command line to the queue directory.

MSP requires a set-user-ID/set-group-ID program to avoid problems with a world-writable directory. It is, however, sufficient to have a set-group-ID program and a group-writable queue directory. This can be fulfilled by a sendmail daemon that is started by root. This topic explains how to use two sendmail configurations to accomplish the goal of having a sendmail binary that is not set-user-ID root, and thus is less problematic in the presence of system configuration and OS problems.

The default configuration, starting with sendmail 8.12, uses one sendmail binary that acts differently based on operation mode and supplied options. When running in a program control environment, two binaries are used, /usr/sbin/sendmail and /bin/sendmail. For information on program control, see "Configuring Security Server (RACF or equivalent) items" on page 1424.

Sendmail must be a set-group-ID (default group: smmspgrp, recommended gid: 25) program to allow for queueing mail in a group-writable directory. Two .cf files are required, sendmail.cf for the daemon and submit.cf for the submission program. For the permissions that should be used, see Table 72 on page 1432.

The SEZAINST(EZARACF) file shows sample commands to add the smmsp user and group, as follows:

```
ADDGROUP SMMSPGRP OMVS(GID(25))
ADDUSER  SENDMAIL DFLTGRP(SMMSPGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
ADDUSER  SMMSP    DFLTGRP(SMMSPGRP) NOPASSWORD OMVS(UID(8000) PROGRAM('/bin/sh')
```

That is, the owner of sendmail is root, the group is smmspgrp, and the binary is set-group-ID. The client mail queue is owned by smmsp with group smmspgrp and is group writable. The client mail queue directory must be writable by smmspgrp, but it must not be accessible for others. That is, do not use world read or execute permissions. In submit.cf, the option UseMSP must be set, and QueueFileMode must be set to 0660. submit.cf is available in /usr/lpp/tcpip/samples/sendmail/cf, which has been built from /usr/lpp/tcpip/samples/sendmail/cf/submit.mc. The file can be used as is, or if you want to add more options, use /usr/lpp/tcpip/samples/sendmail/cf/submit.mc as a starting point.

Recommendation: Do not add options to submit.mc unless you are absolutely sure you need them. Options you might want to change include:

- confTIME_ZONE
- confDELIVERY_MODE is set to interactive in msp.m4 instead of the default background mode

Some features are not intended to work with the MSP. These include features that influence the delivery process (for example, mailertable, aliases), or those that are only important for an SMTP server (for example, virtusertable, DaemonPortOptions, multiple queues). Moreover, relaxing certain restrictions (RestrictQueueRun, permissions on queue directory) or adding features (for example, enabling prog/file mailer) can cause security problems.

Other things do not work well with the MSP and require tweaking or workarounds. For example, to allow for client authentication, it is not sufficient to

just provide a client certificate and the corresponding key, but it is also necessary to make the key group (smmsp) readable and tell sendmail not to complain about it as follows:

```
define(`confDONT_BLAME_SENDMAIL', `GroupReadableKeyFile')
```

When FEATURE(`msp') is coded, the sendmail client will send all mail to the local mail server. If using the sendmail server as the local mail server, review the RELAY_DOMAIN() for the sendmail server. If needed, the sendmail client can be configured to send mail to a different server with this feature.

/usr/lpp/tcpip/samples/sendmail/feature/msp.m4 defines almost all settings for the MSP. Most of these should not be changed at all. Some of the features and options can be overridden if really necessary. It is a bit tricky to do this, because it depends on the actual way the option is defined in feature/msp.m4. If it is directly defined [that is, with define()], the modified value must be defined after the following line:

```
FEATURE(`msp')
```

If it is conditionally defined [that is, with ifdef()], the desired value must be defined before the FEATURE line in the .mc file. To see how the options are defined, read feature/msp.m4.

The .cf file (sendmail.cf or submit.cf) is chosen based on the operation mode. For -bm (default), -bs, and -t, it is submit.cf, if it exists. For all others, it is sendmail.cf. This selection can be changed by -Ac (to use submit.cf) or -Am (to use sendmail.cf).

The daemon must be started by root as usual, for example:

```
/usr/sbin/sendmail -L sm-mta -bd -q1h
```

Note: If you run sendmail from inetd (which, in general, is not recommended), you must specify -Am in addition to -bs.

Mail ends up in the client queue if the daemon does not accept connections or if an address is temporarily not resolvable. The latter problem can be minimized by using the following:

```
FEATURE(`nocanonify', `canonify_hosts')
define(`confDIRECT_SUBMISSION_MODIFIERS', `C')
```

However, the above might have undesired side effects, as discussed in /usr/lpp/tcpip/samples/sendmail/README.m4. In general, it is necessary to clean the queue either with a cronjob or by running a daemon as follows:

```
Cronjob: /usr/sbin/sendmail -L sm-msp-queue -Ac -q
Daemon:  /usr/sbin/sendmail -L sm-msp-queue -Ac -q30m
```

Requirement: If z/OS Security Server program control is used, the cronjob submission must be run from UID 0 and have READ access to the BPX.DAEMON resource in the FACILITY class.

If the option UseMSP is not set, sendmail will complain during queue runs about bogus file permission. If you want a queue runner for the client queue, you probably have to change OS-specific scripts to accomplish this (check the man pages of your OS for more information). You can start this program as root, and it will change its user ID to RunAsUser (smmsp by default, recommended uid: 25). This way, smmsp does not need a valid shell.

Following is a brief summary of how the two configuration files are used:

sendmail.cf
: For the MTA (mail transmission agent). The MTA is started by root as daemon as follows:

```
/usr/sbin/sendmail -L sm-mta -bd -q1h
```

SMTP connections are accepted, on ports 25 and 587 by default. It runs the main queue, /usr/spool/mqueue by default if using /usr/lpp/tcpip/samples/sendmail/cf/sample.cf.

submit.cf
: For the MSP (mail submission program). The MSP is used to submit e-mails. Thus, it is invoked by programs, and maybe users. It does not run as SMTP. It uses /usr/spool/clientmqueue by default if using /usr/lpp/tcpip/samples/sendmail/cf/sample.cf, and can be started to run that queue periodically as follows:

```
/usr/sbin/sendmail -L sm-msp-queue -Ac -q30m
```

Running sendmail as a daemon

Just as sendmail can transport a mail message over a TCP/IP-based network, it can also receive mail that is sent to it over the network. To do this, it must be run in daemon mode. A daemon is a program that runs in the background independent of terminal control.

As a daemon, sendmail is run once, usually when your machine is booted. Whenever an e-mail message is sent to your machine, the sending machine talks to the sendmail daemon that is listening on your machine.

The -bd command-line switch tells sendmail to run in daemon mode. The -q1h command-line switch tells sendmail to wake up once per hour and process the queue. Command-line switches are described in *z/OS Communications Server: IP User's Guide and Commands*.

Configuration hints and tips

This topic contains other required or useful information for configuring sendmail. For further information on these topics, see the *bat book.*

- SuperUser status is needed to start the sendmail daemon.
- The QueueDirectory option defined in the config file tells sendmail where to queue messages that are temporarily undeliverable. This directory must exist before sendmail is started.
- Sendmail is highly dependent on the Domain Name Server (DNS); it is important that the resolver be set up correctly to avoid unnecessary searching for a user. For more information on DNS, see Chapter 15, "Domain Name System," on page 775.
- A program controlled environment is necessary for sendmail to run in daemon mode when BPX.DAEMON is enabled, since many functions of sendmail (especially daemon functions) require it to change the user ID (UID) without prompting for a password. For more information regarding security and sendmail, see *z/OS UNIX System Services Planning* as well as the *bat book*.
- The daemon must be started by root, as usual. Table 72 on page 1432 shows the recommended security file permissions of files that sendmail might use.

Table 72. Sendmail permission table

Path	Type	Owner	Mode	Required or configurable
/	Directory	*root*	555 dr-xr-xr-x	Required
/usr	Directory	*root*	555 dr-xr-xr-x	Required
/usr/sbin	Directory	*root*	555 dr-xr-xr-x	Required
/usr/sbin/sendmail	File	*root*	755 -rwsr-xr-x	Required
/bin/sendmail	File	*smmsp*	755 -rwsr-sr-x	Configurable[1]
/etc/mail	Directory	*root*	555 dr-xr-xr-x	Configurable
/etc/mail/sendmail.cf	File	*root*	444 -r--r--r--	Configurable
/etc/mail/submit.cf	File	*root*	444 -r--r--r--	Configurable
/var/spool/mqueue	Directory	*sendmail*	700 drwx------	Configurable
/var/spool/clientmqueue	Directory	*smmsp*	770 drwxrwx---	Configurable

1. Used only with RACF program control systems.

Rule: When sendmail is attempting to canonify a host name, some broken name servers will return SERVFAIL (a temporary failure) on T_AAAA (IPv6) lookups. To allow sendmail to accept this behavior, ResolverOptions in the configuration file is set to WorkAroundBrokenAAAA by default.

If a system has thousands of users defined in the Users list, the administrator might consider enabling the UNIXMAP class. This increases the speed of the security checks performed by sendmail. APAR OW30858 provides details about what is needed to enable the UNIXMAP class. For additional information on enabling the UNIXMAP class, see *z/OS Security Server RACF Security Administrator's Guide*.

Environment variables

Table 73 provides a list of environment variables that can be explicitly set by sendmail.

Table 73. Environment variables for sendmail

Environment variable	Description
GSK_TRACE	Specifies a bit mask enabling system SSL trace options.
GSK_TRACE_FILE	When set to the name of a file in a directory, enables the system SSL trace.
HOME	The system initializes this variable at login time to a path name of the user's home directory.
HOSTALIASES	The host aliases data set or file.

Configuring popper

POP3 resides on port 110. You can define additional ports if there is a need for additional command-line options for popper. For information on the options that might be suitable for your site, see the *z/OS Communications Server: IP User's Guide and Commands*.

z/OS UNIX popper will most likely be used by those whose local mailer requires a POP3 server. Typically their administrator will provide them with the address or name of the z/OS running the POP3 server, with instructions on where this information should be used.

The authentication method used in this implementation of popper is user ID and password.

The popper implementation can be divided into four steps:

- Update the /etc/services file.
- Update the /etc/inetd.conf file.
- Create the directory for the temporary maildrop file.
- Start inetd.

Update the /etc/services file

You need a port for the POP3 server defined in /etc/services. Add the following line to your /etc/services file. Note that the well-known port 110 is being used in this example:

```
pop3                110/tcp popper
```

Update the /etc/inetd.conf file

Since popper is invoked by INETD, add the following information to your /etc/inetd.conf file, where -d indicates to run popper in debugging mode:

```
pop3       stream tcp nowait bpxroot     /usr/sbin/popper popper -d
```

The debugging option is used to confirm proper installation, as shown in "Correct connection" on page 1434.

Create the directory for the temporary maildrop file

When popper is invoked through a Mail User Agent (MUA) client request, such as GET NEW MESSAGES, popper starts to read the user's mail file system (/usr/mail/username) where sendmail has stored the data, and puts this data (if there are messages) in a temporary maildrop file /usr/mail/popper/ .username.pop. The contents of this file are transmitted to the remote client using the existing POP3 TCP connection.

Since the directory does not exist, create it as follows:

```
/usr/mail/popper/
chmod 777 /usr/mail/popper
```

The popper uses this directory to create and fill the maildrop file. If this directory is not specified or if permissions are incorrect, you will get an error message similar to the following:

```
EZZ7605I:Unable to open temporary maildrop '/usr/mail/popper/.username.pop'
```

Also, inside the POP3 session, you will get an error message similar to the following:

```
-ERR System error, can't open temporary file, do you own it?
```

Start inetd

After updating the inetd.conf file, start INETD. For more information on inetd, see Appendix A, "Setting up the inetd configuration file," on page 1459. Also see *z/OS Communications Server: IP Configuration Reference*.

Correct connection

Following is an example of a working connection to the popper server:

```
Debugging turned on

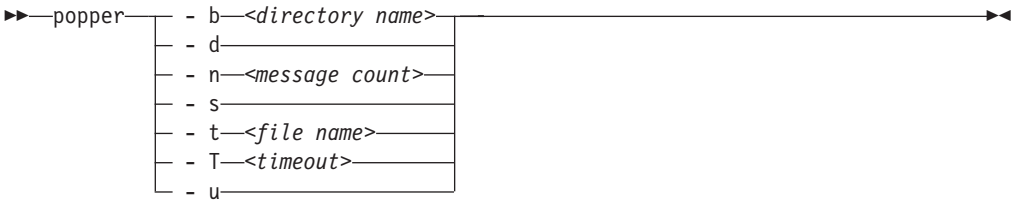
Popper command—administering received mail

If the receiver's MUA does not have direct access to the mail spool file, use Popper to access the mail spool on the local host. z/OS Popper will be used when a POP3 server is needed.

Syntax:



Parameters: The following command line options can be used when invoking Popper.

-b *<directory name>*
Specifies the name of the directory in which bulletins are found. If not specified, /usr/mail/bulletins is used as the default.

-d Requests additional debugging messages be turned on.

-n *<message count>*
Specifies the number of old bulletins to be delivered to new users. If not specified, no bulletins are delivered.

-s Requests statistics logging be turned on.

-t *<file name>*
Specifies a trace file for all message logging. If not specified, messages are logged via the syslog facility.

-T *<timeout>*
Specifies the time, in seconds, before an idle POP3 connection is terminated. RFC 1939 specifies a minimum timeout of 600 seconds, but in practice such a long timeout does not work well. (When a connection gets aborted, the user is locked out of his mailbox for the timeout period.) If not specified, 120 seconds is used as the default timeout period.

-u Requests the user's mailbox be updated on abort. RFC 1939 specifies that mailboxes should not be updated (that is, no messages should be deleted) if a connection is aborted abnormally. This option forces an update to occur despite the aborted connection. If not specified, no update will occur on aborted connections.

Chapter 29. TIMED daemon

TIMED is a daemon that is used to provide the time in response to UDP requests. TIMED gives the time in seconds since midnight January 1, 1900. You can start TIMED from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting TIMED.

Note: TIMED is different from the TIME daemon available as an internal daemon of INETD. INETD cannot be used to start and perform as a listener for TIMED.

Starting TIMED from the z/OS shell

TIMED is installed in the /usr/lpp/tcpip/sbin/ directory.

To start the TIMED server from the command line, issue the **timed** command.

```
timed [-l] [-p port]
```

Following are the parameters used for the **timed** command:

-l Logs all the incoming requests and responses to the system log. Logged information includes the IP address of the requester.

-p port
The TIMED server usually receives requests on well-known port 37. TIMED uses UDP only. You can specify the port in which requests are to be received.

Starting TIMED as a procedure

The following sample shows how to start TIMED as a procedure.

```
//TIMED    PROC
//*
//*   5694-A01 (C) Copyright IBM Corp. 1997, 2002
//*   Licensed Materials - Property of IBM
//*   This product contains "Restricted Materials of IBM"
//*   All rights reserved.
//*   US Government Users Restricted Rights -
//*   Use, duplication or disclosure restricted by

//*   See IBM Copyright Instructions.
//*
//* Function: Time server start procedure
//* SMP/E distribution name: EZATTMDP
//*
//TIMED    EXEC PGM=TIMED,REGION=0K,TIME=NOLIMIT,
//         PARM='POSIX(ON),ALL31(ON),TRAP(OFF)/'
//*STEPLIB DD DISP=SHR,DSN=TCP.SEZALOAD,
//*           VOL=SER=,UNIT=
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//SYSIN    DD DUMMY
//SYSERR   DD SYSOUT=*
```

```
//SYSOUT   DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//CEEDUMP  DD SYSOUT=*
//SYSABEND DD SYSOUT=*
//         PEND
```

Chapter 30. SNTPD daemon

SNTPD is a TCP/IP daemon that is used to synchronize time between a client and a server. Simple Network Time Protocol (SNTP) is a protocol for synchronizing clocks across a WAN or LAN through a specific formatted message. An External Time Reference (ETR), named stratum 0, is chosen as the highest timer reference used for synchronization. A stratum 1 server is attached to and receives the time from the stratum 0 timer. For example, the z/OS sysplex timer could be a stratum 0 timer, and z/OS Communications Server would be a stratum 1 server. A client attached to the stratum 1 server can also be a stratum 2 server, receiving the time from the stratum 1 server, and so on. SNTP uses UDP packets for data transfer with the well-known port number 123. RFC 2030 (Mills 1996) describes SNTP. You can start SNTPD from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting SNTPD.

Steps for starting SNTPD from the z/OS shell

Before you begin: Ensure the existence of the following files. The files used by z/OS UNIX SNTPD and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file.

/usr/sbin/sntpd
This is a symbolic link to /usr/lpp/tcpip/sbin/sntpd, which is a sticky-bit file. The SNTPD member of SEZALOAD contains the executable code for the SNTP server.

/usr/lib/nls/msg/C/sntpdmsg.cat
The message catalog used by the z/OS UNIX SNTPD server.

When restricting low port usage, the port used by SNTPD (default value of 123) should either:

- Be reserved for the name of the SNTPD start procedure
- Use the SAF parameter on the PORT statement to restrict access to the SNTPD port

Note: There is no configuration file specifically for SNTPD.

Perform the following step to start SNTPD from the z/OS shell:

1. Type sntpd & on the command line. This will start SNTPD and send it to the background.

   Following are the optional parameters used for the sntpd command:

   -d Enables debugging. Debug messages go to syslog daemon.

   -df *pathname*
   Enable debugging. Debug messages go to the specified file location.

   -pf *pathname*
   Path for pid file. For example:

```
-pf /var
```

-m *nnnnn*
Acts in multicast mode. Sends multicast updates (TTL=1) on all interfaces every *nnnnn* seconds. Listens to multicast requests and responds with unicast replies. The valid range for **-m** is 1 to 16284.

-b *nnnnn*
Acts in broadcast mode. This parameter sends local broadcasts on all interfaces every *nnnnn* seconds. It also specifies to listen to broadcast requests and respond with unicast replies. The valid range for **-b** is 1 to 16284.

-s *nn* Use *nn* as the stratum level in all replies sent by the server. The valid range for *nn* is 1 to 15. If **-s** is not specified or a value is specified that is not valid, the default stratum level of 1 is used. The stratum level indicates the relative accuracy of the local clock compared to the clocks of other SNTP servers in the network. The value 1 is most accurate and 15 is least accurate.

-? Display the syntax of the command usage and options.

You know that SNTPD has started when the following message appears on the MVS console:

```
EZZ9600I SNTP SERVER READY.
```

Steps for starting SNTPD as a procedure

Before you begin: Obtain a copy of this sample procedure from SEZAINST and store it in one of your PROCLIB concatenation data sets.

Perform the following step to start SNTPD as a procedure:

1. Invoke the procedure using the system operator start command. The following sample, SEZAINST(SNTPD), shows how to start SNTPD as a procedure:

```
//SNTPD    PROC
//*
//* TCP/IP FOR MVS SIMPLE NETWORK TIME PROTOCOL
//* SMP/E DISTRIBUTION NAME: EZASNPRO
//*
//*   5694-A01 (C) COPYRIGHT IBM CORP. 2002.
//*   LICENSED MATERIALS - PROPERTY OF IBM
//*   THIS PRODUCT CONTAINS "RESTRICTED MATERIALS OF IBM"
//*   ALL RIGHTS RESERVED.
//*   US GOVERNMENT USERS RESTRICTED RIGHTS -
//*   USE, DUPLICATION OR DISCLOSURE RESTRICTED BY
//*   GSA ADP SCHEDULE CONTRACT WITH IBM CORP.
//*   SEE IBM COPYRIGHT INSTRUCTIONS.
//*
//* FUNCTION: SNTP DAEMON START PROCEDURE
//*
//SNTPD    EXEC PGM=SNTPD,REGION=4096K,TIME=NOLIMIT,
//         PARM='POSIX(ON),ALL31(ON),TRAP(OFF)/ -d'
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//SYSIN    DD DUMMY
//SYSERR   DD SYSOUT=*
```

```
//SYSOUT   DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//CEEDUMP  DD SYSOUT=*
//SYSABEND DD SYSOUT=*
//*
```

You know that SNTPD has started when the following message appears on the console:

```
EZZ9600I SNTP SERVER READY.
```

Stack affinity

If you are running in a multiple stack environment and want SNTPD to use only a single stack, the environment variable _BPXK_SETIBMOPT_TRANSPORT can be used.

Chapter 31. Remote Execution

This topic describes how to configure and operate both the Remote Execution server and the UNIX Remote Execution server. z/OS Communications Server supports remote execution daemons in both the UNIX and TSO environments.

To execute commands under the UNIX shell, use the RSH command. To execute commands under TSO, use the REXEC command. These requests are serviced by the UNIX daemons, orshd and orexecd, and the TSO RXSERVE daemon.

The differences between the UNIX daemons and the TSO RXSERVE daemon are as follows:

- The UNIX daemons are initiated through the INETD server and can be configured to support a port other than their well-known port.
- The TSO daemon must be active and will only service REXEC and RSH requests on their well-known ports.

Only the UNIX daemons or the TSO daemon can be active at any one time.

UNIX REXEC

The UNIX Remote Execution Protocol Daemon (REXECD) is the server for the REXEC routine. REXECD allows execution of z/OS UNIX commands with authentication based on user names and passwords.

The Remote Shell Server (RSHD) is the server for the remote shell (RSH) client. The server provides remote execution facilities with authentication based on privileged port numbers, user IDs, and passwords.

See “Configuring the z/OS UNIX Remote Execution servers” on page 1447 for more information about configuring this server.

TSO REXEC

The TSO Remote Execution server allows execution of a TSO command that has been received at a remote host. This server runs the Remote EXEcution Command Daemon (REXECD) which supports both the Remote Execution (REXEC) and Remote Shell (RSH) protocols.

The TSO Remote Execution server has affinity for a specific transport in a CINET environment. Configure and execute a unique instance of the server for each TCP/IP stack requiring TSO remote execution services.

This information describes how to configure and operate the Remote Execution server.

Configuring the TSO Remote Execution server

Steps to configure the TSO Remote Execution server:

1. Update AUTOLOG and PORT statements in the PROFILE.TCPIP data set.
2. Determine whether the Remote Execution client will send a Remote Execution (REXEC) command or Remote Shell (RSH) command.

3. Permit remote users to access MVS resources. (Required only if the client is not sending a password.)
4. Update the Remote Execution cataloged procedure.
5. Create a user exit routine (optional).
6. Permit access to JESSPOOL files.

Step 1: Configuring PROFILE.TCPIP for TSO Remote Execution server

If you want the Remote Execution server to start automatically when the TCPIP address space is started, include the name of the member containing the RXSERVE cataloged procedure in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP data set.

```
AUTOLOG
  RXSERVE
ENDAUTOLOG
```

To ensure that port 512 is reserved for the Remote Execution protocol and port 514 for the Remote Shell protocol, add the name of the member containing the Remote Execution cataloged procedure to the PORT statement in *hlq*.PROFILE.TCPIP:

```
PORT
  512 TCP RXSERVE
  514 TCP RXSERVE
```

See *z/OS Communications Server: IP Configuration Reference* for more information about the AUTOLOG and PORT statements.

Step 2: Determine whether Remote Execution client will send REXEC or RSH commands

The Remote Execution client can send commands to the TSO Remote Execution server by the following methods:

1. Sending the Remote Execution (REXEC) command
2. Sending the Remote Shell (RSH) command with a user ID and password separated by a slash (/) character with the **-l** option on the RSH command
3. Sending the Remote Shell (RSH) command without a password

With methods 1 and 2, the TSO Remote Execution server executes the request and passes the password to MVS for verification. (REXEC commands require a password.) When these methods are used, skip Step 3.

With method 3, to enable an RSH client to send RSH commands to the TSO Remote Execution server without specifying a password, Step 3 is required.

Step 3: Permit remote users to access MVS resources (optional)

This step is necessary only if your installation allows users to issue remote execution commands without the requirement of specifying a password on the remote execution client.

Use the following steps to ensure that the server can correctly access necessary MVS resources. You can use z/OS Security Server (RACF) or an equivalent security program.

1. Verify that your system has been configured for allowing surrogate job submission as described in *z/OS Security Server RACF Security Administrator's Guide* (SC28-1915) or by using an equivalent security program.
2. Authorize the TSO Remote Execution server to submit jobs for the MVS user ID specified with the **-l** option of the RSH command. This can be done with the RACF facility as described in *z/OS Security Server RACF Security Administrator's Guide* (SC28-1915), or by using an equivalent security program.
3. Define an *mvs_userid*.RHOSTS.DATA data set and authorize the TSO Remote Execution server userid permission to read this data set. This can be done with the RACF facility as described in *z/OS Security Server RACF Security Administrator's Guide* (SC28-1915), or by using an equivalent security program.

   Note: This is the userid used to start the RXSERVE address space.

   This data set identifies the Remote Execution clients that can execute MVS commands remotely by sending an RSH command.

   When a Remote Execution client sends an RSH request to the TSO Remote Execution server, the request includes the local user ID of the client user (*local_userid*) and, if the client user specified the **-l** option of the RSH command, the request also contains the user ID to use on the remote host (*mvs_userid*). If the client does not specify the **-l** option, the user ID to be used on the remote host is assumed to be the same as the *local_userid*.

   When the TSO Remote Execution server receives an RSH command without a password, the server looks for a data set called *mvs_userid*.RHOSTS.DATA. The *mvs_userid*.RHOST.DATA data set contains one or more entries. Each entry consists of two parts, a fully qualified name of the client user's host and a *local_userid* associated with that host. The *local_userid* is case sensitive. If the data set exists, the server reads it and looks for an entry with a host name that matches the client user's host. If the user ID specified on this entry in the RHOSTS.DATA data set matches the *local_userid* passed on the RSH command, the RSH command continues processing. If the entry does not exist, the server responds to the client with message `EZA4386E Permission denied`.

   Tip: If the client connected to this host through a link-local address, the client's host name generated by the resolver can be in the format *hostname%scope*. Adding *%scope* information to the appropriate RHOSTS.DATA client host definitions results in a more efficient search for a matching client host name. For details on the support for including scope information on configured host names, see *z/OS Communications Server: IPv6 Network and Application Design Guide*.

   In the following example of an RHOSTS.DATA data set, the MVS client user `mvsuser` is allowed to issue the RSH command without a password from host `rs60007` with a local AIX user ID of `aixuser`.

   Example of mvsuser.RHOSTS.DATA data set:

   ```
   rs60007.itso.ral.ibm.com aixuser
   ```

4. Users may be authenticated using Kerberos or GSS. If the username in the Kerberos or GSS credentials matches the local user ID (*local_userid*) of the client supplied by the RSH client, then no password is required.

Step 4: Update the TSO Remote Execution cataloged procedure

Update the TSO Remote Execution cataloged procedure by copying the sample provided in SEZAINST(RXPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Specify the TSO Remote Execution server parameters and modify the JCL as required for your installation.

Tip: You can update the TSO Remote Execution server operating parameters during execution with the MODIFY command. All but MAXCONN, IPV6, and SECLABEL can be changed.

Step 5: Create a user exit routine (optional)

Optionally, you can provide a user exit routine. This routine can be used to alter the JOB and EXEC statement parameters to meet installation-specific requirements such as which system should process the job and/or environment unique accounting information prior to submission of the TSO batch job.

The user exit should have the AMODE(31) and RMODE(ANY) attributes to provide addressability to the input parameters.

On entry to the user exit, register 1 points to the following parameter list:

Offset	Description
0	A pointer to a mixed AF_INET or AF_INET6 address structure
	Offset **Description** **0** 2 bytes (AF_INET or AF_INET6) **2** 2 bytes (server port) **4** 4 or 16 bytes (client AF_INET or AF_INET6 address) **Rule:** The address family must be examined to determine which type of address structure is being used.
4	A pointer to JOB statement parameters
8	A pointer to EXEC statement parameters
12	A pointer to an optional JES control statement

If the server is IPv6 enabled and an IPv4 client connects, the IP address is the 4-byte IPv4 address and not the IPv4-mapped IPv6 address.

The JOB statement parameters can be up to 1024 characters in length and are ended by X'00'. You can modify the parameters with the exit routine. Upon entry, the parameters are set to:

- *user_ID*
- USER=*user_id*
- PASSWORD=*password*
- MSGCLASS=*msgclass*
- SECLABEL=*seclabel*

msgclass is as specified in the Remote Execution cataloged procedure. *user_id* and *password* are as received from the requesting client. *seclabel* is the security label used on the job submission.

For RSH commands without passwords, note that the PASSWORD= parameter is not present. The *userid* in the first positional parameter can be processed by an installation-written JES exit.

The EXEC statement parameters can be up to 256 bytes in length and are ended by X'00'. These parameters can be modified by the exit routine. On entry, it contains the EXEC statement for the procedure specified in the TSOPROC parameter of the Remote Execution server or the default IKJACCNT procedure if TSOPROC is not specified.

The JES control statement parameter can be up to 256 bytes in length and is ended by X'00'. Upon entry, the parameter field is set to X'00'. Any JES control statement added by the user exit will be put between the JOB and the EXEC statement.

The modified JOB and EXEC statements are submitted as a TSO batch job.

The user exit is shipped as a sample in the RXUEXIT member of the SEZAINST data set. See the REXEC topic in *z/OS Communications Server: IP Configuration Reference* for more information about this sample.

Step 6: Permit access to JESSPOOL files

If the SAF resource class JESSPOOL is defined, ALTER access is required to access output files. Alternatively, use a jobname of *prefix**, where *prefix* is defined in RXSERVE.

Configuring the z/OS UNIX Remote Execution servers

This topic describes the z/OS UNIX files used by z/OS UNIX REXECD and RSHD.

Files for z/OS UNIX REXECD

Note: The userid associated with the daemon in /etc/inetd.conf requires superuser authority. See *z/OS UNIX System Services Planning* for a description of the kinds of authority defined for daemons.

The files used by z/OS UNIX REXECD and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file.

/etc/inetd.conf
The configuration parameters for all applications started by inetd are defined in this file.

/usr/sbin/orexecd
The server.

If BPX.DAEMON is specified, then the sticky bit must be set on, and /usr/sbin/orexecd, and orexecd can reside in an authorized MVS data set.

/usr/lib/nls/msg/C/rexdmsg.cat
The message catalog used by the z/OS UNIX REXECD server.

Note: This is not an actual member at this location, but it is a symbolic link to the part in /usr/lpp/tcpip/nls/msg/C/*.

Where the server looks for the message catalog (rexdmsg.cat) depends on the value of NLSPATH and LANG environment variables. If you want to store the msg.cats elsewhere, you need to change the NLSPATH or the LANG environment variables. If rexdmsg.cat does not exist, by default, the software uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.

Files for z/OS UNIX RSHD

The files used by z/OS UNIX RSHD and their locations in the z/OS UNIX file system are as follows:

/etc/services
The ports for each application are defined here.

/etc/syslog.conf
The configuration parameters for usage of syslogd are defined in this file.

/etc/inetd.conf
The configuration parameters for all applications started by inetd are defined in this file.

/usr/sbin/orshd
The server.

If BPX.DAEMON is specified, the sticky bit must be set on, and /usr/sbin/orshd, and orshd can reside in an authorized MVS data set.

/usr/sbin/ruserok
An optional user exit that will authenticate users logging into the z/OS UNIX RSHD server with a null password. See "Setting up the z/OS UNIX RSHD installation exit" for more information.

Note: This exit is required to allow support for null passwords with RSH.

/usr/lib/nls/msg/C/rshdmsg.cat
The message catalog associated with the z/OS UNIX RSHD client is stored here. If this file does not exist, by default, the software uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.

Note: The message catalog is not actually stored here. This is a symbolic link, and the actual member is in /usr/lpp/tcpip/nls/msg/C/*.

Setting up the z/OS UNIX RSHD installation exit

When the **-r** option is enabled, if there is no password specified on the RSH command from the client, z/OS UNIX RSHD will drive the installation exit. When the installation exit is driven, RSHD looks for a program in /usr/sbin named ruserok. This is the only name that it will look for. If /usr/sbin/ruserok is not found, the request will fail.

When the z/OS UNIX RSHD server invokes /user/sbin/ruserok, it will pass parameters in the following order:

1. Host name or the host IP address
2. Local user's UID
3. Remote userid
4. Local userid

If z/OS UNIX RSHD receives a return code of zero from the installation exit, z/OS UNIX RSHD continues. Any nonzero return code from the installation exit will cause RSHD to issue message EZYRS25E to the client and terminate all connections. The following code fragment can be used as an example to begin building a working ruserok installation exit:

```
int main(argc, argv)
     int argc;
     char *argv[];
```

```
char *rhost1;    /* "hostname" or "hostname.domain" of client
                    obtained by caller:
                    gethostbyaddr(getpeername()) or the host
                    ip address used by the gethostbyaddr if
                    it failed to return a "hostname" */
int locuid;      /* uid of the user name on local system */
char *cliuname;  /* user name on client's system */
char *servuname; /* user name on this (server's) system */
int rc = 4;

rhost1 = argv[1];
locuid = atoi(argv[2]);
cliuname = argv[3];
servuname = argv[4];
.
<authenticate user and set rc=0 if valid>
.
return(rc);
```

Configuring TSO and z/OS UNIX Remote Execution servers to use the same port

Since the remote execution servers are generic servers, they attempt to bind to INADDR_ANY when they are started. This allows them to listen on all defined IP addresses. However, this prevents both the TSO and z/OS UNIX Remote Execution servers from listening on the same port, and one of the servers would have to use a nonstandard port. Using the BIND parameter on the PORT reservation statement in the TCPIP profile data set allows both the TSO and z/OS UNIX Remote Execution servers to bind to the same ports using different IP addresses. The following steps illustrate how this can be done. For more information on the PORT reservation statement, see *z/OS Communications Server: IP Configuration Reference*.

1. Define a VIPA address to the TCPIP profile data set. This example shows a static VIPA address, but either a static or dynamic VIPA can be used.

   ```
   DEVICE VIPAD1 VIRTUAL 0
   LINK   VIPA1  VIRTUAL 0 VIPAD1

   HOME
   134.134.134.36       VIPA1
   ```

2. Add PORT statements to the TCP/IP profile for both the TSO and z/OS UNIX Remote Execution servers. One of the servers will bind to the VIPA address. The other can bind to INADDR_ANY by not specifying the BIND parameter. In this example, the z/OS UNIX Remote Execution servers will bind to the VIPA address. Also update the /etc/services file so that exec uses 512 and shell uses 514.

   ```
   512 TCP OMVS BIND 134.134.134.36 ; z/OS Unix REXECD
   514 TCP OMVS BIND 134.134.134.36 ; z/OS Unix RSHD
   512 TCP RXSERVE                  ; TSO REXECD
   514 TCP RXSERVE                  ; TSO RSHD
   ```

   It is important that the server with the BIND parameter is listed before the one without the BIND parameter. This setup directs all requests to ports 512 or 514 with a destination IP address of 134.134.134.36 to the z/OS UNIX Remote Execution servers. Requests to ports 512 or 514 with a local destination IP address that is not 134.134.134.36 are directed to the TSO Remote Execution server.

To verify this setup:

1. Start the stack with the TCP/IP profile changes described above and start RXSERVE and INETD.

   Note: INETD listens for the REXEC and RSH servers under z/OS UNIX.

2. Issue NETSTAT and it should show that both the REXEC servers are listening on port 512 and both RSH servers are listening on port 514. INETD, which listens for the z/OS UNIX Remote Execution servers, only listens on the VIPA address.

```
MVS TCP/IP NETSTAT CS V1R2       TCPIP NAME: TCPCS           21:34:41
User Id  Conn     Local Socket           Foreign Socket         State
-------  ----     ------------           --------------         -----
INETDCS1 0000000D 134.134.134.36..514    0.0.0.0..0             Listen
INETDCS1 0000000E 134.134.134.36..512    0.0.0.0..0             Listen
RXSERVE  00000019 0.0.0.0..514           0.0.0.0..0             Listen
RXSERVE  00000018 0.0.0.0..512           0.0.0.0..0             Listen
```

Chapter 32. Express logon services with the Digital Certificate Access Server

The Digital Certificate Access Server (DCAS) is a z/OS TCP/IP server that you can use for enhanced logon solutions for z/OS applications. DCAS is part of several IBM express logon solutions, such as Express Logon Feature (ELF) and Web Express Logon (WEL), that work with IBM's host emulation products. DCAS provides a service for these solutions (with ELF, DCAS is needed only for the 3-tier solution) by providing them with z/OS user IDs and PassTickets for logon to host applications. A PassTicket is like a password. In addition, DCAS also provides an open interface and can be used by third-party express logon solutions to obtain user IDs and PassTickets for logon to z/OS applications.

Express Logon Feature

Express Logon Feature (ELF) is an enhanced logon solution that is provided by IBM host access products Host on Demand (HoD) and Personal Communications. ELF is also referred to as certificate-based logon. ELF enables you to log on to host applications using an X.509 certificate for authentication. For more information, see "What DCAS provides" and Appendix C, "Express Logon Feature," on page 1489.

Web Express Logon

Web Express Logon (WEL) is a single-signon solution that is provided by IBM host access products Host on Demand (HoD) and Host Access Transformation Services (HATS). WEL enables end-users that have already been authenticated, by Web-based logon for example, to log on to their host-based applications without having to re-authenticate by entering a user ID and password. In this case, the host access product communicates with the DCAS server to obtain a PassTicket. For more information on HoD, see *Web Express Logon Reference*. For more information on HATS, see *Host Access Transformation Services User's and Administrator's Guide*.

Using the DCAS server interface for your logon solutions

DCAS provides an open interface for clients to connect using TCP/IP to obtain information that can be used in providing enhanced host logon solutions. For details on interfacing with DCAS, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

What DCAS provides

In general, DCAS provides a service for returning a PassTicket. A PassTicket is like a password and can be used to log on to z/OS applications. RACF provides PassTicket support using the PTKTDATA class. To understand PassTickets and using the secured signon function, see *z/OS Security Server RACF Security Administrator's Guide*. The type of information DCAS returns depends upon the type of information requested by the client. Also, DCAS configuration controls what type of information is allowed to be provided.

DCAS provides two types of information:

- Certificate-based

Given an x.509 certificate and an application ID, DCAS returns the user ID that has been mapped to the certificate in RACF and a PassTicket. This can be used by logon services that want to provide certificate-based logons. In this case, the certificate provided must be associated with a valid user ID in RACF. For information on using RACDCERT to administer certificates, see *z/OS Security Server RACF Security Administrator's Guide*. This support is used by IBM's Express Logon Feature (ELF) for the 3-tier solution.

- User ID-based

  Given a user ID and an application ID, DCAS returns a PassTicket. In this case, the end-user should already have been authenticated using a method such as Web-based sign on, and the logon solution provider must ensure this authentication prior to requesting the PassTicket. This support is used by IBM's Web Express Logon (WEL).

Requirements:

- You must configure the DCAS server. For details on configuring DCAS, see *z/OS Communications Server: IP Configuration Reference*. The DCAS server must be configured to support the IBM logon solution that you want, or when using it for a general or third-party solution, must be configured to return the information that the client requires. This requires that the system administrator that is configuring DCAS and the logon service provider using DCAS work together. The SERVERTYPE configuration statement in the DCAS server profile determines the type of information that DCAS can provide to connecting clients and services (certificate-based, user ID-based, or both).
- DCAS requires all clients to connect using SSL and the client must be authenticated. DCAS uses IBM System SSL. Review the CLIENTAUTH parameter in the DCAS configuration profile for determining the level of DCAS client authentication. To understand how to configure SSL key rings and certificates for DCAS, see Appendix B, "TLS/SSL security," on page 1461.
- For all supported configurations, DCAS provides a PassTicket for z/OS applications that are targets for express logon. For these applications, a PassTicket data profile must be defined. RACF provides PassTicket support using the PTKTDATA class. For more information, see "Define PassTicket profiles to RACF" on page 1479.

Chapter 33. Miscellaneous server

The Miscellaneous (MISC) server is a server that can be used to test and debug applications.

The MISC server supports the 3 protocols described in RFCs 862, 863, and 864:
- Discard
- Echo
- Character Generator

Discard protocol

The MISC server simply throws away any data it receives. A TCP-based server listens for TCP connections on TCP port 9. If a connection is established, the data is discarded and no response is sent. A UDP-based server listens for UDP datagrams on UDP port 9. When a datagram is received, it is discarded and no response is sent.

Echo protocol

The MISC server returns to the originating application any data that it receives. A TCP-based server listens for TCP connections on TCP port 7. Once a connection is established, any data that is received is sent back to the originating application. A UDP-based server listens for UDP datagrams on UDP port 7. When a datagram is received, the data it contained is sent back as an answering datagram.

Character generator protocol

The MISC server sends a repetitive stream of character data without regard to its content. A TCP-based server listens for TCP connections on TCP port 19. When a connection is established, a stream of data is sent to the connecting application. Any data that is received is thrown away. A UDP-based server listens for UDP datagrams on port 19. When a datagram is received, an answering datagram is sent that contains a random number (between 0 and 512) of characters. The data in the received datagram is ignored.

The data that is generated follows an ordered sequence. It repeats a pattern of 94 printable ASCII characters in a ring, so that character number 0 follows character number 94.

Following is an example of the repeated pattern.

```
!"#$%&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefgh
"#$%&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghi
#$%&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghij
$%&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijk
%&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijkl
&'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklm
'()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmn
()*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmno
)*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnop
*└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopq
└,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqr
,-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrs
-./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrst
./0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstu
/0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuv
0123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvw
123456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwx
23456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxy
3456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz
456789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{
56789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|
6789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|}
789:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|}~
89:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|}~
9:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|}~ !
:;◄=►?@ABCDEFGHIJKLMNOPQRSTUVWXYZ[\]¬_`abcdefghijklmnopqrstuvwxyz{|}~ !"
```

Configuring the MISC server

1. Specify AUTOLOG and PORT statements in *hlq*.PROFILE.TCPIP.
2. Update the MISC server cataloged procedure (MISCSERV).

Step 1: Configuring PROFILE.TCPIP for the MISC server

To allow the MISC server to start automatically when TCPIP is initialized, include the member name of the MISC server cataloged procedure in the AUTOLOG statement in the *hlq*.PROFILE.TCPIP.

```
AUTOLOG
  MISCSERV
ENDAUTOLOG
```

The AUTOLOG entry in *hlq*.PROFILE.TCPIP is optional. You can choose to start the MISC server manually, when it is needed, using the START command:

```
START MISCSERV
```

The MISC server requires ports 7, 9, and 19 for both TCP and UDP. To ensure that these ports are reserved for the MISC server, verify that they are assigned to the member containing the MISC server cataloged procedure in the PORT statement in PROFILE.TCPIP.

```
PORT
    7 UDP MISCSERV
    7 TCP MISCSERV
    9 UDP MISCSERV
    9 TCP MISCSERV
   19 UDP MISCSERV
   19 TCP MISCSERV
```

For more information on these statements, see the *z/OS Communications Server: IP Configuration Reference*.

Step 2: Updating the MISC server cataloged procedure

Update the MISC server cataloged procedure by copying the sample in SEZAINST(MISCSERV) to your system or recognized PROCLIB and modifying the parameters and data set names to suit your local conditions.

MISC server cataloged procedure (MISCSERV)

```
//MISCSERV PROC MODULE=MISCSRV,PARMS=''
//*
//* TCP/IP for MVS
//* SMP/E Distribution Name: SEZAINST(MISCSERV)
//*
//*        Licensed Materials - Program Property of IBM.
//*        "Restricted Materials of IBM"
//*        5694-A01 (C) COPYRIGHT IBM CORP. 1994, 2003
//*        Status = CSV1R5
//*        Distribution library SEZAINST(MISCSERV)
//*
//MISCSERV EXEC PGM=&MODULE,
//           REGION=4096K,TIME=1440,
//           PARM='&PARMS'
//*
//*        The C runtime libraries should be in the system's link list
//*        or add them to the STEPLIB definition here. If you add
//*        them to STEPLIB, they must be APF authorized.  Change
//*        the name as appropriate for your installation.
//*
//STEPLIB  DD DISP=SHR,
//         DSN=TCPIP.SEZATCP
//SYSPRINT DD SYSOUT=*
//SYSIN    DD DUMMY
//SYSMDUMP DD SYSOUT=*
//*
//*        MSMISCSR identifies an optional data set for NLS support.
//*        It specifies the MISC server message repository.
//*
//*MSMISCSR DD DISP=SHR,
//*         DSN=TCPIP.SEZAINST(MSMISCSR)
//*
//*       SYSTCPD explicitly identifies which data set is to be
//*       used to obtain the parameters defined by TCPIP.DATA
//*       when no GLOBALTCPIPDATA statement is configured.
//*       See the IP Configuration Guide for information on
//*       the TCPIP.DATA search order.
//*       The data set can be any sequential data set or a member of
//*       a partitioned data set (PDS).
//*
//SYSTCPD  DD DISP=SHR,
//         DSN=TCPIP.SEZAINST(TCPDATA)
```

Figure 142. MISC server cataloged procedure (MISCSERV)

Specifying the MISC server parameters

The MISC server generates periodic messages whenever a client sends data to ports 7, 9, or 19. If this server runs continually for a long period of time, considerable amounts of spool space can be consumed. Therefore, the MISC server has all tracing turned off by default.

You can enable the trace options for any of the three MISC server protocols using the PARMS= parameter on the PROC statement of the cataloged procedure. These options will be in effect when the server starts.

TRACE
Turns on tracing for any of the specified protocols and must be followed by one or more of these three keywords:

ECho Specifies tracing for the echo protocol on port 7.

DIscard
Specifies tracing for the discard protocol on port 9.

CHargen
Specifies tracing for the character generator protocol on port 19.

DEbug
Specifies tracing for problem determination .

For example, the following statement turns tracing on for the echo and discard protocols.

```
//MISCSERV PROC MODULE=MISCSRV,PARMS='TRACE ECHO DISCARD'
```

Part 3. Appendixes

Appendix A. Setting up the inetd configuration file

inetd is a generic listener program used by such servers as z/OS UNIX telnet server and z/OS UNIX rexec server. Other servers such as z/OS UNIX ftp server have their own listener program and do not use inetd.

inetd.conf is an example of the user's configuration file. It is stored in the /etc directory. Ensure that the inetd services required on your system are enabled using configuration statements like those in the following example:

```
#=====================================================================
# service | socket | protocol | wait/ | user | server  | server program
# name    | type   |          | nowait|      | program |   arguments
#=====================================================================
#
shell    stream    tcp        nowait  OMVSKERN /usr/sbin/orshd orshd -l
exec     stream    tcp        nowait  OMVSKERN /usr/sbin/orexecd orexecd -lv
otelnet  stream    tcp        nowait  OMVSKERN /usr/sbin/otelnetd otelnetd
# Add the following line to enable Kerberos for orshd
kshell   stream    tcp        nowait  OMVSKERN /usr/sbin/orshd orshd -l -k KRB5
```

Figure 143. Adding applications to /etc/inetd.conf

If the rshd, rexecd, or otelnetd service is to support IPv6 clients, then *tcp6* should be specified instead of *tcp*. Kerberos is not supported for IPv6-enabled services, such as z/OS UNIX Telnet, z/OS UNIX rsh, and z/OS UNIX rexec.

For IPv4 connection partners, the terminal ID passed from INETD to RACF (or an equivalent security program) is an 8-byte hexadecimal character string containing an IPv4 address. For example, the IP address 163.97.227.17 is translated to X'A361E311'. RACF interprets this as a terminal logon address and rejects it if it is not previously defined.

For IPv6 connection partners, only IPv4-mapped IPv6 addresses are handled in this way. The IPv4 address portion of the IPv6 address is placed in the terminal ID for RACF validation. No other IPv6 address format is supported through terminal ID RACF validation.

To establish a relationship between the servers defined in the /etc/inetd.conf file and specific port numbers in the z/OS UNIX environment, insure that statements have been added to ETC.SERVICES for each of these servers. See the sample ETC.SERVICES installed in the /usr/lpp/tcpip/samples/services directory for how to specify ETC.SERVICES statements for these servers.

The traces for both the z/OS UNIX rexec and rsh servers are enabled through options in the inetd configuration file (/etc/inetd.conf):

```
#====================================================================
# service | socket | protocol | wait/ | user | server   | server program
# name    | type   |          | nowait|      | program  |   arguments
#====================================================================
#
shell      stream    tcp       nowait OMVSKERN /usr/sbin/orshd orshd -d   1
exec       stream    tcp       nowait OMVSKERN /usr/sbin/orexecd orexecd -d   2
```

Figure 144. Setting traces in /etc/inetd.conf

The traces are turned on for both servers by passing a **-d** argument to the server programs. 1 is the RSHD server and 2 is the REXECD server. All commands executed after the debug flags have been turned on in the inetd configuration file and the inetd server has reread the file will produce trace output.

The trace is written in formatted form to the syslogd facility name daemon with a priority of debug. The trace data can be routed to a file in your Hierarchical File System by specifying the following definition in your syslogd configuration file (/etc/syslogd.conf):

```
  #
  # All ftp, rexecd, rshd
  # debug messages (and above
  # priority messages) go
# to server.debug.a
#
daemon.debug              /tmp/syslogd/server.debug.a
```

In this example, the trace data is written to /tmp/syslogd/server.debug.a in your Hierarchical File System. For more information on syslogd, see "Logging of system messages" on page 34.

For more information about inetd, see *z/OS UNIX System Services Planning* or *z/OS UNIX System Services Command Reference*.

Appendix B. TLS/SSL security

This appendix is a TLS/SSL reference for the z/OS TN3270E Telnet server (Telnet), the FTP server, and the Digital Certificate Access Server (DCAS). The gskkyman utility and RACF are used as examples for certificate and key ring creation and management. References to RACF apply to any other SAF-compliant security products which contain the required support. Host On Demand V4 running on NT is used as a sample Telnet client.

An overview of Secure Socket Layer (SSL) is given first, followed by the detailed steps needed to perform authentication and encryption at the following levels:

- Using gskkyman
  - Server Authentication only
  - Client Authentication Level 1
- Using RACF
  - Server Authentication only
  - Client Authentication Level 1
  - Client Authentication Level 2
  - Client Authentication Level 3

Additional information about the concepts of cryptography and SSL can be found at the following Web sites:

- http://httpd.apache.org/docs/2.0/ssl/ssl_intro.html
- http://www.verisign.com/ssl/ssl-information-center/how-ssl-security-works/index.html

Secure Socket Layer overview

SSL provides data privacy and integrity as well as server and client authentication based upon a Public Key Infrastructure (PKI) method. PKI requires that the server organization generate a public key/private key pair that can be used during negotiations. PKI requires that data encrypted with the public key be decrypted by only the private key and that data encrypted with the private key be decrypted by only the public key. This is considered an asymmetric encryption method because different keys are used at each end of the secure connection. The Server sends its public key to the client when the client requests a connection.

The client and server encrypt SSL parameter negotiations using the PKI method of encryption. One of the most important items negotiated is the encryption algorithm to be used during data transmission. The algorithm chosen will be one that uses the same key at each end of the secure connection. This is known as a symmetric encryption method and is about 1000 times faster than the asymmetric PKI method used during SSL parameter negotiation. The encryption key used by the symmetric encryption method is created and exchanged during SSL negotiation protected by the PKI encryption method.

Some client-server connections support negotiations to determine if the client wants or supports SSL prior to beginning the SSL handshake. Most servers and clients can be configured to immediately start the SSL handshake process or to negotiate whether or not to perform the SSL handshake. See the security

information for the appropriate server or client for information on whether negotiated TLS/SSL is supported and how it is implemented.

The SSL protocol begins with the handshake. During the handshake:

- Server authentication is done by the client.
- Optional client authentication is done by the server.
- An encryption algorithm and single encryption key are chosen to encrypt and decrypt session data between the client and server.

Server authentication

When using SSL to secure communications, the SSL authentication mechanism known as Server Authentication is used. This is the minimum amount of security provided by SSL and allows the client to validate that the Server is what it says it is.

To ensure that someone has not stolen the server's private and public keys and is pretending to be the server, the server sends additional information with the public key so the client can confirm the identity of the server. The complete package of information sent to the client is called a digital certificate which conforms to the X.509 standard.

This X.509 digital certificate includes, among other things, the Distinguished Name (DN) of the Server organization, the public key created by the server organization, the Distinguished Name of the organization issuing the certificate, and the issuer's signature. The organization issuing the certificate may be a well-known Certificate Authority (CA) or you may issue (create) your own certificate, called a self-signed certificate.

To create a signature, the certificate issuer first generates a message digest from the owner's DN, the owner's public key, and the issuer's DN. The message digest is the result of hashing this information down to a small size (usually 128 or 160 bits). The message digest result is unique for that information based on the hashing algorithm used. The message digest is encrypted with the issuer's private key creating the issuer's signature.

When the client receives the server certificate, the client must have the public key of the certificate signer. The public key is used to decrypt the message digest. The server certificate also contains the hashing algorithm used to create the message digest. The client uses the same algorithm to create another message digest using the Distinguished Names and public key information in the received server certificate. If this new message digest exactly matches the decrypted message digest (issuer's signature) created by the certificate issuer, the client can be assured that the certificate has not been altered. This method of authentication is dependent on the security of the private key that is used by the certificate issuer.

To conduct commercial business on the Internet, you should obtain a server certificate signed by a well-known Certificate Authority. Server certificates issued by a well-known CA gives the client high assurance that the server is authentic. Most client key rings have been primed with several well-known CA's certificates. That enables the client to authenticate a Server certificate signed by a well-known CA without having to first obtain the issuer's certificate which includes the public key. For relatively small, private networks within your own enterprise you can create your own self-signed server certificate. The only difference between a CA issued certificate and a self-signed certificate is the issuer's Distinguished Name and who's private key was used to encrypt the message digest. The client needs to

use the correct public key to decrypt the message digest. The CA certificate containing the CA's public key is probably already in the client's key ring and it can be used to decrypt the CA signature (message digest). The self-signed certificate containing the organization's public key needs to be added to the client's list of signer certificates so the client can decrypt the signature (message digest) created when the self-signed certificate was created. Some client products allow the client to add the server certificate to its list of signer certificates when the server certificate is received during SSL negotiation. If the client is confident the certificate really came from the correct server, this is an easy way to add the certificate rather than getting a copy and adding it manually.

For server authentication to work, the server must have a private key and associated server certificate in the server key database file. The gskkyman utility or RACF Common Keyring support can be used to manage the keys and certificates needed for SSL support. If the gskkyman utility was used to create the key ring, a password stash file is also required.

SSL requires a server certificate as part of its server authentication process. The server certificate and the Certificate Authority certificates are stored in a key ring (also referred to as a key database). The server's key ring can be created using the gskkyman utility provided by the System Secure Socket Layer (System SSL) element of z/OS or by using RACF's certificate management support. The key ring is associated with a server or client using server or client specific statements.

Note: Global step-up type certificates are not supported by Telnet profile defined security if the client application sends the handshake complete message to the server before completing the second handshake. AT-TLS enabled Telnet does support global step-up type certificates.

Client authentication

Client authentication provides additional authentication and access control by checking client certificates at the server. This support prevents a client from obtaining a connection without an installation approved certificate.

The server authenticates the client by receiving the client's certificate during the SSL handshake and verifying the certificate is valid. Validation is done by the server the same way the client validates the server's certificate. The client sends a signed certificate to the server. System SSL at the server decrypts the signature (message digest) using the public key of the client certificate issuer found in the server key database file. The server then creates a new message digest using the certificate's Distinguished Names and public key and compares the new message digest with the decrypted one. If they match, the server can be assured the client is authentic. Depending on where the client certificate is stored, up to three different levels of client authentication are available. See the security information for the appropriate server or client for setup details.

Level 1 authentication is performed by system SSL. The client passes an X.509 certificate to the Server as part of the SSL Handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server. That is, the certificate for the CA must be in the key ring used by the Server and designated as trusted. Note that the value of this option alone is based on which CAs are considered trusted. If the CA is a public CA and the certificate is in an easily obtained class, anyone can obtain such a certificate. In this case passing level 1 SSL Client Authentication does not provide much additional security unless coupled with the level 2 RACF support. If the CA is

controlled by the enterprise, some level of access control is provided because the client that possesses such a certificate is at least known to the organization.

Level 2 authentication requires that the client certificate be registered with RACF (or other SAF compliant security product) and mapped to a user ID. This is in addition to the checking done with the first level of client authentication support. The client certificate received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system prior to connection negotiation. This level of support provides additional access control at the server and ensures that the end user is known to have a valid user ID on the server host. Each server uses the returned user ID in a different way. See the security information for the appropriate server or client to see how the user ID is used for a particular server. Level 1 authentication is performed prior to level 2 authentication.

Level 3 authentication provides, in addition to level 1 and level 2 support, the capability to restrict access to the server based on the user ID returned from RACF. In some cases a certificate may be valid and mapped to a user ID but should be valid for only one of several servers. The third level of control uses the SERVAUTH RACF class to restrict access to the server based on client user ID. If the SERVAUTH class is not active or the SERVAUTH profile for the server is not defined, it is assumed level 3 authentication is not requested. If the SERVAUTH class is active and the server profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is in the profile. Otherwise, the connection is dropped. See “Add user IDs to the SERVAUTH profile access list” on page 1478 for RACF setup details.

To enable Client Authentication for each server, use the following server-specific statements:

SERVER TYPE	**FTP**	**Telnet**	**DCAS**
STATEMENT	**SECURE_LOGIN**	**CLIENTAUTH**	**CLIENTAUTH**
AUTH LEVEL 1	REQUIRED	SSLCERT	LOCAL 1
AUTH LEVEL 2	VERIFY_USER	SAFCERT	LOCAL 2
AUTH LEVEL 3	VERIFY_USER	SAFCERT	LOCAL 3

Level 1 client authentication is done by SSL using a gskkyman key ring or a RACF key ring. If the client certificate was issued by a well-known Certificate Authority, it is likely the CA certificate is already primed in the gskkyman key ring. The CA certificate is probably also in RACF. However, all CA certificates in RACF initially have a status of NOTRUST. The CA certificate must be set to TRUST and connected to the appropriate RACF key ring. See “Update CA certificates to TRUST status” on page 1475 for detailed information. If the certificate issuer (a CA or self-signed) is not part of the list of well-known CAs, the key ring must be primed with the signer certificate of the CA or the self-signed client certificate.

After Level 1 authentication is performed by SSL using either key ring, the certificate is passed to the server which accesses the RACF database for Level 2 and Level 3 authentication.

Encryption algorithms

After authentication is performed, the client and server must agree on a symmetric encryption method and generate a single encryption key to use for data

encryption. The agreed-on key is exchanged using the PKI method of encryption. Once the symmetric encryption algorithm (such as DES) and a single encryption key are chosen, all data exchanges use this algorithm and key instead of the PKI method of encryption.

In an SSL-encrypted session, all data is encrypted using the symmetric encryption algorithm immediately before it is sent to the client. Data from the client is decrypted immediately after it is received. The encryption algorithm that is used for the connection depends on a combination of the encryption algorithm list the SSL subsystem supports, the list the server wants to use, and the encryption algorithms the client requests. During the SSL handshake the client sends a list of encryption algorithms it is willing to use. The server submits its list and the SSL subsystem picks an algorithm all parties support giving preference to the order specified by the server. If the server does not support any of the encryption algorithms requested by the client, the connection is closed. The Telnet, FTP and DCAS servers and the FTP client use the SSL support provided by the System Secure Sockets Layer (System SSL) element of z/OS. The encryption algorithms supported by the servers and client are therefore dependent on the level of System SSL installed. The following encryption algorithms are supported by the base level of System SSL: NULL, RC2 export, RC4 export, DES. The System SSL Level 3 feature is required for Triple DES and RC4 non-export (128 bit) encryption algorithms. The encryption algorithm list can be customized for the servers and client to a subset of the System SSL list. See the security information for the appropriate server or client for specific server and client statements used for encryption list creation.

Encryption is provided either by BSafe software shipped with System SSL or by hardware. There is no TCP profile definition that controls whether the cryptographic hardware will be used for secure connections. When SSL initialization has completed, System SSL checks if ICSF is installed and active and if the hardware is enabled and loaded with the necessary Master Keys. If the hardware is not available at that time, all subsequent encryption is performed using software. If hardware is valid and ICSF is active at that time, the public key functions required during the SSL handshake and requests for encryption using DES and Triple-DES algorithms will be sent to the hardware. Otherwise, all cryptographic functions will be performed by software. Encryption requests using RC2 or RC4 algorithms are always performed by software. Also note that if ICSF subsequently becomes unavailable, System SSL will assume the hardware encryption is still wanted and encryption processing using DES or Triple-DES algorithms will fail until access to the hardware is restored. If subsequent session handshakes are attempted, they will also fail. Completion of SSL initialization is different for each server and client. See the security information for the appropriate server or client to understand when SSL initialization is complete and how to refresh SSL.

If hardware encryption is to be used, be sure that the RACF user ID associated with the server has read access to the RACF CSFSERV class resources. If ICSF is available but the server has not been given access to these resources, the SSL initialization may fail. The reason code is likely to be 4 (bad password) because System SSL will attempt to use the hardware encryption during processing of the key ring.

Enable CSFSERV resources

If hardware encryption and ICSF are installed, system SSL verifies that the user ID associated with the server is permitted to use CSFSERV resources. The RACF administrator should permit the RACF user ID to use the CSFSERV resources described here.

```
PERMIT service-name CLASS(CSFSERV) ID(serverid) ACCESS(READ)
```

The following CSFSERV resources (service-names) are accessed by System SSL.

1. CSFCKI Clear Key Import
2. CSFCKM Clear Key Import Multiple
3. CSFDEC DES and TripleDES Decipher
4. CSFENC DES and TripleDES Encipher
5. CSFOWH MD5 and SHA1 Hashing
6. CSFRNG Random Number Generate
7. CSFPKB RSA Key Token Build
8. CSFPKX RSA Public Key Extrace
9. CSFPKE RSA Public Key Encipher
10. CSFPKD RSA Private Key Decipher
11. CSFPKI RSA Key Import
12. CSFDSG Digital Signature Generate
13. CSFDSV Digital Signature Verify

z/OS FTP users can either permit every FTP client user ID to these general resource profiles, or they can mark these profiles as delegated and permit only the FTP daemon user ID to the profiles.

In the following example, resource CSFENC in class CSFSERV is delegated, and only the FTP daemon user ID (FTPD for this example) needs to be permitted. Make these changes before starting FTPD.

```
Permit the FTP daemon to the resource:
     PERMIT CSFENC CLASS(CSFSERV) ID(FTPD) ACCESS(READ)
Mark the resouce profile as delegated:
     RALTER CSFSERV CSFENC APPLDATA('RACF-DELEGATED')
Refresh the CSFSERV class:
     SETROPTS RACLIST(CSFSERV) REFRESH
```

For more examples, see the EZARACF sample in SEZAINST. For more information on authorizing daemons to use delegated resources, see *z/OS Security Server RACF Security Administrator's Guide*.

The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data using ICSF/MVS. Set this option to 65527 or greater, because this is the maximum TCP/IP packet size.

The System SSL GSKSRVR server provides the capability to determine whether cryptographic hardware is being used through its DISPLAY CRYPTO operator command (for example, f gsksrvr,d crypto). The System SSL GSKSRVR server is not automatically started. For additional information on the SSL started task and setting up and using the GSKSRVR server, see *z/OS Cryptographic Services System SSL Programming*.

For additional information on controlling who can use cryptographic keys and services, see *z/OS Cryptographic Services ICSF Administrator's Guide*.

Creating and managing keys and certificates at the server

The gskkyman utility or RACF Common Keyring support can be used to manage the keys and certificates needed for SSL support.

The following table describes the steps necessary to implement the different levels of SSL security for each key ring management product.

		Key ring management product	
SSL function	**Steps**	**gskkyman**	**RACF**
Server Auth	1. Create a key ring file 2. Create a server certificate **If server certificate is self-signed** 3. Extract server certificate from server key ring 4. Add server certificate to client key ring	1. Page 1470 2. Page 1471 3. Page 1473 4. Page 1485	1. Page 1476 2. Page 1476 3. Page 1477 4. Page 1485
Client Auth Level 1	1. Set up server authentication **If client certificate is self-signed** 2. Extract client certificate from client key ring 3. Add client certificate to server key ring	1. See above 2. Page 1482 3. Page 1474	1. See above 2. Page 1482 3. Page 1474
Client Auth Level 2	1. Set up server authentication 2. Set up level 1 authentication 3. Associate certificate to RACF User ID[1]	1. See above 2. See above 3. Page 1478	1. See above 2. See above 3. Page 1478
Client Auth Level 3	1. Set up server authentication 2. Set up Level 1 authentication 3. Set up Level 2 authentication 4. Add User IDs to the server's SERVAUTH profile access list	1. See above 2. See above 3. See above 4. Page 1478	1. See above 2. See above 3. See above 4. Page 1478
Express Logon Feature	1. Set up server authentication 2. Set up level 1 authentication (optional for DCAS) 3. Set up Level 2 authentication (optional for DCAS) 4. Define PassTicket profiles	1. See above 2. See above 3. See above 4. Page 1479	1. See above 2. See above 3. See above 4. Page 1479

1. The gskkyman utility cannot associate a user ID with a client. If gskkyman is used for key ring and certificate management, a second security product is needed to associate the certificate to a user ID. In this example, RACF is used for the association while system SSL continues to use gskkyman.

Certificate file types

This information mentions several certificate formats. Below is a high level summary of the differences.

- PKCS12 files are used to move the server certificate to another server key ring. Because this format contains the private key, the file is usually password protected. IBM recommends only using this format when required.
  - Commonly used file extension is .p12
  - Contains private key, public key and certificate
  - Created by
    - HOD export function

      When the HOD client specifies a client certificate to send to the server during SSL processing, it must be in this format. The private key portion is not sent to the server.
    - Netscape export function
    - gskkyman "Export keys to a PKCS12 file" function
- Certificate files are normally needed when a self-signed certificate is used. In this case, each self-signed certificate appears to be signed by a unique CA. Therefore, the client's key ring (if this is a self-signed server certificate) or server's key ring (if this is a self-signed client certificate) must be primed to recognize the issuer of the self-signed certificate. This format can be used to prime a key ring with the issuer's CA certificate. This format can also be used when registering a client certificate with RACF.
  - Commonly used file extensions are .crt and .der
  - Contains public key and certificate
  - Created by
    - HOD extract function
    - gskkyman's "Create a self-signed certificate" function

Common terminology

The following variable names are used throughout the appendix:

tnserverid
: The user ID defined to RACF given superuser status that is associated with the job started for Telnet. This is the job name of the stand-alone Telnet application.

dcasserverid
: The user ID defined to RACF given superuser status that represents the Digital Certificate Access Server.

ftpserverid
: The user ID defined to RACF given superuser status that represents the FTP daemon and all spawned FTP Servers.

serverid
: The user ID defined to RACF given superuser status that represents any of the servers above.

userid The user ID that is associated with a client certificate in the RACF key ring database. Or the TSO user ID that requires authority to issue certain RACF commands.

Copying z/OS UNIX files to MVS data sets

Certificate and database files are often stored in z/OS UNIX file system formats and sometimes need to be copied into MVS data set formats. MVS data sets can be created from z/OS UNIX files by using the TSO OGET command with the BINARY option and can be protected using RACF. For example:

```
OGET '/tmp/telnet/mvs180.kdb' 'TCPCS6.MVS180.KDB' BINARY
OGET '/tmp/telnet/mvs180.sth' 'TCPCS6.MVS180.STH' BINARY
```

The MVS data set names should be the z/OS UNIX file names prefixed by one or more high-level qualifiers. The same high-level qualifiers must be used for both the key ring and the stash file. This ensures that the name relation used to generate the stash file from the key ring file is unchanged. See *z/OS UNIX System Services Command Reference* for more information on the use of the OGET command.

Using the gskkyman utility

This topic gives examples of how to use the gskkyman utility to:

- Create key rings
- Create a server self-signed certificate
- Extract a server certificate
- Add client certificates into a key ring

The gskkyman utility is a command-line utility. It prompts you for the information you need to perform a task. If you make an error, it issues a message and prompts you again for the information.

The gskkyman utility is documented in *z/OS Cryptographic Services System SSL Programming*. You should read the gskkyman information there before starting to use gskkyman.

Additional information and examples can also be found in the following IBM Redbooks:

- *SecureWay Communications Server for OS/390 V2R8 TCP/IP: Guide to Enhancements*
- *IBM SecureWay Host On-Demand 4.0: Enterprise Communications in the Era of Network Computing*

To run gskkyman, you must have access to the z/OS Cryptographic Services message catalogs and DLLs. The C DLL Library (that is, SYS1.SCLBDLL) must be available and APF authorized to avoid possible abends caused by trying to access a nonexisting or non-APF authorized system. For example, if the z/OS Cryptographic Service DLL library is not part of the linklist concatenation, an "export STEPLIB=SYS1.SIEALNKE" command might be needed. For additional information, see *z/OS Cryptographic Services System SSL Programming*.

The gskkyman utility is shipped with z/OS in System SSL as a part of the Cryptographic Services Base element of z/OS. It supports the generation of key sizes of 1024 or 2048 bits. Note that if you have existing keys with a size of 512, these keys are still usable. The gskkyman utility runs under the z/OS shell and can create several types of z/OS UNIX files. System SSL requires the following files:

- A key ring file (also known as a key database).
- A password file (also known as a stash file) which contains the password associated with the key ring file.

The key ring file and the stash file are used by the server to obtain the server's certificate and the public/private key pair used during SSL handshake processing. The server uses the stash file as the mechanism to obtain the key ring password rather than using a configuration parameter which might be accessible to a larger number of people. The stash file is created by using gskkyman's 'Store encrypted database password' function on the main menu.

Security of these files is an installation responsibility. It is recommended to restrict the file access to users with superuser authority.

The server must have read and write access to the key database and read access to the password file.

Note: The gskkyman utility accepts only the z/OS UNIX files.

The gskkyman utility allows you to enter the fully qualified path and file name when it prompts you for a key ring, certificate request, or certificate file name. However, you should change to the path where the file will be stored before you start gskkyman.

Create a key ring file

Before starting gskkyman, we suggest that you start in the directory where the key ring is to be created. Otherwise, be sure to include the full file name when specifying the key ring name.

1. Start gskkyman. This will display the *Database Menu*. Select *Create new database* (option 1).
2. Specify the key database name, password, and expiration information as requested.
3. Create a password file (also known as a stash file) by selecting *Store database password* (option 10) from the *Key Management Menu*.

Following is a sample of the gskkyman output for creating a key database. Sample user replies are shown in **bold** characters.

1. The *Database Menu* that starts the process for creating a key database is shown below. Select the *Create new database* option.

```
       Database Menu

   1 - Create new database
   2 - Open database
   3 - Change database password
   4 - Change database record length
   5 - Delete database

   0 - Exit program

Enter option number: 1
```

2. Specify the key database name, password, and expiration information as requested.

```
Enter key database name (press ENTER to return to menu): server.kdb
Enter database password (press ENTER to return to menu):
Re-enter database password:
Enter password expiration in days (press ENTER for no expiration): 365
Enter database record length (press ENTER to use 2500):

Key database /SYSTEM/usr/keyring/server.kdb created.

Press ENTER to continue.
```

3. Pressing enter brings up the *Key Management Menu* as follows. Create the password file by selecting the *Store database password* option.

```
    Key Management Menu

  Database: /SYSTEM/usr/keyring/server.kdb

   1 - Manage keys and certificates
   2 - Manage certificates
   3 - Manage certificate requests
   4 - Create new certificate request
   5 - Receive certificate issued for your request
   6 - Create a self-signed certificate
   7 - Import a certificate
   8 - Import a certificate and a private key
   9 - Show the default key
  10 - Store database password
  11 - Show database record length

   0 - Exit program

Enter option number (press ENTER to return to previous menu): 10
Database password stored in /SYSTEM/usr/keyring/server.sth.

Press ENTER to continue.
```

Pressing enter returns you to the *Key Management Menu*. You can proceed to create your server certificate or exit.

Create a server self-signed certificate

See the gskkyman documentation for the steps necessary to create a CA-signed server certificate. With gskkyman, you can create your own self-signed certificate for testing:

1. From the *Database Menu*, open your key ring file (Option 2–*Open database*). From the *Key Management Menu*, select *Create a self-signed certificate* (option 6).
2. Specify the certificate type to be created from one of the end user certificate options. The type of end user certificate created depends on the security requirements of your installation.
3. Specify the label, subject name, and length of time the certificate is valid as requested.
4. After the certificate is created, set the certificate as the default by selecting *Manage keys and certificates* (option 1), selecting the certificate you created, followed by selecting *Set key as default* (option 3).

The following is a sample of the gskkyman output for creating a self-signed certificate. Sample user replies are shown in **bold** characters.

1. The *Key Management Menu* that starts the process for creating a self-signed certificate is shown below. Select *Create a self-signed certificate* (option 6).

```
     Key Management Menu

     Database: /SYSTEM/usr/keyring/server.kdb

 1 - Manage keys and certificates
 2 - Manage certificates
 3 - Manage certificate requests
 4 - Create new certificate request
 5 - Receive certificate issued for your request
 6 - Create a self-signed certificate
 7 - Import a certificate
 8 - Import a certificate and a private key
 9 - Show the default key
10 - Store database password
11 - Show database record length

 0 - Exit program

Enter option number (press ENTER to return to previous menu): 6
```

2. The *Certificate Type* menu will be displayed. Select one of the server certificate types. Make sure you pick a certificate type that your client applications support.

```
       Certificate Type

   1 - CA certificate with 1024-bit RSA key
   2 - CA certificate with 2048-bit RSA key
   3 - CA certificate with 4096-bit RSA key
   4 - CA certificate with 1024-bit DSA key
   5 - User or server certificate with 1024-bit RSA key
   6 - User or server certificate with 2048-bit RSA key
   7 - User or server certificate with 4096-bit RSA key
   8 - User or server certificate with 1024-bit DSA key

Select certificate type (press ENTER to return to menu): 5
```

3. You will then be asked for the certificate data and the certificate will be created.

```
Enter label (press ENTER to return to menu): selfsignedcert
Enter subject name for certificate
  Common name (required): test server certificate
  Organizational unit (optional): dev
  Organization (required): dev
  City/Locality (optional):
  State/Province (optional):
  Country/Region (2 characters - required): US
Enter number of days certificate will be valid (default 365): 5000

Please wait .....

Certificate created.

Press ENTER to continue.
```

4. Make the self-signed certificate the default server certificate. Pressing enter returns you to the *Key Management Menu* shown in step 1 above. Select *Manage keys and certificates* (option 1). This will bring up the *Key and Certificate List* menu shown below. Select the number that corresponds to the self-signed certificate just created.

```
       Key and Certificate List

       Database: /SYSTEM/usr/keyring/server.kdb

   1 - selfsignedcert

   0 - Return to selection menu

Enter label number (ENTER to return to selection menu, p for previous list): 1
```

This will bring up the *Key and Certificate Menu*. Select *Set key as default* (option 3).

```
       Key and Certificate Menu

       Label: selfsignedcert

   1 - Show certificate information
   2 - Show key information
   3 - Set key as default
   4 - Set certificate trust status
   5 - Copy certificate and key to another database
   6 - Export certificate to a file
   7 - Export certificate and key to a file
   8 - Delete certificate and key
   9 - Change label

   0 - Exit program

Enter option number (press ENTER to return to previous menu): 3

Default key set.
```

To use the new default server certificate, the server must reinitialize its SSL environment. See the security information for the appropriate server or client for SSL initialization details. The self-signed server certificate will need to be added to the client's key database as a CA. For additional information, see "Extract the server certificate from the key ring."

Extract the server certificate from the key ring

If using a self-signed server certificate, the server certificate must be added to the client's key database as a CA certificate. Some clients provide the capability to extract the server's certificate when the client connects to the server. For some clients, however, this process must be done manually by exporting the server's certificate to a file, sending the server's certificate file to the client, and adding the server's certificate to the client's key database.

The server certificate can be exported to a file from the *Key and Certificate Menu*. If you have just opened your key ring file and are at the *Key Management Menu*, select *Manage keys and certificates* (option 1) and select the certificate you want to export from the list. You will then see the *Key and Certificate Menu*.

1. Select *Export certificate to a file* (option 6).
2. Specify the desired format and file name.

The following is a sample of the gskkyman output for exporting a certificate. Sample user replies are shown in **bold** characters.

1. The *Key and Certificate Menu* that starts the export process follows. Select *Export certificate to a file* (option 6).

```
       Key and Certificate Menu

       Label: selfsignedcert

   1 - Show certificate information
   2 - Show key information
   3 - Set key as default
   4 - Set certificate trust status
   5 - Copy certificate and key to another database
   6 - Export certificate to a file
   7 - Export certificate and key to a file
   8 - Delete certificate and key
   9 - Change label

   0 - Exit program

Enter option number (press ENTER to return to previous menu): 6
```

2. The *Export File Format* menu is displayed, and you will be asked to select the export format and to enter a file name.

```
       Export File Format

   1 - Binary ASN.1 DER
   2 - Base64 ASN.1 DER
   3 - Binary PKCS #7
   4 - Base64 PKCS #7

Select export format (press ENTER to return to menu): 1
Enter export file name (press ENTER to return to menu): binservercert.der

Certificate exported.
```

   If using ftp to send the export file to the client, remember to send in binary format if the file format chosen above was binary.

Add client certificates to the server key ring

If using a client self-signed certificate, the certificate must be added to the server key ring as a CA certificate. Send the client certificate to the MVS host using FTP (with the BINARY send option if the certificate was extracted in binary format). The client may be the DCAS client (DCAR), FTP client, or Telnet client. Use gskkyman's 'Import a certificate' option to obtain the client CA from the binary DER file. If the client certificate was issued by a well-known CA, only the signer's certificate needs to be in the key ring. The gskkyman utility primes its key rings with several well-known CAs.

Using RACF's Common Keyring support

This topic gives examples of how to use RACF Common Keyring support to:

- Create key rings
- Create a server self-signed certificate
- Extract a server certificate
- Add client certificates into a key ring

RACF can be used to manage the keys and certificates normally stored in the key database. All the functions that the gskkyman utility provides, are also available in

the RACF support. However, because RACF can manage multiple key rings, certificates and key rings are added independently. A certificate is then connected to one or more key rings.

All the server key rings and certificates are stored in the RACF database. There are no separate key database or stash files.

See *z/OS Security Server RACF Security Administrator's Guide* for information about how to use RACF to manage your key database information.

For detailed information on the RACDCERT command and other commands that might be useful in managing your RACF key ring data, see *z/OS Security Server RACF Command Language Reference* for the full syntax and description of these commands.

RACF key ring names, labels, and so on are case sensitive. When adding the key ring name to the server profile, be sure that the correct case is used.

Before using RACF to store your key database information:

1. Ensure that RACDCERT is defined as an authorized TSO command in the IKJTSOxx member.
2. The well-known CA certificates are initially marked as NOTRUST in the RACF database and you will have to update the CA certificates that you plan to support to TRUST status.
3. Refresh the applicable RACF class after making changes.
4. There are various ways to register the client certificate with RACF or set up a RACF Certificate Name Filter. For a complete description of RACF management of digital certificates and options available, see *z/OS Security Server RACF Security Administrator's Guide*. If using RACF's Certificate Name Filtering with MultiID filters, Telnet client authentication processing only matches filters that specify generic (*) criteria.
5. Most tasks related to certificates are managed using the RACDCERT command. The issuer of these commands must have appropriate RACF authority to the IRR.DIGTCERT.function resource in the FACILITY class with UPDATE, CONTROL, or READ ACCESS. See *z/OS Security Server RACF Security Administrator's Guide* for more information on controlling the use of the RACDCERT command and for a complete description of functions needed for key ring and certificate use.
6. For best performance, consider RACLISTing the DIGTCERT and DIGTRING classes.

RACF panels also support most of the certificate and key ring functions and can be used to perform these actions.

Configuring RACF services for the servers

This topic describes some commands needed for configuring RACF for the servers. These commands are in EZARACF in the SEZAINST data set.

Update CA certificates to TRUST status: Several well-known CA certificates are primed in the RACF database but are initially marked NOTRUST. To use the certificate, it must be changed to TRUST status. As an example, the commands below show how to change the Verisign Class 3 CA to trusted status and then connect it to a key ring.

```
RACDCERT CERTAUTH ALTER( LABEL('Verisign Class 3 Primary CA')) TRUST

RACDCERT ID(serverid) CONNECT (CERTAUTH    RING(SERVERKeyring)
      LABEL('Verisign Class 3 Primary CA') USAGE(CERTAUTH)  )
```

Activate the DIGTCERT, DIGTRING, and optional DIGTNMAP classes: The DIGTCERT and DIGTRING classes must be active before defining certificates or key rings to RACF by using the SETROPTS commands. For example:

```
SETROPTS CLASSACT(DIGTCERT)
SETROPTS CLASSACT(DIGTRING)
```

If using Certificate Name Filtering, ensure that the DIGTNMAP class is active. For example:

```
SETROPTS CLASSACT(DIGTNMAP)
```

Also be sure to do a refresh after any changes. For example:

```
SETROPTS RACLIST(DIGTCERT) REFRESH
SETROPTS RACLIST(DIGTRING) REFRESH
SETROPTS RACLIST(DIGTNMAP) REFRESH
```

Allow SSL key ring confirmation: System SSL verifies that the server RACF user ID does have access to the key ring. Therefore, if the server is started as an MVS started procedure, you must permit the RACF user ID associated with the server to have control access to the IRR.DIGTCERT.LISTRING. For example:

```
RDEFINE FACILITY  (IRR.DIGTCERT.LISTRING)  UACC(NONE)
PERMIT  IRR.DIGTCERT.LISTRING  CLASS(FACILITY)  ID(serverid) ACCESS(CONTROL)
```

To access a certificate authority (CA) or site certificate, the server must have control access to the IRR.DIGTCERT.LIST resource in the FACILITY class. For example:

```
RDEFINE FACILITY  (IRR.DIGTCERT.LIST)  UACC(NONE)
PERMIT  IRR.DIGTCERT.LIST  CLASS(FACILITY)  ID(userid) ACCESS(CONTROL)
```

If the server certificate was added as a site certificate, the server must have control access to the IRR.DIGTCERT.GENCERT resource in the FACILITY class. For example:

```
RDEFINE FACILITY  (IRR.DIGTCERT.GENCERT)  UACC(NONE)
PERMIT  IRR.DIGTCERT.GENCERT  CLASS(FACILITY)  ID(userid) ACCESS(CONTROL)
```

If the DCAS is started from a TSO user ID under the z/OS UNIX shell, you must also permit that ID. For example:

```
RDEFINE FACILITY  (IRR.DIGTCERT.LISTRING)  UACC(NONE)
PERMIT  IRR.DIGTCERT.LISTRING  CLASS(FACILITY)  ID(userid) ACCESS(CONTROL)
```

Create a key ring file

Use the following RACF command to add (create) a server key ring and associate it with the server RACF user ID:

```
RACDCERT ID(serverid) ADDRING(SERVERRING)
```

To delete or list a key ring:

```
racdcert ID(serverid) delring(SERVERRING)
racdcert ID(serverid) listring(SERVERRING)
```

Create a server self-signed certificate

See the RACF documentation for the steps necessary to create a CA-signed server certificate. To create a self-signed server certificate called XXXDN, for user ID

serverid, use the following command, where CN is the common name and OU is the organization unit name. Additional options are available within SUBJECTSDN.

```
RACDCERT ID(serverid)  GENCERT  SUBJECTSDN(CN('UNIT1') OU('TESTING') C('US') ) TRUST
  WITHLABEL('XXXDN') SIZE(1024)
```

To connect the certificate to a key ring and make it the default certificate, use the following command. This example assumes a key ring called serverRing has already been created.

```
RACDCERT ID(serverid) CONNECT(ID(serverid)  LABEL('XXXDN') RING(SERVERRING) DEFAULT)
```

Extract a server certificate from a server key ring

If using FTP to send the server self-signed certificate to the client, use RACDCERT Export to export the server certificate to an MVS data set in DER format. The server self-signed certificate must be added to the client key ring to prime it for decrypting the server certificate. EXPORT generally implies exporting both a certificate and private key. However, the CERTDER format instructs the command to export only the certificate in DER format, which is generally considered an EXTRACT. Use the following RACF command:

```
RACDCERT ID(serverid) EXPORT(LABEL('XXXDN')) DSN('dataset name') FORMAT(CERTDER)
```

Add client certificates to the server key ring

If using a client self-signed certificate, the certificate must be added to the server key ring as a CA certificate. Send the client certificate to the MVS host using FTP (with the BINARY send option). The client may be the DCAR, FTP client, or Telnet client. If the client certificate is issued by a well-known CA, only the signer's certificate needs to be in the key ring. The well-known CA certificates are initially marked as NOTRUST and must be updated to TRUST status.

The client self-signed certificate must be registered into the RACF database before the certificate can be associated with a key ring. Associate the certificate to a RACF user ID to register the certificate into RACF. For example, the following command uses the binary DER client certificate in an MVS data set named SSCLNTCERT.USER2.DER, associates it with RACF user ID USER2, and gives it a label of CLNTCERT_USER2:

```
RACDCERT ID(USER2) ADD('SSCLNTCERT.USER2.DER') WITHLABEL('CLNTCERT_USER2') TRUST
```

This command requires that the certificate be defined in an MVS data set. If the certificate is defined in the z/OS UNIX file system, you can use the TSO OGET command (with the BINARY send option) to move the certificate to an MVS data set.

Use the RACDCERT CONNECT command to connect the client certificate to the RACF key ring as a CA certificate. In this example, the RACF user ID associated with the server is serverid and the key ring name used by the server is serverRing:

```
RACDCERT ID(serverid) CONNECT (ID(USER2) RING(serverRing)
  LABEL('CLNTCERT_USER2') USAGE(CERTAUTH) )
```

Be sure to refresh the DIGTCERT and DIGTRING class. For example:

```
SETROPTS RACLIST (DIGTRING) REFRESH
SETROPTS RACLIST (DIGTCERT) REFRESH
```

Reinitialize SSL: Reinitialize the server SSL to pick up the certificates that have been added to the key database. See the security information for the appropriate server or client to understand when SSL initialization is complete and how to refresh SSL.

Add user IDs to the SERVAUTH profile access list

With level 3 authentication, you specify the user IDs that are allowed to connect into a specific Telnet port, DCAS server, or FTP port by associating the user IDs to each server's RACF SERVAUTH profile. See the security information for the appropriate server or client for level 3 setup. The user ID associated with the client certificate can then be checked against the SERVAUTH class profile entry. The use of this RACF class is optional. If the SERVAUTH RACF class is active and a RACF profile for the port is defined, this level of RACF authorization will be verified prior to connection negotiation. If the SERVAUTH class is not active or there is no RACF profile, this indicates that this level of check is not required and the client is allowed to connect to the server as long as the client certificate was validated.

TN3270E Telnet server: The RACF profile name is:

```
EZB.TN3270.sysname.tcpname.PORTnnnnn
```

where nnnnn is the port number with leading zeros. The profile name can contain wildcards to the extent that the security product allows. All security product rules (for example wildcards, PROTECTALL, and so on) apply. For example, the profile name for TCP stack TCPCS running on system MVSA for port 992 would be:

```
EZB.TN3270.MVSA.TCPCS.PORT00992
```

If all systems will use the same access list, and RACF generic profile checking is active for the SERVAUTH class, the following profile name could be used:

```
EZB.TN3270.*.TCPCS.PORT00992
```

To protect all ports with a single profile, the following security product profile name could be used:

```
EZB.TN3270.MVS.TCPCS.PORT*
```

To restrict access on a port basis, the following RACF setup is needed and must be done by a user ID that has authority to issue the specified RACF commands:

- Activate the RACF SERVAUTH class, if not active:
  ```
  SETROPTS CLASSACT(SERVAUTH)
  ```
- Define the profile for the Telnet port:
  ```
  RDEFINE  SERVAUTH   EZB.TN3270.sysname.tcpname.PORTnnnnn  UACC(NONE)
  ```
- Permit the user ID associated with TCP to the port profile:
  ```
  PERMIT EZB.TN3270.sysname.tcpname.PORTnnnnn CL(SERVAUTH) ID(tcpuserid) ACCESS(READ)
  ```
- Ensure the SERVAUTH class is RACLISTed. If it is not, RACLIST it:
  ```
  SETROPTS RACLIST(SERVAUTH)
  ```
- Refresh the SERVAUTH class before using:
  ```
  SETROPTS RACLIST(SERVAUTH) REFRESH
  ```

DCAS: The RACF profile name is:

```
EZA.DCAS.cvtsysname
```

- Activate the RACF SERVAUTH class, if not active:
  ```
  SETROPTS CLASSACT(SERVAUTH)
  ```
- Define the profile:
  ```
  RDEFINE SERVAUTH EZA.DCAS.cvtsysname UACC(NONE)
  ```
- Permit the user ID associated with TCP to the port profile:
  ```
  PERMIT EZA.DCAS.cvtsysname CLASS(SERVAUTH) ACCESS(CONTROL) ID(dcasid)
  ```
- Ensure the SERVAUTH class is RACLISTed. If it is not, RACLIST it:

```
SETROPTS RACLIST(SERVAUTH)
```

- Refresh the SERVAUTH class before using:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Note: The RACF user ID associated with the certificate and the EZA.DCAS.cvtsysname can be any valid user ID.

FTP server: The RACF profile name is:

```
EZB.FTP.sysname.ftpdaemonname.PORTnnnnn
```

where nnnnn is the port number. The profile name can contain wildcards to the extent that the security product allows. All security product rules (for example wildcards, PROTECTALL, and so on) apply. For example, the profile name for FTP daemon FTPD running on system MVSA for port 992 would be:

```
EZB.FTP.MVSA.FTPD.PORT992
```

If all systems will use the same access list and RACF generic profile checking is active for the SERVAUTH class, the following profile name could be used:

```
EZB.FTP.* .FTPD.PORT992
```

To protect all ports with a single profile, the following security product profile name could be used:

```
EZB.FTP.MVS.FTPD.PORT*
```

To restrict access on a port basis, the following RACF setup is needed and must be done by a user ID that has authority to issue the specified RACF commands:

- Activate the RACF SERVAUTH class, if not active:

```
SETROPTS CLASSACT(SERVAUTH)
```

- Define the profile for the FTP port:

```
RDEFINE  SERVAUTH   EZB.FTP.sysname.ftpdaemonname.PORTxxxxx  UACC(NONE)
```

- Permit the user ID associated with the FTP daemon to the port profile:

```
PERMIT EZB.FTP.sysname.ftpdaemonname.PORTnnnnn CL(SERVAUTH)   ID(tcpuserid)  ACCESS(READ)
```

- Ensure the SERVAUTH class is RACLISTed. If it is not, RACLIST it:

```
SETROPTS RACLIST(SERVAUTH)
```

- Refresh the SERVAUTH class before using:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Define PassTicket profiles to RACF

The following recommendations apply when defining PassTicket profiles to RACF:

- Use the SETROPTS CLASSACT(PTKTDATA) command to activate the PTKTDATA class.
- Use the SETROPTS RACLIST (PTKTDATA) command to RACLIST the PTKTDATA class.
- For each application to which users want to gain access with a PassTicket, you must define a PTKTDATA class profile. For example, to give users access to TSO, define a profile for TSO using the following command:

```
RDEFINE PTKTDATA  TSO3050
                  SSIGNON(KEYMASKED(key_value))
                  UACC(NONE)
```

The DIGTNMAP and DIGTCRIT classes support profiles. The application ID used for DIGTCRIT profiles must be the same as that used on the HOD V5 Application ID popup window.

Defining profiles for applications such as TSO can be tricky because RACF has special methods for naming profiles. For more information, see *z/OS Security Server RACF Security Administrator's Guide*.

Add the client certificate to the RACF server key ring and associate the client certificate with a user ID.

Define a PassTicket profile for each application accessed by Express Logon. The application ID portion of the profile must match that configured on the HOD V5 workstation Application ID popup window.

```
SETR  CLASSACT(PTKTDATA)        //* Activate the PassTicket data class
SETROPTS  RACLIST(PTKTDATA)     //* Raclist the class
SETR RACLIST(PTKTDATA) REFRESH
RDEFINE   PTKTDATA  TSO3390  SSIGNON(KEYMASKED(key_value))  UACC(NONE)
```

Migrating an existing gskkyman key database to RACF

To migrate from an existing key database (kdb) created by gskkyman, each certificate that the customer has added must be individually exported and then added to the RACF database. The RACF database is already primed with some well-known Certificate Authorities (CA), so it is not necessary to migrate these CA certificates to RACF. Note however, that the well-known CAs are initially marked as NOTRUST in the RACF database and you will have to update the CA certificates that you plan to support to TRUST status.

To migrate a server certificate from your kdb created by gskkyman to RACF:

1. Use gskkyman to export the certificate and key to a PKCS12 format file:
   a. Open the key database file that you want to migrate.
   b. Select **List/Manage keys and certificates**.
   c. Select the certificate to be exported.
   d. Select **Export the certificate and key to a file**, supply the name of the z/OS UNIX file where the certificate and key will be stored (in PKCS12 format) and enter the password to protect the file when prompted.
2. Use the OGET command described in "Copying z/OS UNIX files to MVS data sets" on page 1468 to create an MVS data set.
3. Add the certificate and key to the RACF database and assign it to a user, if applicable. If this is the server certificate, assign it to the user ID associated with the server. For example:

   ```
   RACDCERT ID(serverid) ADD('Serverid.mycert.p12') WITHLABEL('ServerCert')
   PASSWORD('mypw') TRUST
   ```

You will also need to create a key ring for your server. For example:

```
RACDCERT ID(serverid) ADDRING(serverring)
```

Then connect the appropriate certificates to the key ring. For example, to connect the default server certificate that was migrated above ('ServerCertificate') to the 'serverring' that we associated with serverid:

```
RACDCERT ID(serverid) CONNECT( ID(serverid) LABEL('ServerCert')
RING(ServerRing) DEFAULT )
```

Creating and managing keys and certificates at the client

Normally, a client certificate should be obtained from a well-known Certificate Authority (CA). The Certificate Authority's root certificate needs to be included in the server's key data base as a trusted authority in order for the client's certificate to pass the SSL protocol's client authentication process. If the client certificate has been issued by a well-known CA, the client certificate need not reside in the server's key database. If an installation uses self-signed client certificates for testing purposes, each certificate appears to be issued by a unique CA. Therefore, each self-signed client certificate must be added to the server's key database as a CA.

If you also want verification that the client certificate is registered with your security product, the client certificate must reside in the server's security product database (using the RACDCERT command with the ADD option is one way to add the client certificate to RACF). See “Using RACF's Common Keyring support” on page 1474 for more information on using RACF to store certificates. If the installation is using self-signed client certificates and requests verification that the client certificate is registered with the security product, the client certificate must reside in both the server's key database (as a CA certificate) and in RACF.

Steps to create a self-signed client certificate vary depending on the source of the client certificate. See “Create a self-signed client certificate” for details on creating a client certificate using HOD's Certificate Management utility.

After the client certificate has been created and extracted as a DER data file at the client, FTP the binary DER data file to the z/OS host using FTP's binary option. If using RACF for the key ring, level 2 client authentication, or level 3 client authentication, an MVS data set will need to be created. If FTP created a z/OS UNIX file, use the OGET command described in “Copying z/OS UNIX files to MVS data sets” on page 1468 to create an MVS data set.

Create a self-signed client certificate

See HOD's online documentation for additional details. This sample uses a locally installed HOD V4 client on an NT system using HODs Key Management Utility.

1. On the HOD client, go to HOD's Certificate Management panels (go to Start, Programs, Host On Demand, Administration, Certificate Management.) and open up the key database by selecting the open icon. Usually a key database will exist. If you have never used the key database, it might have a default password (usually ncod - the help menu should contain help information that specifies the default password for your system) or you can select the new option. If new is selected, the correct path and file name will normally be filled in by HOD. Do not change this file name. The HOD key database is normally in HOD's bin subdirectory and named HODClientKeyDb.kdb.

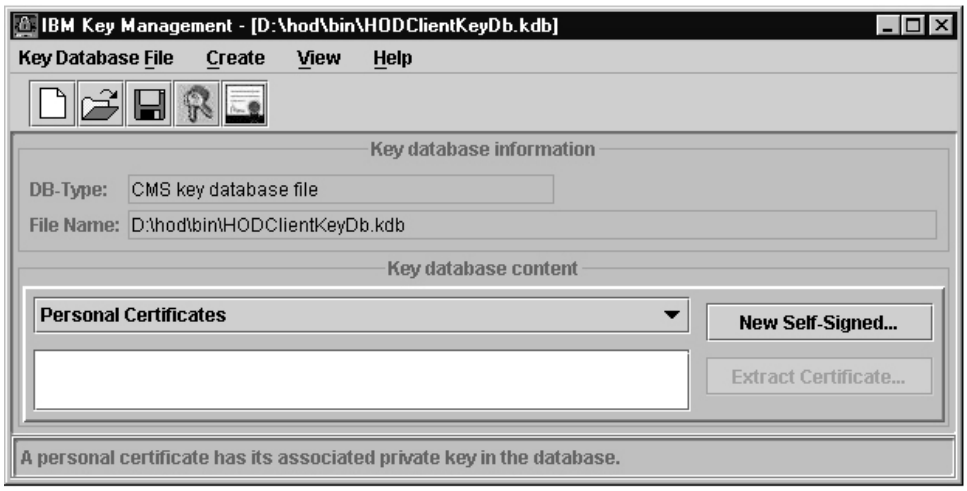

Figure 145. IBM Keys Management

If *Personal Certificates* is not displayed, click the drop-down list arrow and select *Personal Certificates* from the pull-down list.

2. Create a self-signed personal certificate by selecting the *New Self-Signed* button. The *Create New Self-Signed Certificate* screen is displayed.

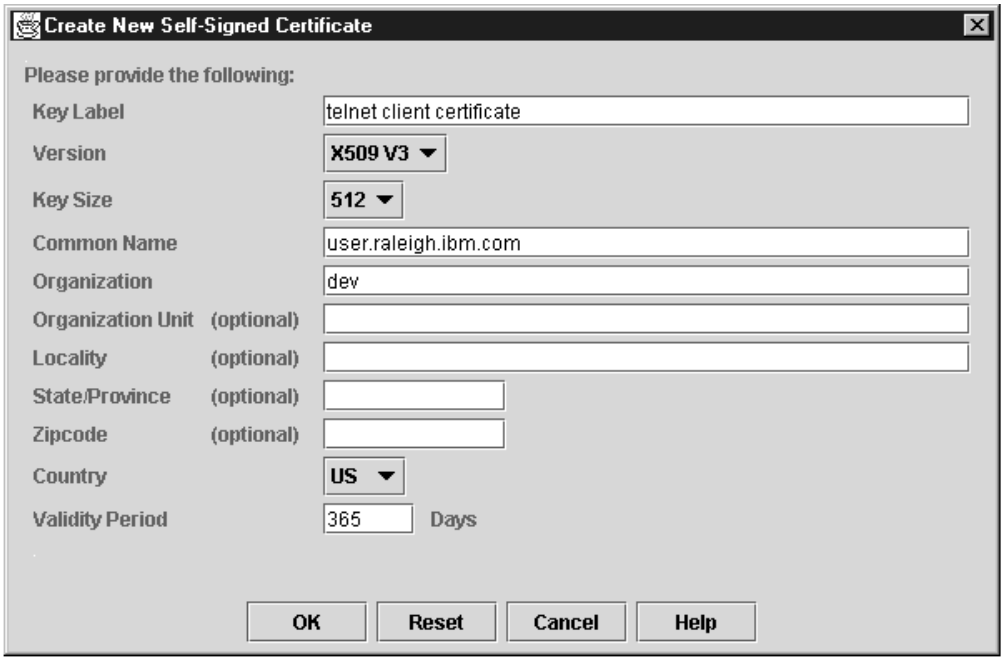

Figure 146. Create New Self-Signed Certificate

Fill in the requested information and then click OK. The new certificates will now be in the personal certificates list.

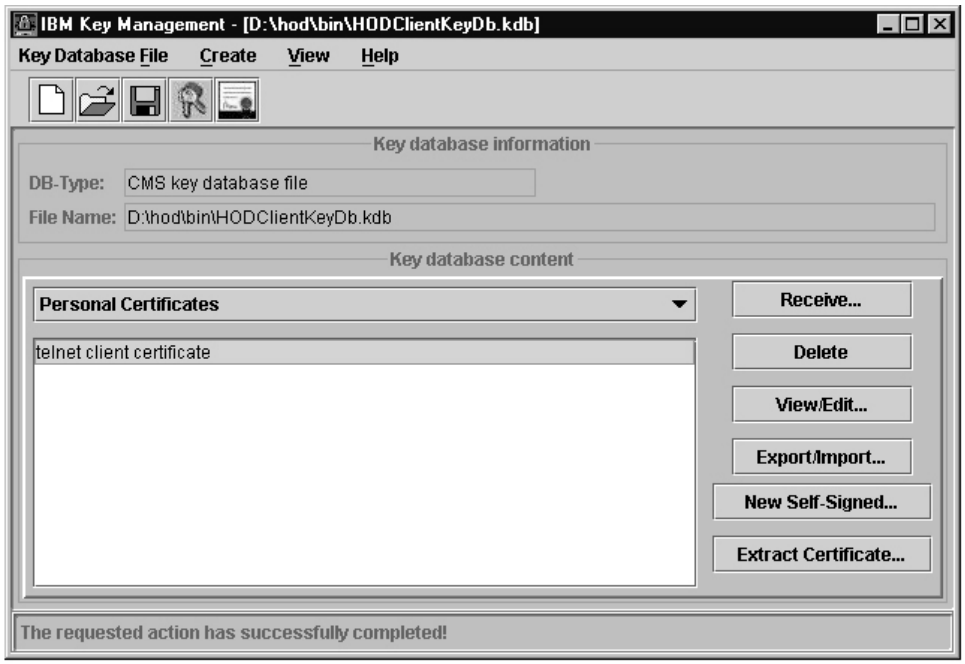

Figure 147. IBM Key Management

3. Use the export function by selecting the Export/Import button to create a PKCS12 file. This is the file that the HOD client will use.

   Specify the path and file where the exported PKCS12 file will be stored and click OK. Enter a password to protect the file when prompted.

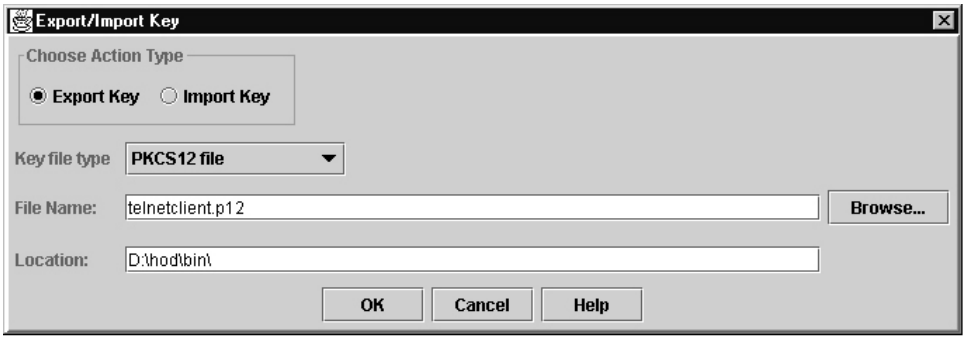

Figure 148. Export/Import Key

4. Create the certificate file that will be used to prime the server's key ring with the CA for the self-signed client certificate.

   Use the Extract Certificate function from the panel shown in Figure 147 to create a binary DER data file. This file will have the format filename.der.

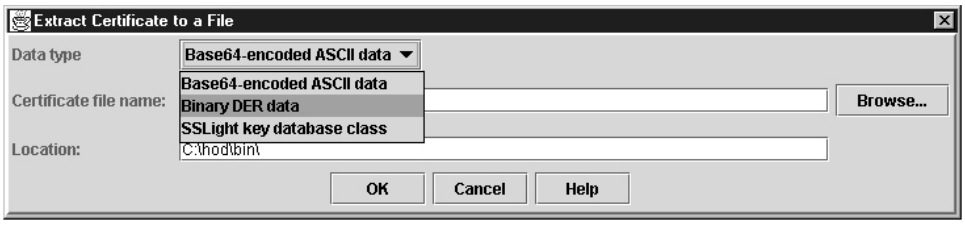

Figure 149. Extract Certificate to a File

Specify the path and file where the exported binary DER file will be stored and click on OK. This is the file you will FTP to the server host.

5. When you start a session from HOD to a port that requires a client certificate, HOD will display a panel that requests the client certificate file and password. The pkcs12 file created in step 3, should be specified.

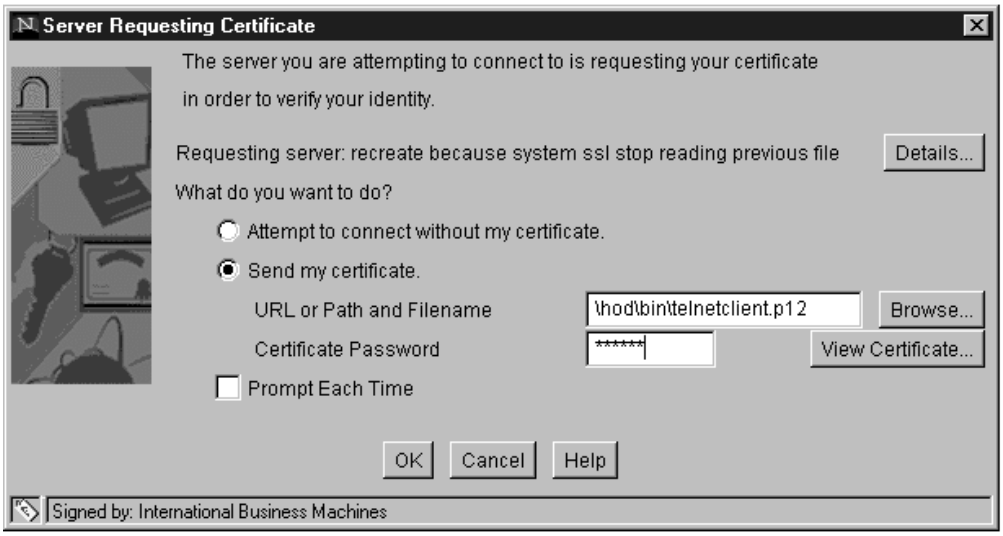

Figure 150. HOD connection using a client certificate

Note: If using HOD and you are connecting to a port that requires a client certificate, the security properties for the connection must indicate that a certificate should be sent. The following example shows the HOD Security properties screen.

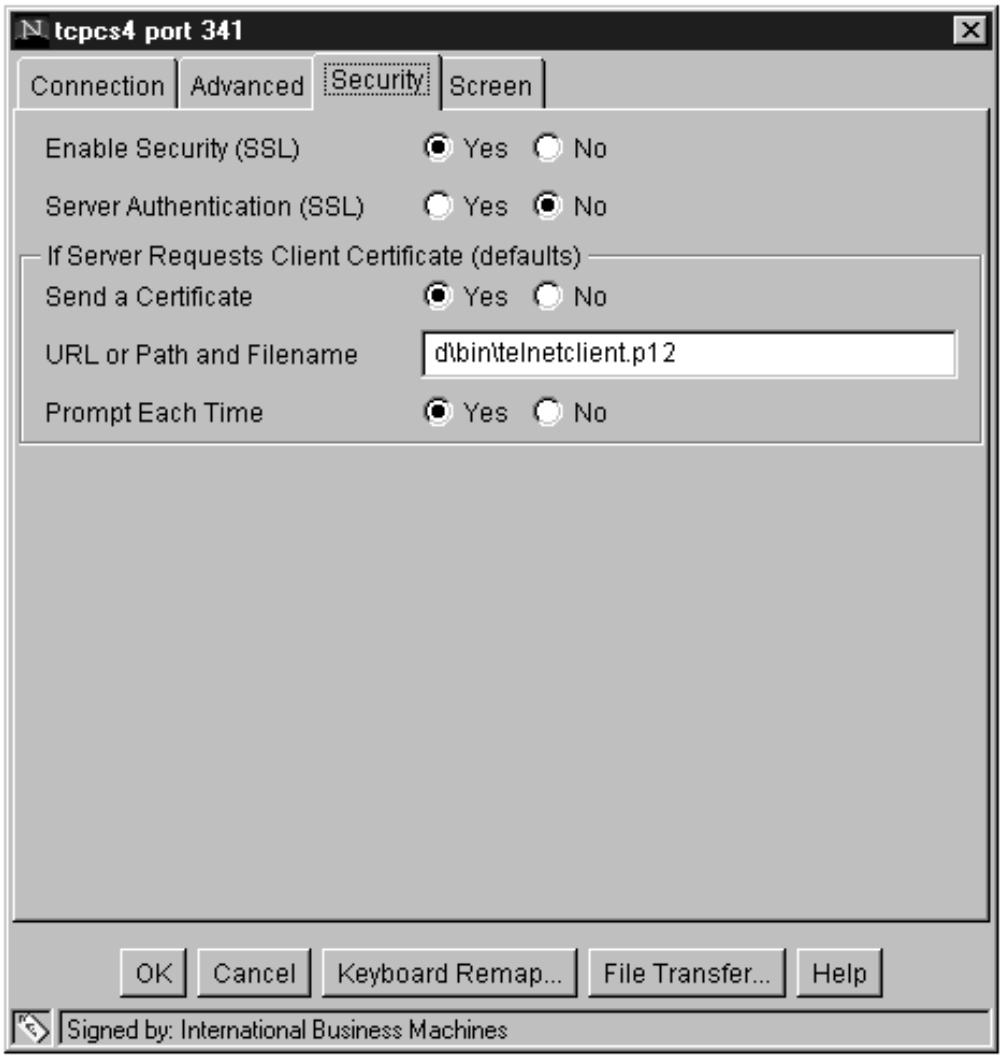

Figure 151. HOD security properties

Add server certificates to the client key ring

1. Get the server certificate information to the client machine.
   - Extract the server certificate from the server key ring. FTP can be used to ship the server certificate file to the client.
   - Newer versions of HOD allow you to extract the server information directly from the HOD client window during connection setup and eliminate the need to FTP the server certificate to the clients. The following is an example of using this method. Once the server side has been configured for the secure port and the port is active:
     – Setup your hod client to connect into the secure port and try the connection.
     – If the connection fails with a 662 (indicating the 'server presented a certificate that was not trusted'), you do not have the certificate of the CA that issued the server certificate in your client's key ring.
       - From the client window, select communication from the action bar, then select security. Information for the server certificate should be

displayed:

Figure 152. Security Information

- Select extract and indicate binary format and where to store the certificate, then click OK.

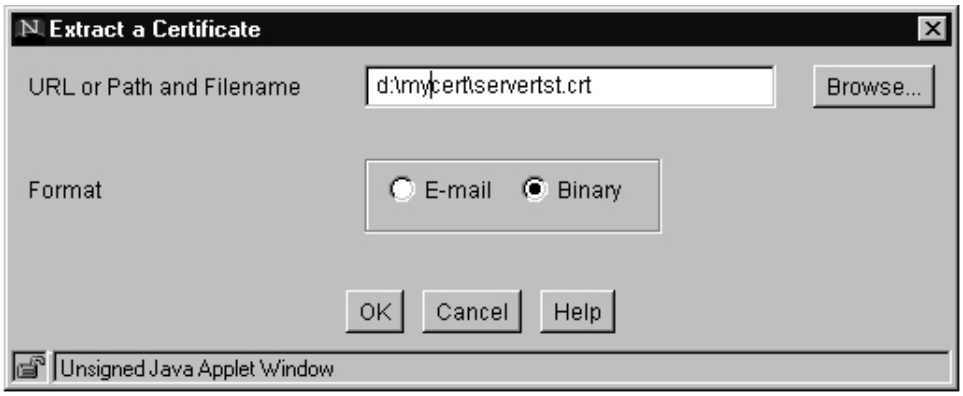

Figure 153. Extract a Certificate

If the action was successful, the following is displayed, which indicates that the server certificate information is on your client system.

Figure 154. Certificate was extracted

2. Add the self-signed server certificate to HOD's CustomizedCAs:

- On the HOD client, go to HOD's Certificate Management panels. To do this, select Start, Programs, IBM Host On-Demand, Administration, Certificate Management.
- Open the CustomizedCAs.class file. If customized CA certificates have previously been added to HOD, or if this is the first customized CA, create a new class file by:
  - Selecting File, then New.
  - Click on the Key Database Type arrow and select SSLight key database class. This automatically fills in the required filename and path

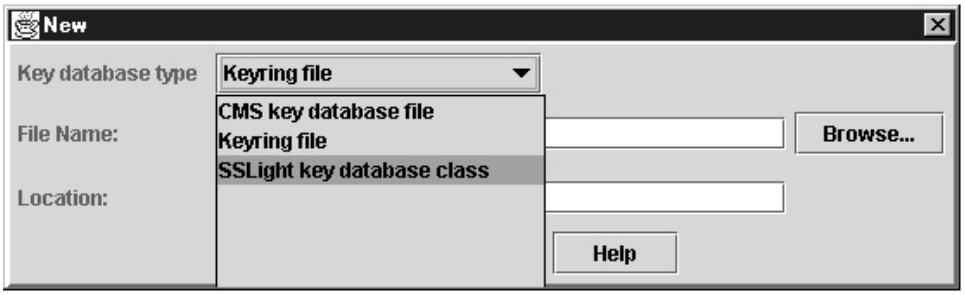

Figure 155. Creating a new CustomizedCAs.class

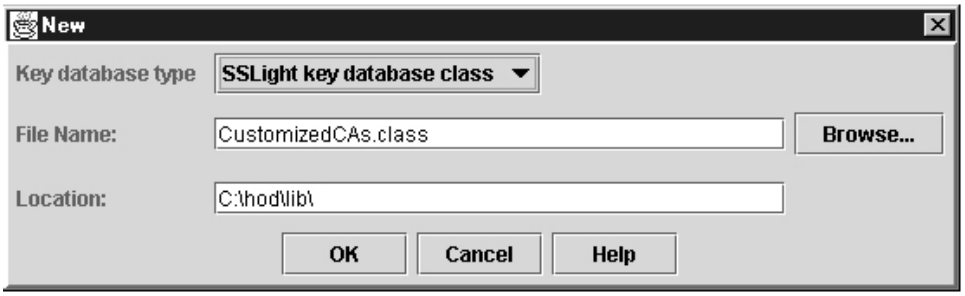

Figure 156. Default location displayed

  - Click OK. The *Signed Certificates* window is displayed.
  - Add the server certificate information:
    - Select ADD. The *Add CA's Certificate from a File* window is displayed.
    - Select data type 'Binary DER data'.

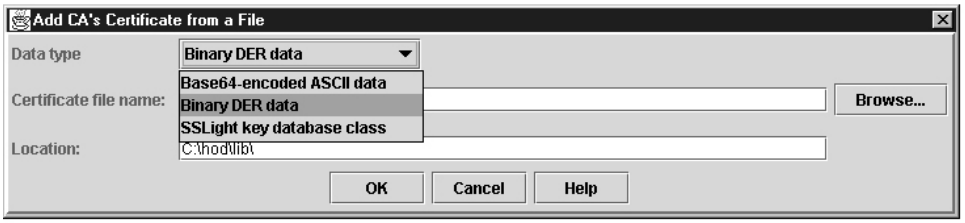

Figure 157. Add CA's Certificate From a File

  - Specify the path and name of the binary certificate file that was FTPed from the server or the file extracted using the HOD client window above. Click on the OK button to complete the add.

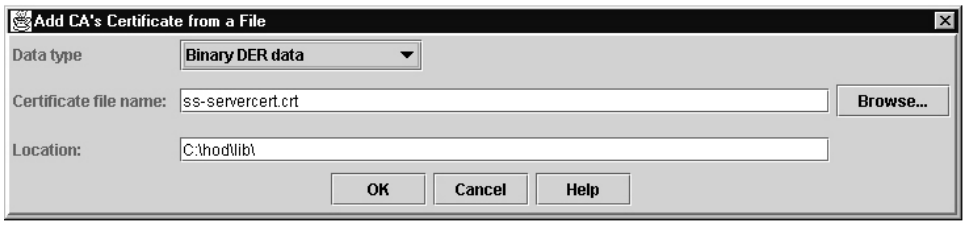

Figure 158. Add CA's Certificate From a File — continued

- Close the CustomizedCAs.class after completing the ADD.

3. Restart HOD to pick up the updated CustomizedCAs.class.

Appendix C. Express Logon Feature

Users accessing SNA applications using Telnet clients such as Host On Demand are generally required to know the user ID and password for the application they want to access. The ID-and-password authentication process creates several potential problems. For example, users may forget their IDs and passwords. If they do forget, the passwords must be reset by a system administrator, a time-consuming process. On the other hand, writing down the IDs and passwords or sharing them with someone else creates a security risk, especially since passwords are usually valid for relatively long periods of time.

IBM's solution to these problems is the Express Logon Feature (ELF), a process which allows a user on a workstation with a Telnet client and an X.509 certificate to log on to a SNA application without entering an ID or password. The Express Logon Feature is supported on two-tier and three-tier network designs. The two-tier design utilizes the z/OS TN3270E Telnet server. The three-tier design utilizes a middle-tier Telnet server and a Digital Certificate Access Server (DCAS).

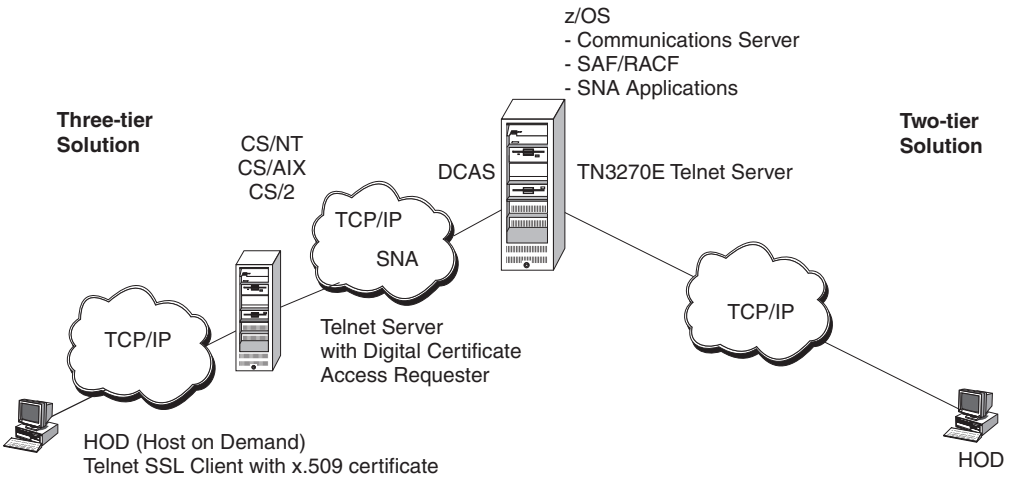

Figure 159. Express Logon network

Both network designs require a Telnet client workstation that supports Secure Sockets Layer (SSL) connections with client authentication and an X.509 certificate. Using RACF services in z/OS, the client certificate must be associated with a valid user ID. The only client-side product that supports the Express Logon Feature is the IBM WebSphere Host On Demand V5.0 and later releases.

The two-tier design requires the z/OS TN3270E Telnet server with SSL, client authentication, and Express Logon functions turned on. See “Express Logon Feature” on page 635 for server setup information.

The three-tier design requires a middle-tier Telnet server and a Digital Certificate Access Server (DCAS). A middle-tier Telnet server, so called because it does not reside on the host, but rather between the Telnet workstation client and the host. This server includes a Digital Certificate Access Requester (DCAR). The middle-tier IBM Telnet servers supporting Express Logon are:

- CS2 6.1

- CS/NT 6.1.1 PTF
- CS/AIX 6.0.0.1 PTF

Note: The term *DCAR* is used to describe the part of the Telnet middle-tier server that supports the Express Logon Feature and communicates as a client with the DCAS. It is not separate from the Telnet middle-tier server. The term *DCAR* might not be used in other information that describes ELF but has been used here to simplify the description of this function.

A Digital Certificate Access Server (DCAS) resides on the host. DCAS uses RACF services to obtain a user ID that has been mapped to a digital certificate.

The host also provides RACF Secured Signon services, which the DCAS or the MVS host Telnet server use to generate a *PassTicket*. A PassTicket is a RACF token similar to a password except that it is valid only for ten minutes.

In a typical scenario, a Host On Demand client wants to log on to a TSO application on the host.

- In the two-tier design, the user starts a secure connection with level 2 client authentication, which passes the client certificate to the TN3270E Telnet server. The TN3270E Telnet server uses RACF Secured Signon services to obtain a user ID and PassTicket.
- In the three-tier design, the user starts the Telnet connection to the middle-tier Telnet server. The client of the DCAS is the middle-tier Telnet server or DCAR, which attempts to log on to an SNA application for the workstation client. The DCAS receives a digital certificate from the DCAR and returns a user ID and PassTicket. Secure communication is used between the DCAS and the DCAR. The server recognizes that the client wants the Express Logon function and invokes the DCAR, which opens a secure connection with client authentication and passes the workstation's certificate and application name to the DCAS on the host. The DCAS uses RACF Secured Signon services to obtain a user ID and PassTicket, which the DCAS returns to the DCAR. The DCAR passes this information back to the middle-tier Telnet server.

In both cases the ELF-enabled client and server now have enough information to complete the logon to TSO. This occurs without the user ever having to enter a user ID or password.

Note: You can use RACF or any other SAF-compliant security product that supports PassTickets with Express Logon.

Configuring RACF services for Express Logon

At a minimum, you must register all workstation client certificates with RACF using the RACDCERT command. This associates the certificates with the IDs of users who are attempting to log on. In the two-tier solution, the certificate is passed from the client to the TN3270E Telnet server. In the three-tier solution, the certificate is passed from the client to the middle-tier Telnet server, then to the DCAR, and then to the DCAS.

You must also create a RACF PTKTDATA profile for each application ID the end user is attempting to access. The PTKTDATA profile allows the DCAS or z/OS TN3270E Telnet server to obtain a PassTicket and user ID for the application. In the three-tier solution, the DCAS must pass the PassTicket and user ID back to the DCAR. For Host On Demand, the application ID part of the profile name must be

the same as that configured in the Host On Demand Express Logon Application ID popup window. In most cases, the application name with which the user logs on will match the application ID portion of the RACF PTKTDATA class profile. However, for TSO and some other applications, the names and IDs may not match:

- If VTAM generic resources are used for TSO, define the application name portion on the RACF profile using the TCASGNAM defined in the TSOKEYxx, SYS1.PARMLIB member.
- If VTAM generic resources are not used, define the application name on the RACF profile as TSO.
- When configuring for TSO application logon, use the format TSO<SID> in the PassTicket profile, where SID is the SMF system ID defined in the SMFPRMxx member of SYS1.PARMLIB. (For example, if the SID is 3390, you would type TSO3390 in the profile.) For details, see *z/OS Security Server RACF Security Administrator's Guide*.

For applications that allow shared user IDs (multiple users request access to the application simultaneously with the same user ID), you must specify the APPLDATA('NO REPLAY PROTECTION') option on the RDEFINE command in the PTKTDATA profile. This bypasses the default RACF protection against replay of PassTickets.

Configuring the Express Logon components

The following describes, in general terms, how to set up and configure currently supported Express Logon components:

- Host On Demand Telnet client
- z/OS TN3270E Telnet server
- Middle-tier Telnet server (CS/2 V6.1, CS/NT 6.1.1, and CS/AIX 6.0.0.1)
- DCAS - see Appendix B, "TLS/SSL security," on page 1461

For details on configuring each product, see the appropriate documentation for that product.

Configuring the Host On Demand Telnet client

To setup and configure the Host On Demand client, follow these steps:

1. For each application to which the end user will log on, create a macro to record the logon screen of the application.

   The end user plays this macro when displaying the logon screen on the workstation.
2. Enter the application ID in the application ID popup window.

   The application ID must be the same name specified on the z/OS for the application ID portion of the PTKTDATA profile. The ID in the profile in most cases must be the same as the application name.
3. Use the Host On Demand key-management utility to:
   a. Create a key database (key ring).
   b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
   c. Use FTP to transmit the middle-tier Telnet certificate to the workstation and store the server certificate in the key database of the client.
   d. Use FTP to transmit the Host On Demand Telnet client certificate to the middle-tier server and store in the SSL key database of the server.

4. Use FTP to transmit the workstation certificate to an MVS data set on the z/OS host. Use the RACF Certificate Services RACDCERT command to associate the certificate with a valid user ID.

Configuring the z/OS TN3270E Telnet server

Express Logon Feature requires SSL with level 2 client authentication functionality at the server. Once that level of security is working, specify the EXPRESSLOGON parameter statement to enable ELF in the z/OS TN3270E Telnet server.

Configuring the middle-tier Telnet server (CS/2 example)

The middle-tier server is a Telnet server such as CS/2 V6.1, that communicates with the Host On Demand client using an SSL connection with client authentication. The middle-tier server DCAR also communicates with the DCAS on the host. The DCAS and DCAR communicate over a TCP/IP connection using SSL with client authentication.

To configure the Telnet server, follow these steps:

1. Configure the NDF file for the Express Logon function and communication with the DCAS using the following command:

```
DEFINE_EXPRESS_LOGON_SUPPORT
        ENABLED(YES)
        DCAS_ID(9.25.55.182)
        DCAS_ID_TYPE(IP_ADDRESS)
        DCAS_PORT(8990)
```

2. Use the local key management utility to store the workstation client certificate and the DCAS certificate in the local key ring:
   a. Create a key database file.
   b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
   c. Store the workstation client certificate and the DCAS certificate in the key ring of the server.
3. Use FTP to transmit the DCAR certificate to the z/OS host and use gskkyman or RACF Certificate Services to store the DCAR certificate in the DCAS key ring.

Appendix D. Using HCD

This information includes examples of panels that are used to define IQD channels and devices for z/OS Communications Server using HCD.

1. Select processors

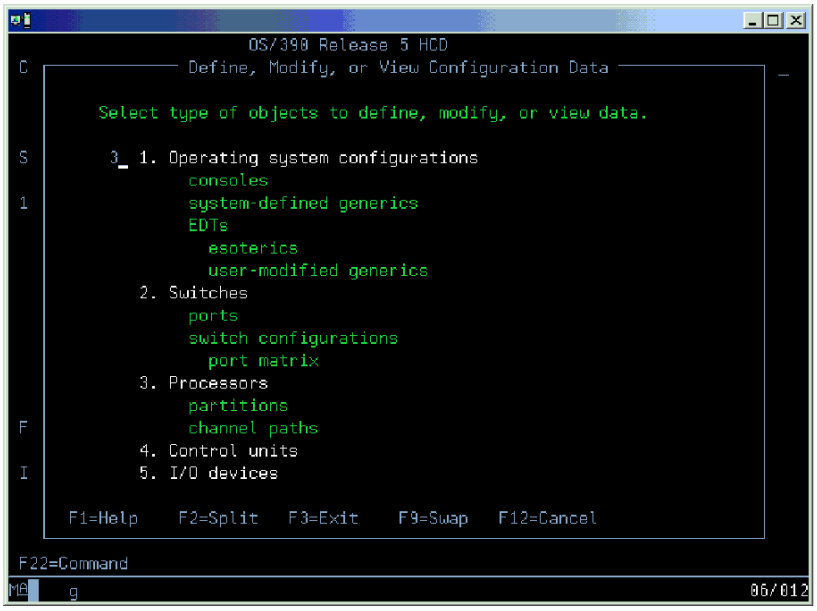

Figure 160. Select processors

2. Select 'S' Work with attached channel paths

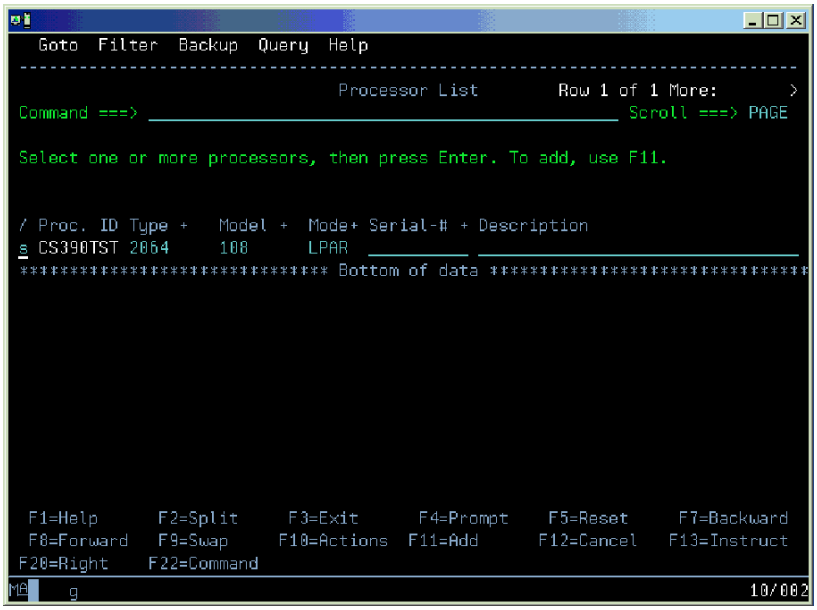

Figure 161. Work with attached channel paths

3. On the Channel Path List enter the Add command (or press F11) to initiate the Define Channel Path dialog.

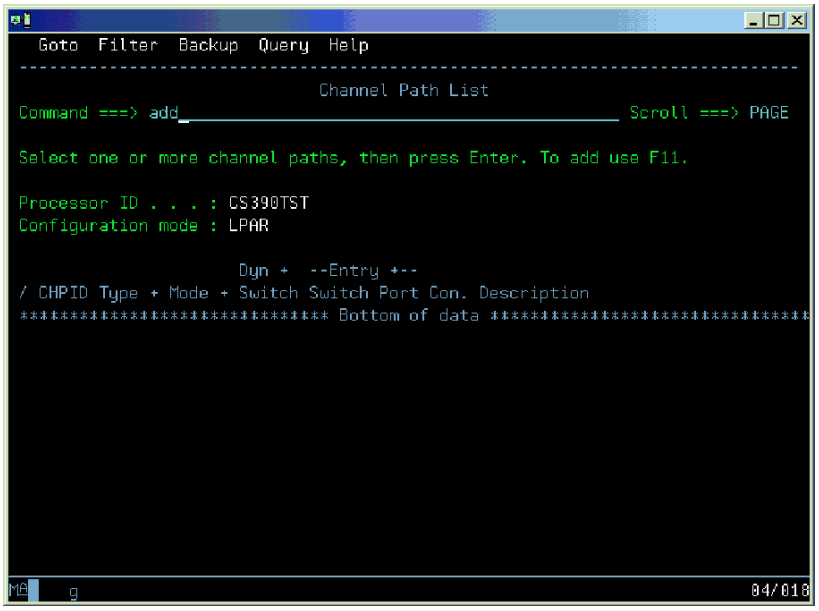

Figure 162. Initiate the Define Channel Path dialog

4. Fill in the Add Channel Path panel, then press Enter (Select SHR for Operation mode to share IQD Chpids across LPARs).

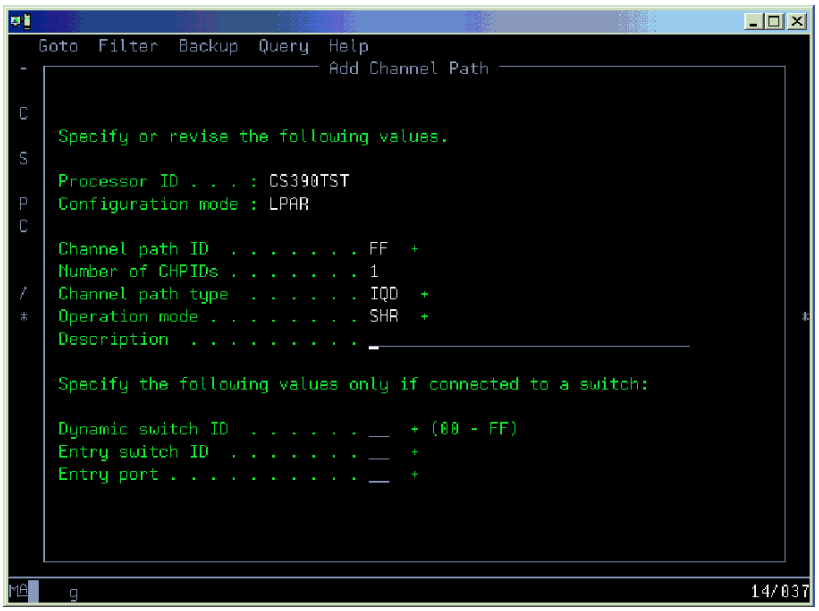

Figure 163. Add channel path

5. For an IQD channel path, the Specify Maximum Frame Size panel pops up with the default value of 16 KB.

Figure 164. Specify Maximum Frame Size

Or change the frame size to desired size:

Table 74. Frame size specification

Maximum Frame Size	TCP/IP MTU size
16K	8K
24K	16K
40K	32K
64K	56K

6. Define the channel path access list that each LPAR should have access to.

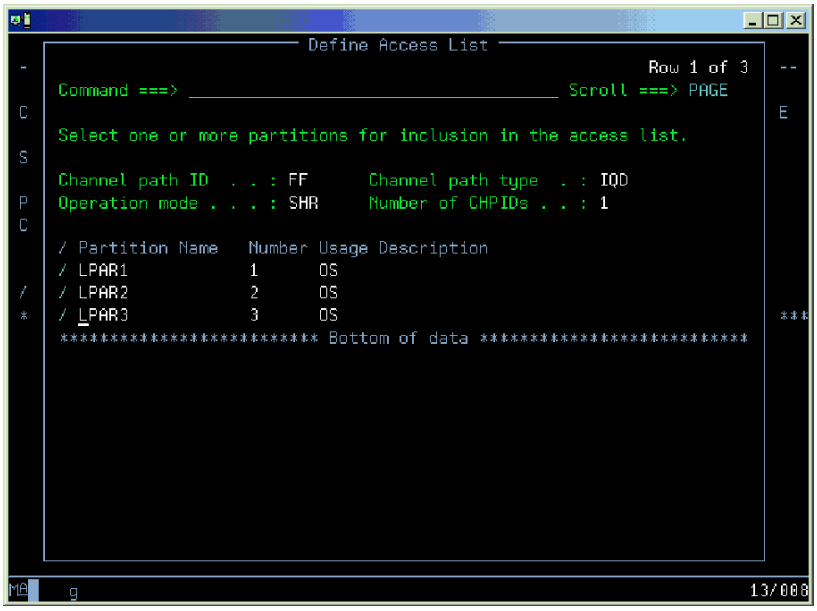

Figure 165. Define the channel path access list

7. Having pressed Enter, the Channel Path List is redisplayed with channel path number FF defined.

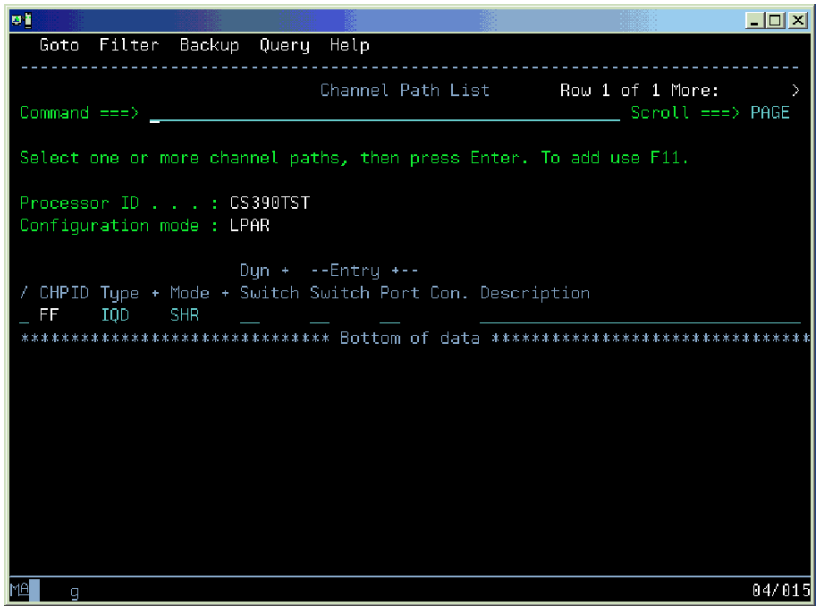

Figure 166. Channel path number FF defined

8. As the next step, add the control unit(s) to the IQD channel path. Select the defined channel path with action "Work with attached control units" (action code 'S').

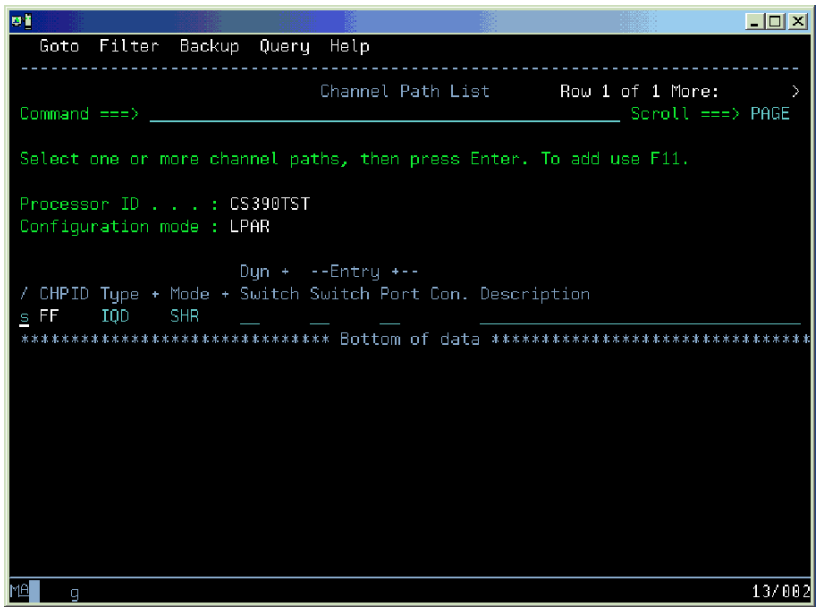

Figure 167. Work with attached control units

9. An empty control unit list is displayed. Enter the 'Add' command or F11.

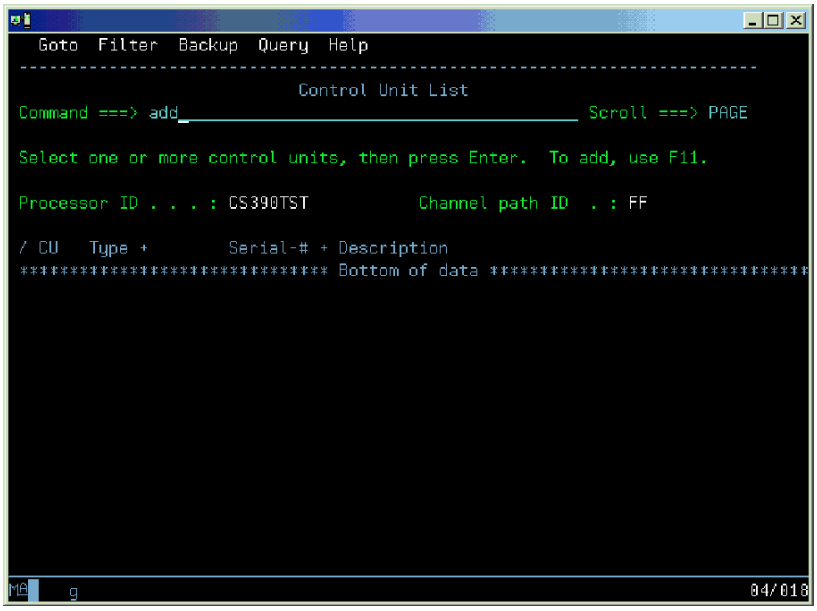

Figure 168. Add the control unit(s)

10. Define a control unit of type 'IQD' for channel path FF.

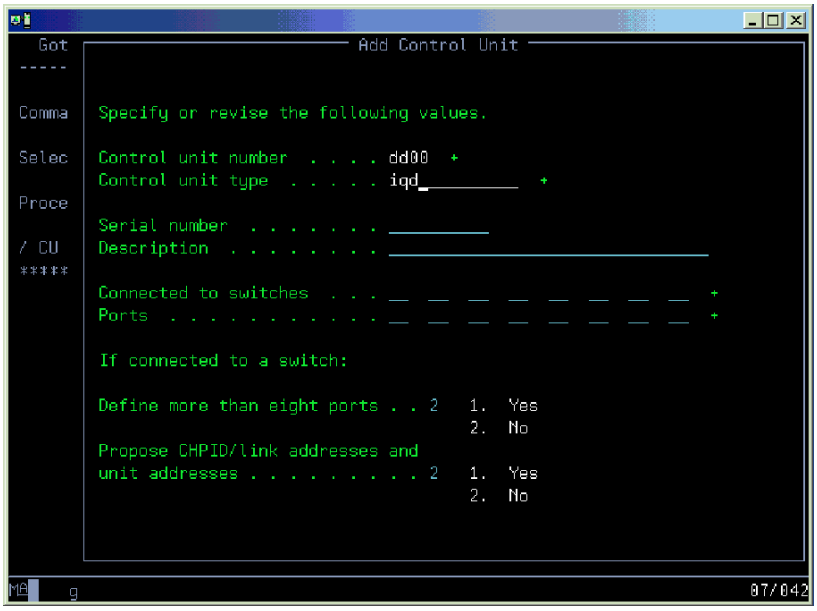

Figure 169. Define a control unit

11. Define it to the processor:

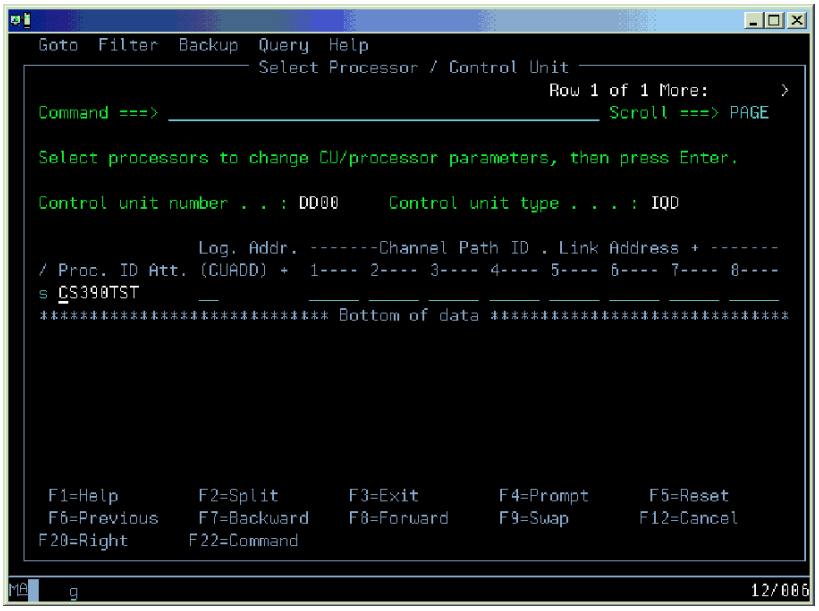

Figure 170. Define it to the processor

12. The processor settings are already preset. Pressing Enter, returns to the Select Processor/Control unit panel. Pressing Enter again, returns to the Control Unit List panel which shows the currently defined control unit.

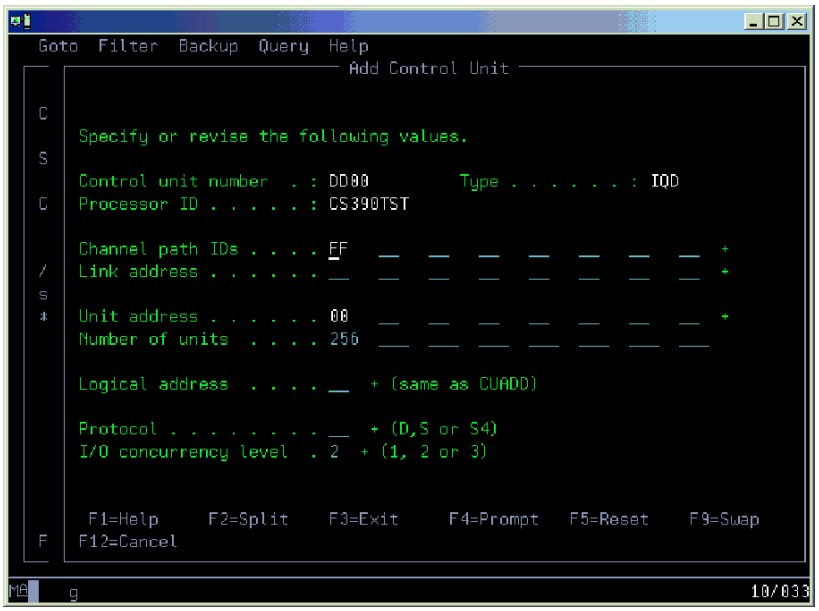

Figure 171. Currently defined control unit

13. Next, define the devices. Successively, select a control unit and perform action "Work with attached Devices".

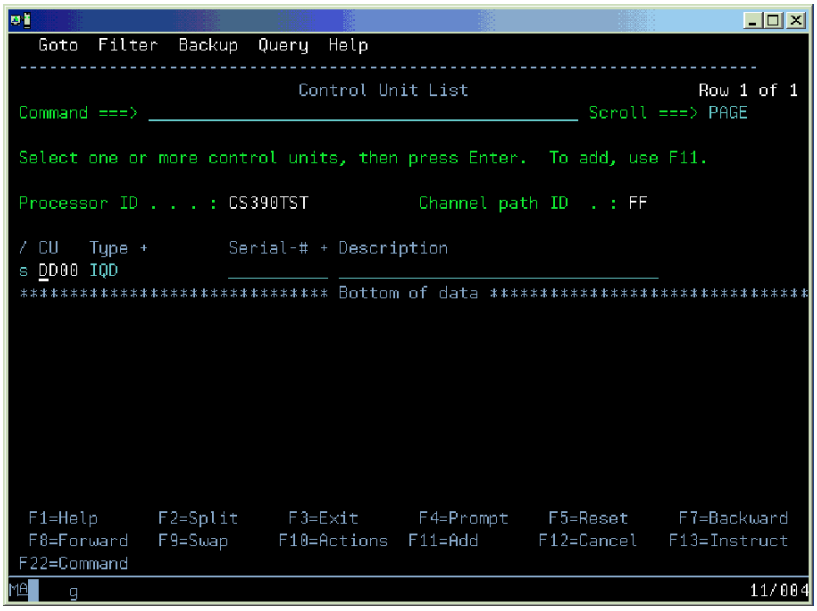

Figure 172. Define the devices

14. This leads to an empty device list.

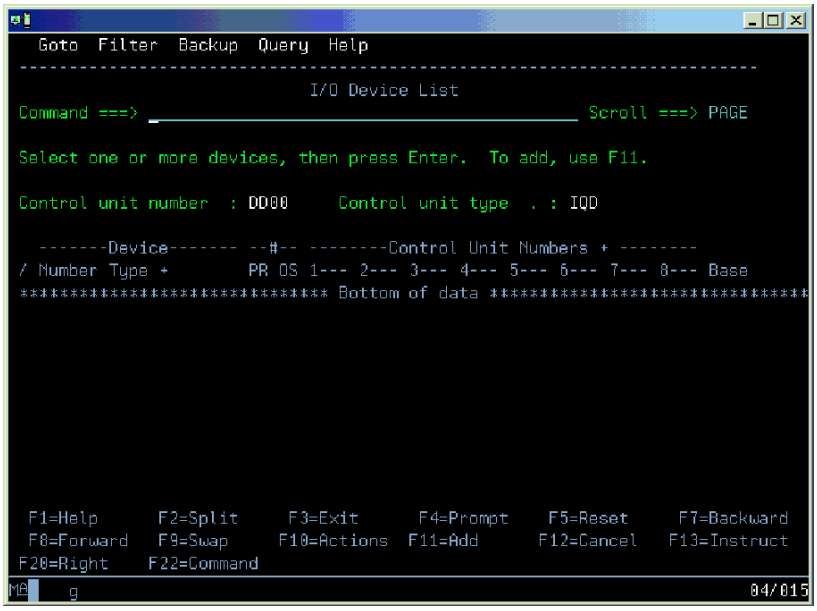

Figure 173. Empty device list

15. Perform the Add action to define the devices for the control unit selected in the previous step.

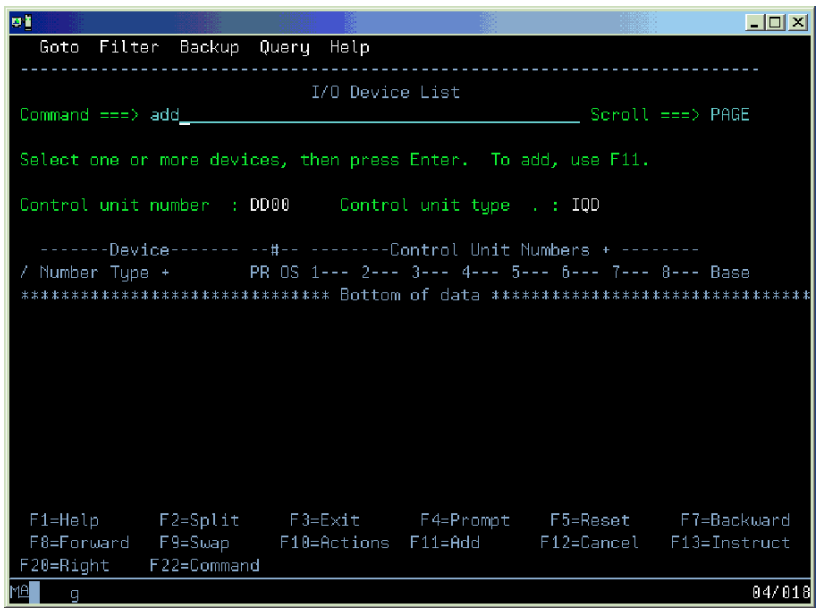

Figure 174. Define the devices for the control unit

16. Add devices of type IQD to the selected control unit.

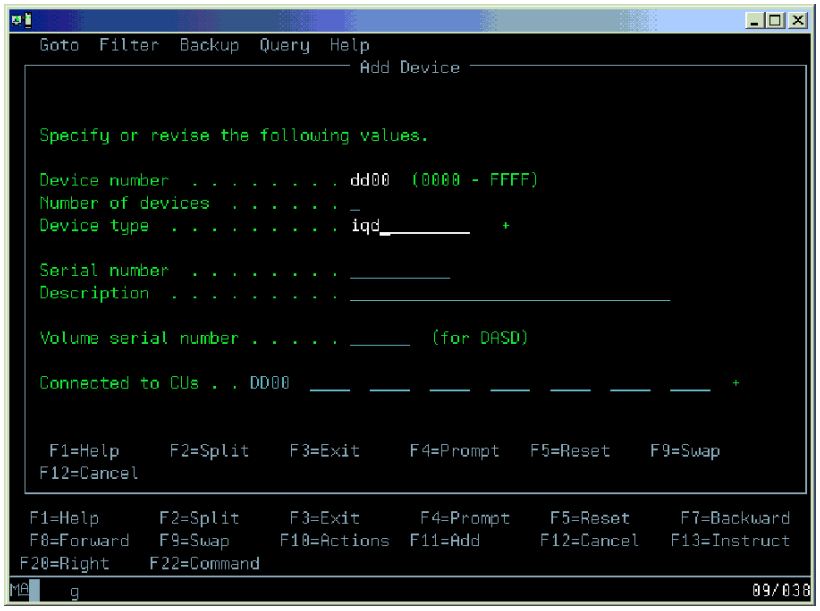

Figure 175. Add devices of type IQD

17. If the number of devices has been left unspecified (as in this example), HCD defines 10 devices.

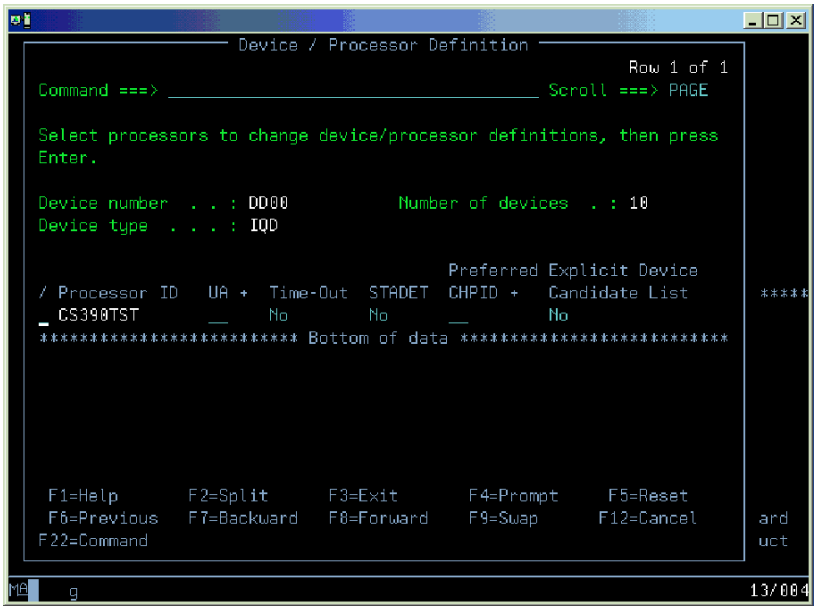

Figure 176. Define number of devices

18. Hit enter and the next panel displayed will be:

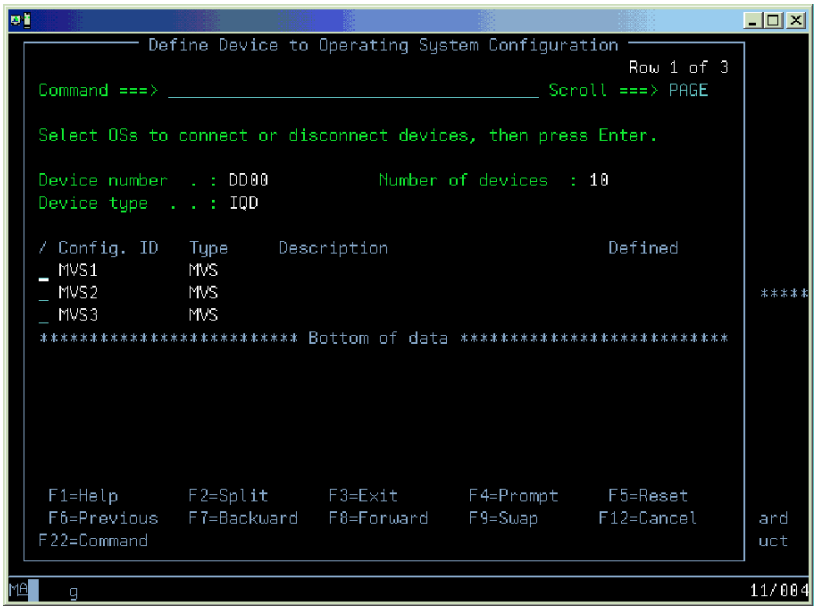

Figure 177. Define device to operating system

19. Next, define the devices to the operating system by selecting an 'S' on each system you want to have them defined on.

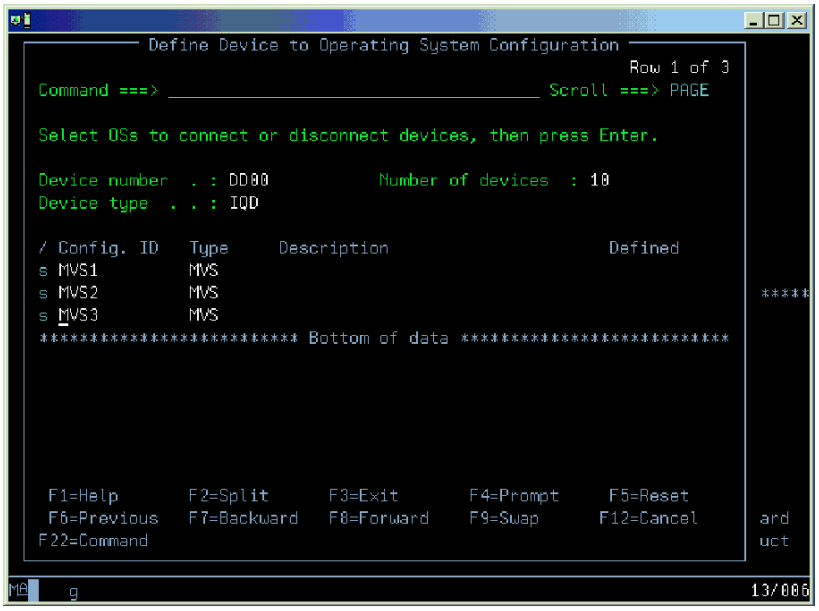

Figure 178. Select systems

20. The device parameters are shown with default values. Press Enter, to complete the definition for each system.

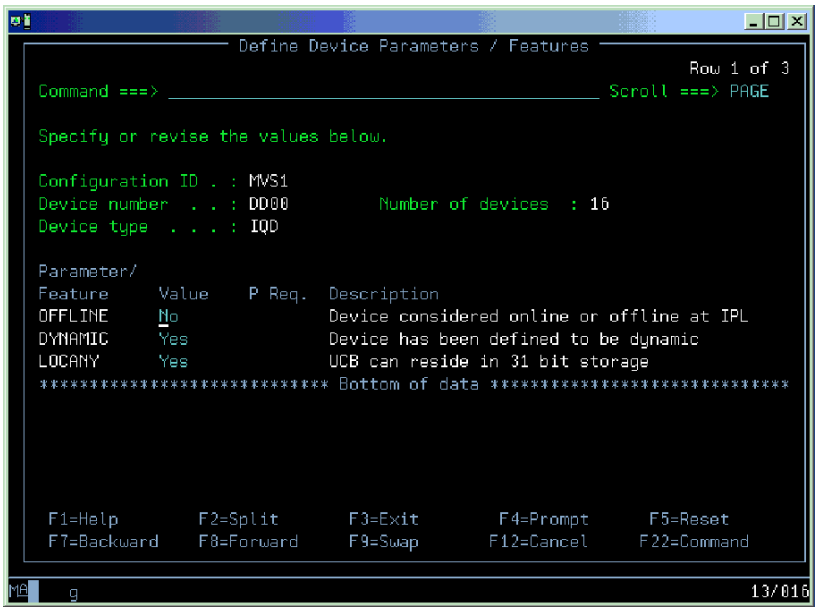

Figure 179. Complete the definition

21. Press Enter until you return to the I/O device list panel, the definition for channel path FF is complete.

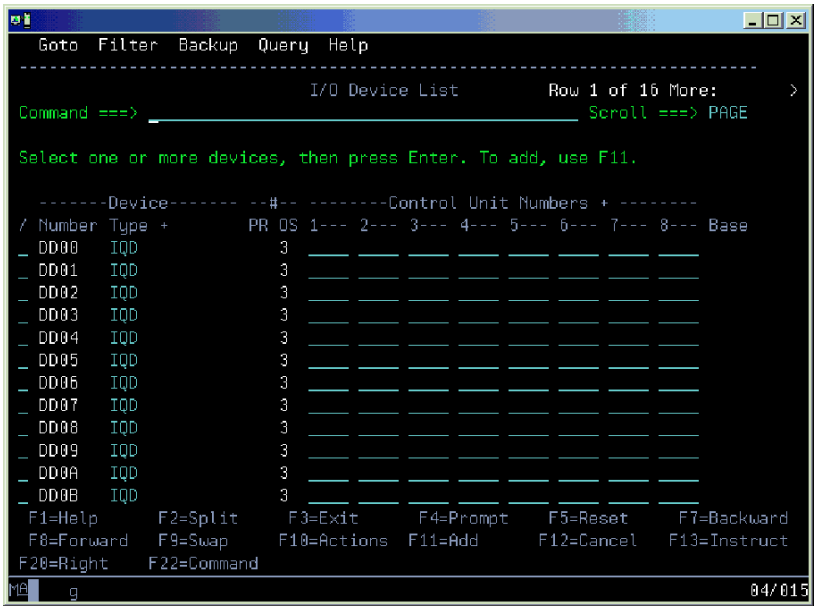

Figure 180. Definition completed

The sample IOCP input for this example would be:

```
----+----1----+----2----+----3----+----4----+----5----+----6----+----7--
         CHPID PATH=(FF),SHARED,                                        *
               PARTITION=((LPAR1,LPAR2,LPAR3),(LPAR1,LPAR2,LPAR3)),     *
               TYPE=IQD,OS=00
         CNTLUNIT CUNUMBR=DD00,PATH=(FF),UNIT=IQD
         IODEVICE ADDRESS=(DD00,010),CUNUMBR=(DD00),UNIT=IQD
```

Appendix E. Steps for preparing to run IP security

Perform the following steps to prepare to run the IKE daemon:

1. Set the appropriate UNIX System Services parameters.
2. Authorize the IKE daemon to the external security manager.
3. Authorize the **ipsec** command to the external security manager.
4. Authorize IP security to ICSF/MVS (optional).
5. Set up the IKE daemon for RSA signature mode authentication (optional).

These steps are described in detail in the following subtopics.

Step 1: Setting appropriate UNIX System Services parameters

Verify that AF_UNIX and AF_INET are defined in the BPXPRMxx member of SYS1.PARMLIB. If the domains are not defined, see *z/OS UNIX System Services Planning* for the steps to customize the BPXPRMxx parmlib member.

Step 2: Authorizing the IKE daemon to the external security manager

To authorize the IKE daemon to RACF, perform the steps in "Steps for authorizing the IKE daemon to RACF." The commands that are used are in EZARACF in the SEZAINST data set.

Steps for authorizing the IKE daemon to RACF

Perform the following steps to authorize the IKE daemon to RACF:

1. Add user ID `IKED`, and add `IKED` to the STARTED class as follows:

```
ADDUSER  IKED     DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0)  HOME('/'))
RDEFINE  STARTED  IKED.*            STDATA(USER(IKED))
PERMIT   BPX.DAEMON CLASS(FACILITY) ID(IKED)     ACCESS(READ)
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED)  REFRESH
```

2. Allow the IKED to access SYS1.PARMLIB as follows:

```
PERMIT   SYS1.PARMLIB  ID(IKED)        ACCESS(READ)
```

3. Enable the IKED to access certificates by issuing the appropriate commands.
   - If the certificates used by the IKED are not site certificates, enable the IKED to access the certificates on an ESM key ring by issuing the following commands:

```
RDEFINE  FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
RDEFINE  FACILITY IRR.DIGTCERT.LIST     UACC(NONE)
PERMIT   IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACCESS(READ)
PERMIT   IRR.DIGTCERT.LIST     CLASS(FACILITY) ID(IKED) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

   - If the certificates used by the IKED are site certificates, enable the IKED to access them by issuing the following commands:

```
RDEFINE  FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
RDEFINE  FACILITY IRR.DIGTCERT.LIST     UACC(NONE)
RDEFINE  FACILITY IRR.DIGTCERT.GENCERT  UACC(NONE)
```

```
PERMIT   IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACCESS(UPDATE)
PERMIT   IRR.DIGTCERT.LIST     CLASS(FACILITY) ID(IKED) ACCESS(READ)
PERMIT   IRR.DIGTCERT.GENCERT  CLASS(FACILITY) ID(IKED) ACCESS(CONTROL)
SETROPTS RACLIST(FACILITY) REFRESH
```

4. Enable the IKED to run as nonswappable.

   If you have defined the BPX.STOR.SWAP resource to RACF, you can enable the IKED using the following commands:

   ```
   PERMIT BPX.STOR.SWAP CLASS(FACILITY) ID(IKED) ACCESS(READ)
   SETROPTS RACLIST(FACILITY) REFRESH
   ```

Step 3: Authorizing the ipsec command to the external security manager

To authorize the **ipsec** command to RACF, perform the steps in "Steps for authorizing the ipsec command to RACF." The commands that are used are in EZARACF in the SEZAINST data set. For more information about **ipsec** command security and the SERVAUTH profile, see *z/OS Communications Server: IP System Administrator's Commands*.

Steps for authorizing the ipsec command to RACF

Perform the following steps to authorize the **ipsec** command to RACF:

1. Define access control for the **ipsec** command.

   The **ipsec** command uses both display and control features. You can control access to each feature independently.

   - To control access to both the display and control capabilities of the **ipsec** command, issue the following commands:

     ```
     SETROPTS GENERIC(SERVAUTH)
     RDEFINE  SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.* UACC(NONE)
     PERMIT   EZB.IPSECCMD.sysname.tcpprocname.* CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     SETROPTS GENERIC(SERVAUTH) REFRESH
     ```

   - To control access specifically to the display capabilities of the **ipsec** command for a stack, issue the following commands:

     ```
     RDEFINE  SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.DISPLAY UACC(NONE)
     PERMIT   EZB.IPSECCMD.sysname.tcpprocname.DISPLAY CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```

   - To control access specifically to the display capabilities of the **ipsec** command for global defensive filters, issue the following commands:

     ```
     RDEFINE  SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY UACC(NONE)
     PERMIT   EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```

   - To control access specifically to the control capabilities of the **ipsec** command for a stack, issue the following commands:

     ```
     RDEFINE  SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.CONTROL UACC(NONE)
     PERMIT   EZB.IPSECCMD.sysname.tcpprocname.CONTROL CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```

   - To control access specifically to the control capabilities of the **ipsec** command for global defensive filters, issue the following commands:

     ```
     RDEFINE  SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL UACC(NONE)
     PERMIT   EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL CLASS(SERVAUTH) ID(userid) ACCESS(READ)
     ```

   Tip: These SERVAUTH profiles provide **ipsec** command access to only the local stack. For information about SERVAUTH profiles for controlling **ipsec** command access for the network security services (NSS) server, see "Network security services for the IPSec discipline" on page 145.

2. To refresh the in-storage RACF profiles in the SERVAUTH class, issue the following command:

   ```
   SETROPTS RACLIST(SERVAUTH) REFRESH
   ```

Step 4: Authorizing IP security to ICSF/MVS (optional)

IP security can take advantage of the encryption and decryption functions that are available on zSeries hardware in the following ways:

- Encrypting and decrypting TCP/IP packet data in an IPSec tunnel.
- Encrypting signature data included as part of IKE message flows. This encryption is performed only when digital signature authentication is requested.

This encryption support is provided by the combination of the Integrated Cryptographic Feature (ICRF) on the processor and the Integrated Cryptographic Service Facility/MVS (ICSF/MVS) software product. ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depends on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in *z/OS Cryptographic Services ICSF Overview*.

To use this support, ICSF/MVS must be started and running. Preferably, start ICSF/MVS prior to starting TCP/IP. However, it can also be started when TCP/IP is active. For details on configuring ICSF, see *z/OS Cryptographic Services ICSF Administrator's Guide*. ICSF provides SAF controls that you can optionally use to restrict access to these cryptographic services. To view a sample procedure for generating the corresponding SAF profiles for various CSFSERV services, see the `Cryptographic Services Authorization` section of the EZARACF sample in the SEZAINST dataset.

Requirement: If you plan to control access to the ICSF cryptographic support, TCP/IP and other applications must be permitted to access the ICSF/MVS cryptographic services (CSFSERV).

Guideline: If you do not have any reason to restrict access to the ICSF cryptographic support, you should not activate the CSFSERV resource class, define any of the profiles listed below, or permit any applications or users to these profiles. If you do need set up controls in the CSFSERV resource class, complete the steps below to enable use of ICSF for IP security.

Steps for setting up profiles in the CSFSERV resource class

Perform the following steps to set up profiles in the CSFSERV resource class:

1. Determine the SAF profiles that you will use within the CSFSERV resource class:
   a. If you have CP Assist for Cryptographic Function (CPACF) enabled on your processors and you want to take advantage of it, you must have ICSF started but you do not need to grant permission to any SAF profiles.
   b. If you do not have CPACF enabled, but you do have a cryptographic coprocessor, in order to take advantage of it you must perform the following steps:
      1) Permit TCP/IP, and all affected network applications that will send or receive traffic protected by IP security, to the following profiles:
         - CSFCKI
         - CSFCKM (used only for Triple DES)
         - CSFDEC1
         - CSFENC1
         - CSFOWH1

2) Permit the IKED and the NSSD to the following profiles:
   - CSFDSG
   - CSFDSV
   - CSFPKI

c. If you are using AES encryption in TCP/IP for manual or dynamic tunnels, then you must permit TCP/IP and all affected network applications that will send or receive IP security-protected traffic to the following profiles:
   - CSFDEC1
   - CSFENC1

d. If you are using AES encryption in the IKED for dynamic tunnels, then you must permit the IKED to the following profiles:
   - CSFDEC
   - CSFENC

e. If you are using SHA2 or AES-XCBC authentication in TCP/IP, then you must permit TCP/IP and all affected network applications that will send or receive IP security-protected traffic to the following profiles:
   - CSF1HMG
   - CSF1TRC
   - CSF1TRD
   - CSFMGN1

f. If you are using SHA2 or AES-XCBC authentication in the IKED, then you must permit the IKED to the following profiles:
   - CSF1HMG
   - CSF1TRC
   - CSF1TRD
   - CSFOWH

g. If you are using Diffie-Hellman groups 19, 20, or 21 in the IKED, then you must permit the IKED to the following profiles:
   - CSF1DVK
   - CSF1GAV
   - CSF1GKP
   - CSF1TRC
   - CSF1TRD

h. If you are using digital signature authentication in the IKED, then you must permit the IKED to the following profiles:
   - CSFDSG
   - CSFDSV
   - CSFPKI

i. If you are using digital signature authentication in the NSSD, then you must permit the NSSD to the following profiles:
   - CSF1HMG
   - CSF1TRC
   - CSF1TRD
   - CSFDSG
   - CSFDSV
   - CSFIQF
   - CSFMGN

- CSFOWH
- CSFPKI

j. If you are using elliptic curve signature authentication in the NSSD, then you must permit the NSSD to the following profiles:
   - CSF1GAV
   - CSF1PKS
   - CSF1PKV

k. If you have enabled FIPS 140 support in TCP/IP, then TCP/IP and all affected network applications that will send or receive IP security-protected traffic (such as the Ping command and DB2, for example) must be permitted to the following profiles:
   - CSF1HMG
   - CSF1SKD
   - CSF1SKE
   - CSF1TRC
   - CSF1TRD
   - CSFRNG

l. If you have enabled FIPS 140 support in TCP/IP and you are using manual tunnels, then the z/OS Communications Server Policy Agent must be permitted to the CSF1TRC profile.

m. If you have enabled FIPS 140 support in the IKED, then you must permit the IKED to the following profiles:
   - CSF1HMG
   - CSF1SKD
   - CSF1SKE
   - CSF1TRC
   - CSF1TRD
   - CSFOWH

2. Define the appropriate profiles in the CSFSERV class:
   ```
   RDEFINE CSFSERV profile-name UACC(NONE)
   ```
3. Give TCP/IP access to the appropriate profiles:
   ```
   PERMIT profile-name CLASS(CSFSERV) ID(stackname) ACCESS(READ)
   ```
4. For network applications that run under a specific user ID (such as the Ping command or DB2, for example), give access to the user ID to the appropriate profiles:
   ```
   PERMIT profile-name CLASS(CSFSERV) ID (userid)
   ```
5. Activate the CSFSERV class and refresh the in-storage RACF profiles:
   ```
   SETROPTS CLASSACT(CSFSERV)
    SETROPTS RACLIST(CSFSERV) REFRESH
   ```
6. Set the MAXLEN ICSF/MVS installation option to 65535 or greater because this is the maximum TCP/IP packet size. The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data using ICSF/MVS.

Step 5: Setting up the IKE daemon for digital signature authentication (optional)

You can configure the IKE daemon to use its own certificate service or to use the certificate service from a network security services (NSS) server. You can control whether to use the native certificate service or the NSS certificate service at the stack level. A single stack can use either the native certificate service or the NSS certificate service, but it cannot use both. If the IKED is to use an IKEv2 signature-based authentication method on behalf of a stack, that stack must be defined as a network security services (NSS) client.

By default, the IKE daemon uses the native certificate service for all stacks. Certificates for stacks configured to use the native certificate service must reside on the key ring specified by the KeyRing parameter of the IkeConfig statement.

The IKE daemon native certificate service does not consult certificate revocation information when it authenticates a digital signature. If you want revocation checking, then direct the IKED to use the IPSec certificate service of an NSS server and enable revocation checking for the remote security endpoint. For information about enabling revocation checking for a remote security endpoint using the KeyExchangeAction statement, see *z/OS Communications Server: IP Configuration Reference*.

The IKE daemon can be directed to use an NSS server's certificate service for an individual stack by specifying the Cert option on the ServiceType parameter of an NssStackConfig statement for that stack. The NssStackConfig statement is specified in the IKE daemon configuration file. The NSS server does not have to reside on the same system as the IKE daemon. The location of the NSS server is specified by the NetworkSecurityServer parameter and optionally the NetworkSecurityServerBackup parameter of the IkeConfig statement. For more information about the IkeConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

Certificates for stacks configured to use an NSS server for certificate service must reside on the key ring specified on the KeyRing parameter of the NssConfig statement in the NSS server configuration file. For more information about the NssConfig statement, see *z/OS Communications Server: IP Configuration Reference*.

Figure 181 on page 1511 shows a partial configuration for the IKE daemon on system SYSTEMA and an NSS server. The NetworkSecurityServer parameter on the IkeConfig statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. Two NssStackConfig statements are shown. The ClientName parameters associate a local TCP/IP stack with an NSS client name. This is the name by which the NSS server knows this stack. The UserId parameter associates the client name with a user ID defined on the NSS server's system. Both the client name and user ID are used by the NSS server to verify that an NSS client is authorized to request certificate service, and to determine what certificates the client is authorized to use (For additional details, see “Steps for authorizing resources for NSS” on page 1152). The KeyRing parameter on the IkeConfig statement identifies the location of certificates for all stacks for which there are no NssStackConfig statements. The KeyRing parameter on the NssConfig statement identifies the location of certificates for all NSS client stacks that use the NSS server certificate service.

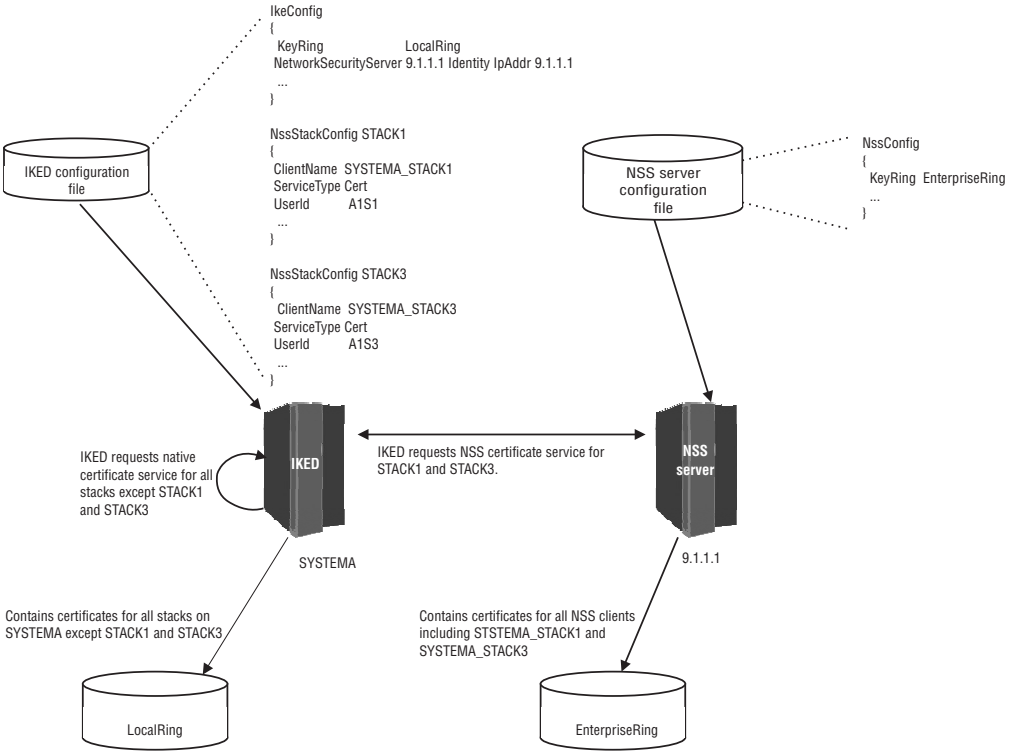

Figure 181. Partial configuration for the IKE daemon and an NSS server

The following subtopics provide steps for setting up the IKE daemon for RSA signature mode authentication:

- When the native certificate service is utilized
- When the certificate service of an NSS server is utilized

Before you begin: Use the following references to understand the concepts that are involved in using digital certificates with RACF:

- For more information about RACF key rings and digital certificates, see *z/OS Security Server RACF Security Administrator's Guide*.
- For more information about controlling the use of the RACDCERT command, see *z/OS Security Server RACF Security Administrator's Guide*.
- For a complete description of the facilities and authorizations that are needed to create and modify digital certificates and key rings, see *z/OS Security Server RACF Command Language Reference*.

Steps for setting up the IKE daemon for digital signature authentication when the native certificate service is used

Perform the following steps to set up the IKE daemon for digital signature authentication when the native certificate service is being used:

1. Define RACF facilities and access controls.
2. Define profiles to control access to the RACDCERT command.
3. Create a RACF key ring for the user ID under which the IKED is to run.
4. Install an X509 digital certificate to be used by the native IKE certificate service.

Step 1: Define RACF facilities and access controls

To support RSA signature mode authentication in phase 1 negotiations, perform the following steps to give the IKE daemon the required access to a RACF key ring:

1. If they are not already defined, create the definitions that are required to allow certificates to be stored and accessed from the RACF database by issuing the following TSO commands:

   ```
   RDEFINE FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.LIST UACC(NONE)
   ```

2. To permit the IKED to the facilities, issue the following TSO commands:

   ```
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(IKED) ACC(READ)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACC(READ)
   ```

3. Refresh the FACILITY class:

   ```
   SETROPTS RACLIST(FACILITY) REFRESH
   ```

Step 2: Define profiles to control access to the RACDCERT command

The RACF database provides digital certificate and key ring support through the RACDCERT command. The administrator who is responsible for managing the RACF key ring for the IKED needs appropriate access to this command. Perform the following steps to define profiles to control access to this command:

1. If they are not already defined, create the definitions that are required to control access to the basic RACDCERT actions by issuing the following TSO commands:

   ```
   RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
   RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
   ```

2. Issue the following TSO commands (where *userid* is the ID of the person who will be executing the RACDCERT command to manage digital certificates):

   ```
   PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(userid) ACC(CONTROL)
   PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
   ```

3. Refresh the FACILITY class:

   ```
   SETROPTS RACLIST(FACILITY) REFRESH
   ```

Step 3: Create a RACF key ring for the user ID under which the IKED is to run

Digital certificates are made available to the IKE daemon by connecting them to a key ring that is owned by the IKE daemon. To create a key ring for the IKE daemon, issue the following TSO command:

```
RACDCERT ID(IKED) ADDRING(ikeyring)
```

The value used for *ikeyring* is case sensitive.

Step 4: Install an X509 digital certificate to be used by the native certificate service

The procedure for installing a digital certificate on a SAF key ring for the native certificate service to use is similar to the procedure for installing a digital certificate on a SAF key ring for the NSS certificate service to use. For details, see "IPSec certificate management" on page 1514.

Steps for setting up the IKE daemon for digital signature authentication using the certificate service of an NSS server

Perform the following steps to set up the IKE daemon for digital signature authentication when the certificate service of an NSS server is being used:

1. Update the IKE daemon configuration file to define NSS clients.
2. Install X509 digital certificates for NSS clients on the NSS server's key ring.
3. Authorize the NSS clients.
4. Enable HTTP Certificate Lookup (optional)

Step 1: Update the IKE daemon configuration file to define NSS clients

The IKE daemon configuration file must be updated to include the NetworkSecurityServer parameter and optionally the NetworkSecurityServerBackup parameter on the IkeConfig statement. These parameters identify the location of the NSS server. In addition, an NssStackConfig statement with a ServiceType value Cert must be added for each stack that will use the NSS certificate service. For additional details about configuring the IKE daemon, see *z/OS Communications Server: IP Configuration Reference*.

Step 2: Install X509 digital certificates for NSS clients on the NSS server's key ring

This step must be performed on the system where the NSS server will run.

The procedure for installing a digital certificates on a SAF key ring to be used by the NSS server is similar to the procedure used for installing a digital certificate on a SAF key ring for use by the native certificate service. For details, see "IPSec certificate management" on page 1514.

Step 3: Authorize the NSS clients

This step must be performed on the system where the NSS server will run.

NSS clients defined in the IKE daemon configuration file must be authorized to use the NSS server's certificate service. For authorization details, see step 7 on page 1154.

Step 4: Enable HTTP Certificate Lookup (optional)

The following actions occur during a phase 1 IKE exchange:

- Peers exchange encoded certificate information in certificate payloads
- The NSS server provides the IKED with certificate information to send
- The IKED forwards the encoded certificate information that it received from the NSS server

IKEv2 defines two new encoding types that require the use of an HTTP server:

- Hash and URL of a certificate
- Hash and URL of a certificate bundle

The NSS server supports these new encoding types; however, by default the IKED does not support sending or receiving them.

Use the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements in the IP security policy configuration file to enable the IKED to use the hash and URL encoding types. Code the appropriate value on the CertificateURLLookupPreference parameter:

- Disallow, which is the default value, indicates that the IKED will not send the new encoding type and will ignore the new encoding type when received.
- Tolerate indicates that the IKED will not send the new encoding type, but it will accept the new encoding type when received.
- Allow indicates that the IKED may send the new encoding type and it will accept the new encoding type when received.

Rule: You must configure the NSS server appropriately before the IKED can send the new encoding types.

Enabling this capability might result in smaller messages being exchanged between the IKED and its remote security endpoint as well as the IKED and the NSS server; however, it may also result in increased latency during an IKEv2 negotiation.

For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see *z/OS Communications Server: IP Configuration Reference*. For more details about configuring the NSS sever to use the new certificate encoding types, see "Using hash and URL certificate encoding types" on page 1166.

IPSec certificate management

The IKE daemon and NSS server require the ability to retrieve digital certificates from a RACF key ring, each associated with a particular identity, and also to perform operations with the associated private key. The IKED can own multiple certificates on its RACF key ring. The NSS server can own multiple certificates for multiple NSS clients (that is, stacks). You can install an X509 digital certificate in the following ways:

- Generate an X509 digital certificate and have it signed by a certificate authority.
- Generate a self-signed X509 digital certificate.
- Migrate an existing key database to a RACF key ring.

Steps for generating an X509 digital certificate and having it signed by a certificate authority

Before you begin: Assume that you have an X509 digital certificate that has the X500 distinguished name `CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US` and the domain name `ibm.com`. The certificate identifies the local IKE daemon that executes on z/OS with the user ID `IKED`.

Tip: If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. Modify the user ID in the examples to be the user ID that is running the NSS server and modify the key ring to be the key ring that is configured in the NSS server's configuration file.

Perform the following steps to install the X509 digital certificate:

1. Generate a self-signed certificate for the server:

```
RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US'))
                  WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))
```

2. Do one of the following:
   - RACF supplies certificates for many commercial certificate authorities. If you are using one of these supplied certificate authority certificates, follow the steps for supplied digital certificates in *z/OS Security Server RACF Security Administrator's Guide*.
   - If the certificate authority you are using is not one of the supplied certificate authorities, obtain the root certificate of the certificate authority that is to sign the certificate of the IKED, and place it in an MVS data set (for example, USER1.EXTCA1.CERT). Add it to the RACF database as follows:

     ```
     RACDCERT ID(IKED) ADD('USER1.EXTCA1.CERT') WITHLABEL('External CA') CERTAUTH
     ```

3. Create a certificate request to send to the chosen certificate authority. The certificate request that you create is based on the certificate that was created in step 1. Place this certificate into a data set called USER1.SYSTEMA.STACK1.GENREQ as follows:

   ```
   RACDCERT ID(IKED) GENREQ(LABEL('SYSTEMA STACK1')) DSN('USER1.SYSTEMA.STACK1.GENREQ')
   ```

4. Send the certificate request to the certificate authority. The certificate request is in base 64-encoded text. Typically, the request is sent to the certificate authority by cutting and pasting the certificate request into an e-mail that is sent to the certificate authority.

   The certificate authority validates the certificate. If the certificate is approved by the certificate authority, it is signed by the certificate authority and returned to the requester.

5. Receive the returned certificate into a data set (for example, USER1.SYSTEMA.STACK1.CERT). The returned certificate is in base 64-encoded text. This can be done by cutting and pasting, with FTP, or with another technique.

6. Replace the self-signed certificate with the certificate that is signed by the certificate authority. The certificate is replaced only if the user ID that is specified as the ID value on the RACDCERT ADD command is the same user ID that was specified when the certificate was created. Ensure that the user ID is the same. Otherwise, the certificate is added, rather than replacing the self-signed certificate, and does not contain the certificate's private key.

   ```
   RACDCERT ID(IKED) ADD('USER1.SYSTEMA.STACK1.CERT') WITHLABEL('SYSTEMA STACK1')
   ```

7. Connect the certificate to an existing key ring:

   ```
   RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1') RING(ikeyring) USAGE(PERSONAL))
   ```

8. Connect the certificate authority's certificate to the key ring:

   ```
   RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('External CA') RING(ikeyring) USAGE(CERTAUTH))
   ```

   This completes the certificate hierarchy from root to SYSTEMA STACK1.

9. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

   ```
   Keyring   IKED/ikeyring
   ```

Requirement: If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the RACF database for the system on which the NSS server runs. For details about these profiles, see "Steps for authorizing resources for NSS" on page 1152.

You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity `CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US` from the certificate's subject name, and the FQDN identity `ibm.com` from the certificate's alternate subject name.

You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the Ring Associations field. Verify that the certificate authority was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT CERTAUTH LIST(LABEL('External CA')
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

Steps for generating a self-signed X509 digital certificate

Before you begin: The certificate that is assigned to the secure server is a locally-signed certificate rather than one signed by a certificate authority. Assume that the local certificate authority has the distinguished name of `OU='Local Certificate Authority',O=IBM,C=US`.

Requirement: If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. The user ID in the examples must be the user ID running the NSS server and the key ring must be the key ring configured in the NSS server's configuration file.

Perform the following steps to implement a locally signed server certificate:

1. Generate a self-signed certificate to represent the local certificate authority:

   ```
   RACDCERT CERTAUTH GENCERT SUBJECTSDN(OU('Local Certificate Authority') O('IBM') C('US'))
   KEYUSAGE(CERTSIGN) WITHLABEL('IBM Local Certificate Authority')
   ```

   This certificate is used as the certificate authority certificate.
2. Export the certificate to a data set (in this case, USER1.LOCCERTA.CERT):

   ```
   RACDCERT CERTAUTH EXPORT(LABEL('IBM Local Certificate Authority')) DSN('USER1.LOCCERTA.CERT')
   ```
3. Create a certificate for the server that is signed with the certificate authority certificate that was created in step 1:

   ```
   RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US'))
   WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))
   SIGNWITH(CERTAUTH LABEL('IBM Local Certificate Authority'))
   ```
4. Connect the certificate to an existing key ring:

   ```
   RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1') RING(ikeyring) USAGE(PERSONAL))
   ```
5. Connect the local certificate authority certificate to the key ring:

   ```
   RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('IBM Local Certificate Authority') RING(ikeyring) USAGE(CERTAUTH))
   ```

   This completes the certificate hierarchy from root to SYSTEMA STACK1.
6. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

   ```
   Keyring   IKED/ikeyring
   ```

Requirement: If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the

RACF database for the system on which the NSS server runs. For details about these profiles, see “Steps for authorizing resources for NSS” on page 1152.

You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity `CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US` from the certificate's subject name, and the FQDN identity `ibm.com` from the certificate's alternate subject name.

You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the `Ring Associations` field. Verify that the certificate authority was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT CERTAUTH LIST(LABEL('IBM Local Certificate Authority'))
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

Steps for migrating an existing key database to a RACF key ring

Before you begin: To migrate an existing key database file to a RACF key ring, see the information on migrating key database files to RACF key rings in *z/OS Cryptographic Services System SSL Programming*.

Perform the following steps to migrate keys and certificates that are stored in an existing z/OS key database into a RACF key ring:

1. Using gskkyman, export the certificate and private key to a password-protected PKCS#12 file. For details on copying a certificate with its private key, see *z/OS Cryptographic Services System SSL Programming*.
2. Copy the newly created PKCS#12 file to an MVS data set.
3. Use the RACDCERT command with the ADD operand to define a certificate and private key. The data set name that was created in step 2 contains the certificate.
4. Use the RACDCERT command with the ADDRING operand to create a new key ring in RACF.
5. Use the RACDCERT command with the CONNECT operand to add the certificate and private key to one or more existing RACF key rings.

Appendix F. Using an LDAP server for policy definitions

Lightweight Directory Access Protocol (LDAP) is a fast-growing technology for accessing common directory information. LDAP has been embraced and implemented in most network-oriented middleware. As an open, vendor-neutral standard, LDAP provides an extendable architecture for centralized storage and management of information that needs to be available for today's distributed systems and services.

Note: If the z/OS LDAP server is used, a DB2 backend is required.

Policy object model overview

Policies consist of several related objects. The main object is the *policy rule*. A policy rule object refers to one or more *policy condition*, *policy action*, or *policy time period condition* objects, and also contains information on how these objects are to be used. Policy time period objects are used to determine when a given policy rule is active. Active policy objects are related in a way that is analogous to an 'IF' statement in a program. For example:

```
IF condition THEN action
```

In other words, when the set of conditions referred to by a policy rule are TRUE, then the policy actions associated with the policy rule are executed.

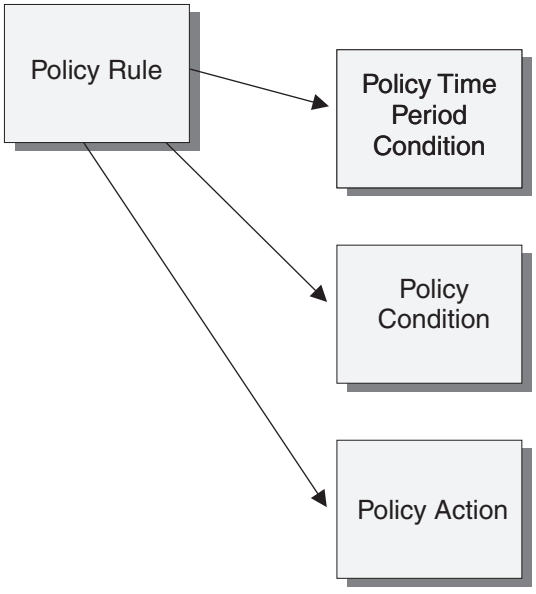

Figure 182. Basic policy objects

Policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a *simple* rule, and one with more conditions is known as a *complex* rule. Complex policy rules can have their conditions evaluated according to one of two different methods. The first is Disjunctive Normal Form (DNF), which means an ORed set of ANDed conditions. The second is Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. In order to accomplish these evaluations, individual policy conditions are assigned an

arbitrary group number, and also an indication of whether or not the condition is negated. For example, consider the following set of conditions for a policy rule:

```
C1:  Group Number = 1, Condition Negated = FALSE
C2:  Group Number = 1, Condition Negated = TRUE
C3:  Group Number = 1, Condition Negated = FALSE
C4:  Group Number = 2, Condition Negated = FALSE
C5:  Group Number = 2, Condition Negated = FALSE
```

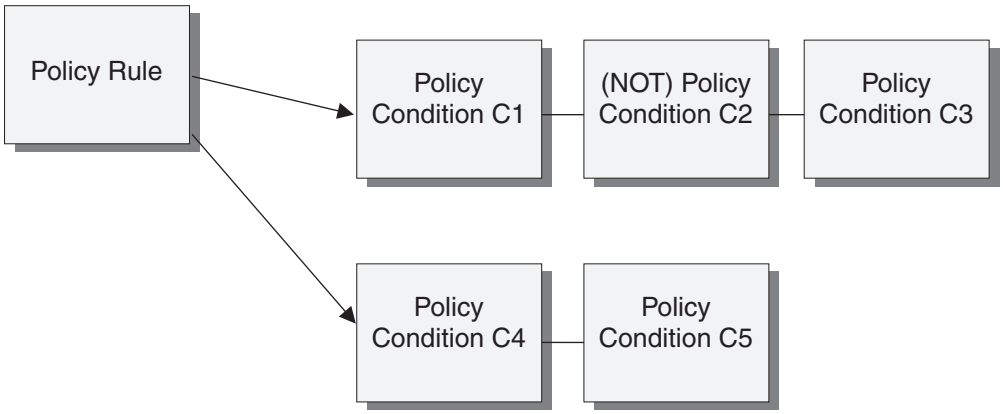

Figure 183. Complex policy conditions

If the conditions are to be evaluated using DNF, then the overall condition for the policy rule is:

```
(C1 AND (NOT C2) AND C3) OR (C4 AND C5)
```

On the other hand, if CNF is used to evaluate the conditions, then the overall condition for the policy rule is:

```
(C1 OR (NOT C2) OR C3) AND (C4 OR C5)
```

Complex rules can be split into multiple simple rules. Negated conditions are not allowed in a rule if explosion is to be performed. Consider the following set of conditions for a policy rule:

```
C1:  Group Number = 1, Condition Negated = FALSE
C2:  Group Number = 1, Condition Negated = FALSE
C3:  Group Number = 1, Condition Negated = FALSE
C4:  Group Number = 2, Condition Negated = FALSE
C5:  Group Number = 2, Condition Negated = FALSE
```

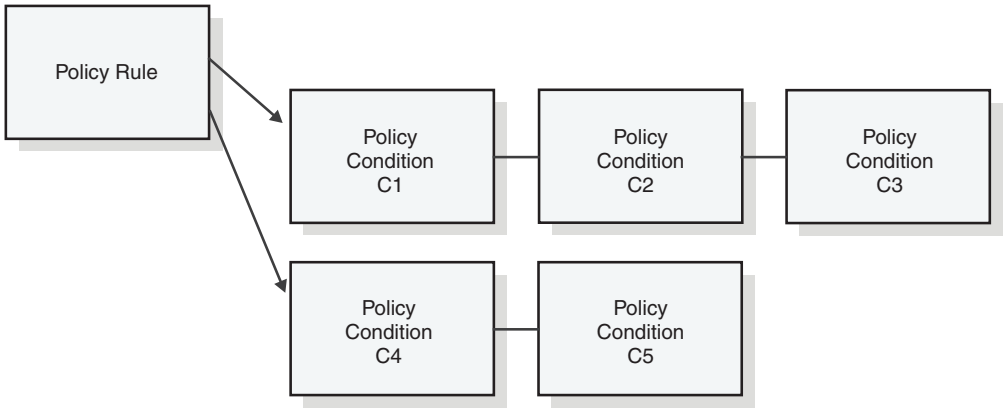

Figure 184. Complex policy conditions before explosion

If DNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

```
Simple Rule 1:  C1 AND C2 AND C3
Simple Rule 2:  C4 AND C5
```

If CNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

```
Simple Rule 1:  C1 AND C4
Simple Rule 2:  C1 AND C5
Simple Rule 3:  C2 AND C4
Simple Rule 4:  C2 AND C5
Simple Rule 5:  C3 AND C4
Simple Rule 6:  C3 AND C5
```

Policy actions specify actions to take when the set of conditions for a policy rule evaluate to TRUE. The policy model allows multiple actions for a policy rule. Many policy rules typically use only a single action, but multiple actions make sense for some policy types.

Policy conditions and actions can either be specific to a single rule, or be reusable among several policy rules. To allow either type of conditions and actions, and to specify related information such as condition group number and negation indicator, several other policy objects are required. First are *policy condition association* and *policy action association* objects. These objects contain condition and action related attributes, respectively, and may directly contain policy conditions and actions (rule-specific).

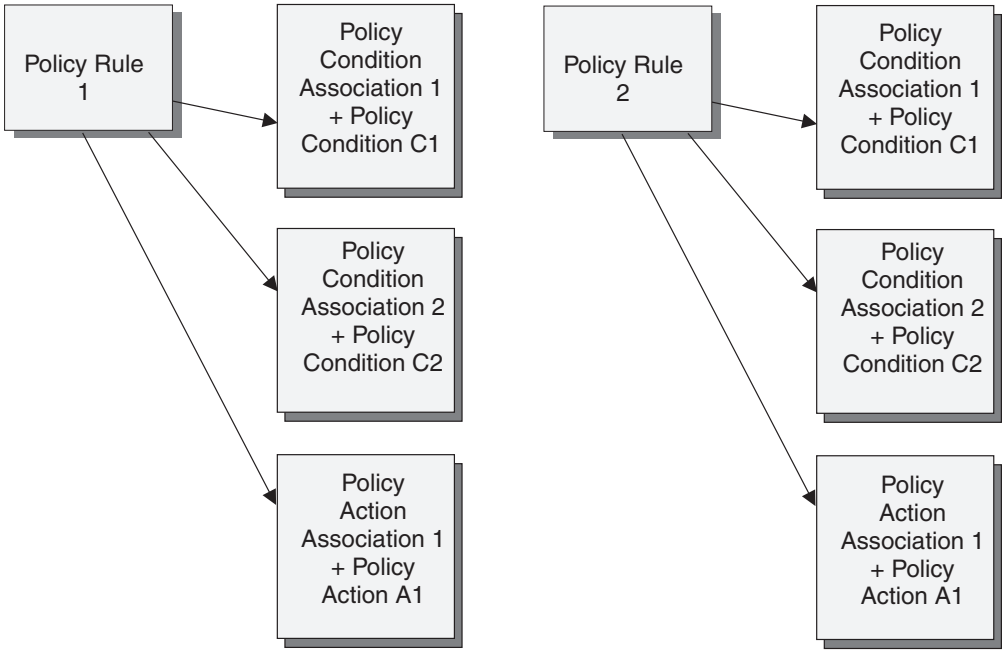

Figure 185. Rule-specific conditions and actions

The policy association objects alternatively may refer to conditions and actions (reusable). *Policy condition instance* and *policy action instance* objects are used to represent reusable policy conditions and actions, respectively.

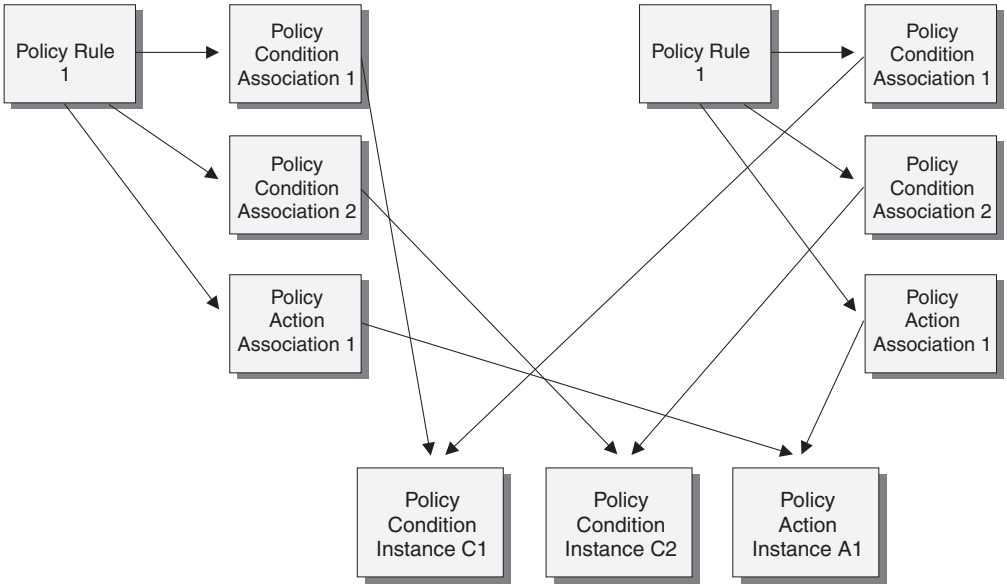

Figure 186. Reusable conditions and actions

Primarily for administrative grouping of policy rules, the *policy group* object is used. Policy groups can refer either to policy rules or to policy groups. This allows related policy rules to be grouped together, and also allows policy groups to be grouped to any needed level of nesting.

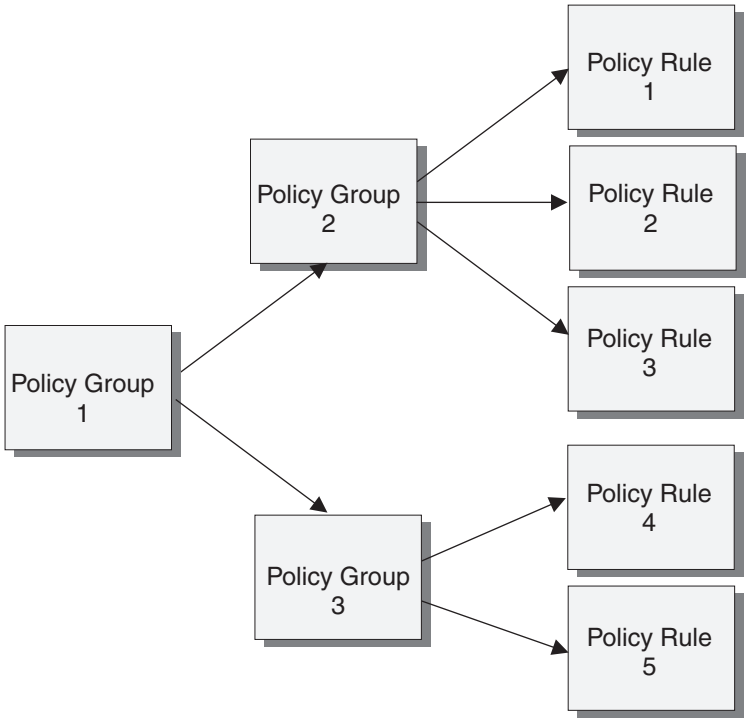

Figure 187. Policy groups

Overview of the object classes

Policies defined on an LDAP server are comprised of one or more objects, each with a defined object class, and a unique name. Object names are in the form of LDAP Distinguished Names (DNs), which are text strings composed of individual parts known as Relative Distinguished Names (RDNs). The structure of the naming defines a hierarchical tree, in a manner similar to directories in a hierarchical file system. For example, consider the following set of objects:

```
Object 1, DN: o=IBM, c=US
Object 2, DN: cn=group_1, o=IBM, c=US
Object 3, DN: cn=group_5, o=IBM, c=US
Object 4, DN: cn=group_1_sub_A, cn=group_1, o=IBM, c=US
```

This set of objects can be viewed as a tree, with Object 1 as the root. Objects 2 and 3 are branches under the root, with Object 4 a branch under Object 2. The names used are attributes of the objects they define. For example, Object 2, whose name starts with "cn=group_1" contains a cn attribute with the value group_1. See *z/OS Integrated Security Services LDAP Server Administration and Use* for more information on LDAP naming.

Object class names define the type of each LDAP object. The *top* object class is predefined and is the root of all other object classes.

There are three types of object classes.

Abstract object classes
: Used to define broad concepts, such as policy and to define basic attributes that apply to all subclasses.

Structural object classes
Basic building blocks, and are the only type of object class that can be instantiated as real objects on an LDAP server.

Auxiliary object classes
Used to define attributes that are shared among different structural object classes, or are used to extend the basic set of objects.

Attributes from auxiliary classes are *attached* to structural objects by including them in the structural objects, and also by including the auxiliary object class as one of the values of the objectClass attribute in the structural object.

The following object classes are recognized by the Policy Agent. The indentation defines subclasses. For example, ibm-policyGroup is a subclass of ibm-policy, and therefore inherits all of the attributes defined for ibm-policy.

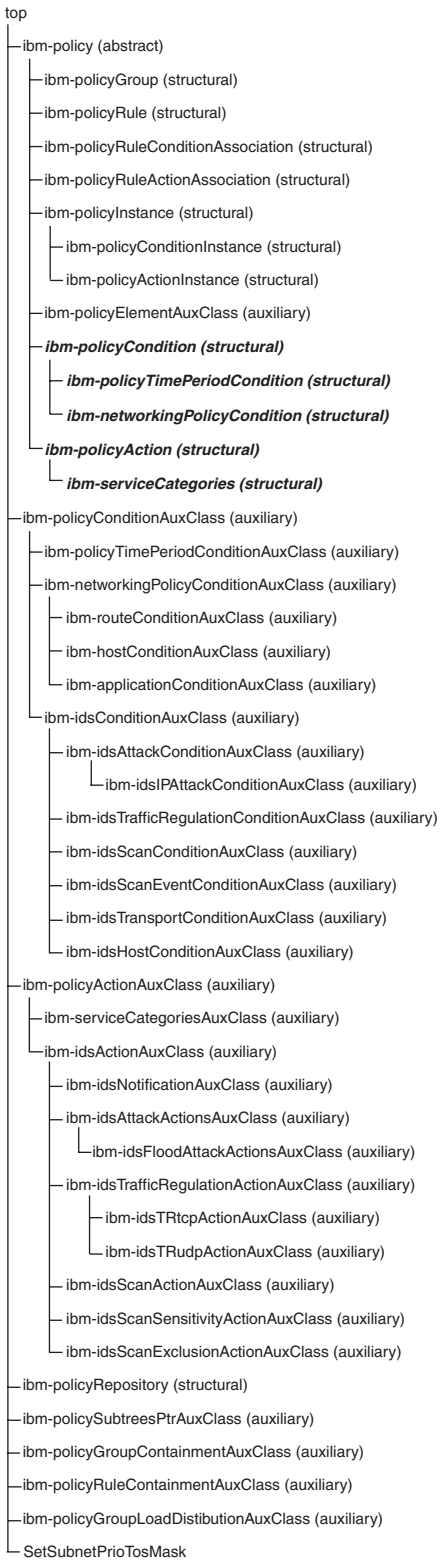

Figure 188. LDAP schema object class hierarchy

Note: The classes identified in bold italics in Figure 188 are for schema version 2 and are mutually exclusive with the schema version 3 classes with similar names.

Object class name	Purpose of object
Top	Used to anchor the LDAP hierarchical tree root.
ibm-policy	Used as the root for all policy objects.
ibm-policyGroup	Defines a policy group object.
ibm-policyRule	Defines a policy rule object.
ibm-policyRuleConditionAssociation	Defines an association between a policy rule object and a policy condition.
ibm-policyRuleActionAssociation	Defines an association between a policy rule object and a policy action.
ibm-PolicyInstance	Defines an instance of a reusable policy object.
ibm-PolicyConditionInstance	Defines an instance of a reusable policy condition object.
ibm-PolicyActionInstance	Defines an instance of a reusable policy action object.
ibm-PolicyElementAuxClass	Defines an auxiliary class that can be used to *tag* non-policy objects as though they were policy objects.
ibm-policyCondition	Defines a policy condition object. (**schema version 2** — supported for migration)
ibm-policyTimePeriodCondition	Defines an auxiliary class to represent time periods during which a policy rule is considered to be active. (**schema version 2** — supported for migration)
ibm-networkingpolicyCondition	Defines a subclass of ibm-PolicyCondition used to define networking policy conditions. (**schema version 2** — supported for migration)
ibm-policyAction	Defines a policy action object. (**schema version 2** — supported for migration)
ibm-serviceCategories	Defines an auxiliary class to represent a set of QoS attributes for a policy action. (**schema version 2** — supported for migration)
ibm-policyConditionAuxClass	Defines an auxiliary class for generic policy conditions.
ibm-policyTimePeriodConditionAuxClass	Defines an auxiliary class to represent time periods during which a policy rule is considered to be active.
ibm-networkingPolicyConditionAuxClass	Defines an auxiliary class used to define networking policy conditions.
ibm-routeConditionAuxClass	Defines an auxiliary class to represent QoS routing conditions for a policy rule.
ibm-hostConditionAuxClass	Defines an auxiliary class to represent QoS host (end-point) conditions for a policy rule.

Object class name	Purpose of object
ibm-applicationConditionAuxClass	Defines an auxiliary class to represent QoS application and transport conditions for a policy rule.
ibm-idsConditionAuxClass	Defines an auxiliary class to represent generic IDS conditions.
ibm-idsAttackConditionAuxClass	Defines an auxiliary class to represent IDS attack conditions.
ibm-idsIPAttackConditionAuxClass	Defines an auxiliary class to represent IDS IP attack conditions.
ibm-idsTrafficRegulationConditionAuxClass	Defines an auxiliary class to represent IDS Traffic Regulation conditions.
ibm-idsScanConditionAuxClass	Defines an auxiliary class to represent IDS global scan conditions.
ibm-idsScanEventConditionAuxClass	Defines an auxiliary class to represent IDS scan event conditions.
ibm-idsTransportConditionAuxClass	Defines an auxiliary class to represent IDS transport conditions.
ibm-idsHostConditionAuxClass	Defines an auxiliary class to represent IDS host conditions.
ibm-policyActionAuxClass	Defines an auxiliary class for generic policy actions.
ibm-serviceCategoriesAuxClass	Defines an auxiliary class to represent a set of QoS attributes for a policy action.
ibm-idsActionAuxClass	Defines an auxiliary class to represent generic IDS actions.
ibm-idsNotificationAuxClass	Defines an auxiliary class to represent notification options for IDS actions.
ibm-idsAttackActionsAuxClass	Defines an auxiliary class to represent attack attributes for IDS actions.
ibm-idsFloodAttackActionsAuxClass	Defines an auxiliary class to represent flood-specific attack attributes for IDS actions.
ibm-idsTrafficRegulationActionAuxClass	Defines an auxiliary class to represent generic Traffic Regulation attributes for IDS actions.
ibm-idsTRtcpActionAuxClass	Defines an auxiliary class to represent Traffic Regulation TCP attributes for IDS actions.
ibm-idsTRudpActionAuxClass	Defines an auxiliary class to represent Traffic Regulation UDP attributes for IDS actions.
ibm-idsScanActionAuxClass	Defines an auxiliary class to represent global scan attributes for IDS actions.
ibm-idsScanSensitivityActionAuxClass	Defines an auxiliary class to represent scan sensitivity attributes for IDS actions.
ibm-idsScanExclusionActionAuxClass	Defines an auxiliary class to define scan exclusion lists for IDS actions.

Object class name	Purpose of object
ibm-policyRepository	Defines a repository for generic reusable policy objects.
ibm-policySubtreesPtrAuxClass	Defines an auxiliary class to represent pointers to subtrees in the LDAP directory tree to be retrieved by the Policy Agent. This allows entire subtrees to be retrieved at once, improving retrieval performance in some situations.
ibm-policyGroupContainmentAuxClass	Defines an auxiliary class for binding a policy group object to another policy group.
ibm-policyRuleContainmentAuxClass	Defines an auxiliary class for binding a policy rule object to another policy group.
ibm-policyGroupLoadDistributionAuxClass	Defines an auxiliary class to represent load distribution attributes for policy groups. The load distribution attributes are applied to all policy rules that are pointed to by groups to which this auxiliary class has been attached.
SetSubnetPrioTosMask	Defines a mapping of outbound IPv4 packet Type of Service (ToS) byte or IPv6 packet Traffic Class values to QDIO device priorities and Virtual LAN (VLAN) user priorities.

Policy objects are used to accomplish the following objectives:

- Group related objects together. Policy groups can contain related policy rules, and can also contain other policy groups. This allows objects to be grouped in various administrative ways. If the resulting objects will be retrieved by any Policy Agent prior to z/OS Communications Server V1R2, then the object should not include the values ibm-policyGroupContainmentAuxClass, ibm-policyRuleContainmentAuxClass or ibm-policyGroupLoadDistributionAuxClass for the objectClass attribute.
- Specify conditions for a policy rule. The conditions are used to filter traffic packets, and can specify attributes such as source and destination port, application name, protocol, and so on. Policy rules can be either simple or complex, depending on the nature of the specified conditions. When a single condition is specified, the rule is a simple rule. This single condition can be composed of any of the condition attributes, but only one instance of each. For example, only a single destination port range can be specified in a simple rule. Complex rules specify more than one condition. The specified conditions are organized into one or more levels, and each level is composed of one or more conditions. Each condition can be composed of one instance of any of the condition attributes. The conditions can thus be thought of as a two-dimensional array. Any individual condition can be negated. Two types of processing are applied to the conditions, depending on the specified condition list type:
  - Disjunctive Normal Form (DNF). DNF conditions are logically ANDed at each level, and ORed between levels.
  - Conjunctive Normal Form (CNF). CNF conditions are logically ORed at each level, and ANDed between levels.

For example, suppose five conditions are specified, two at one level and three at another:

```
Level 1: C1, NOT C2
Level 2: C3, C4, C5
```

If DNF is specified, the conditions are evaluated as:

```
(C1 AND NOT C2) OR (C3 AND C4 AND C5)
```

CNF evaluation of the same conditions is:

```
(C1 OR NOT C2) AND (C3 OR C4 OR C5)
```

This allows a wide variety of conditional logic to be defined for policy rules.

- Specify time periods during which policy rules are active. Active policy rules are those that are installed in a TCP/IP stack by the Policy Agent. A wide variety of attributes are available to specify time periods, and up to 25 time periods can be specified for any policy rule. The policy rule is active if any of the specified time intervals include the current time.
- Specify actions to take on behalf of traffic that maps to active policy rules, based on the evaluation of its conditions. QoS Actions contain a scope attribute that indicates the type of policy being defined, namely Differentiated Services, RSVP, or both Differentiated Services and RSVP. Up to four actions can be specified for each rule, but only one action per scope can be active at a time. IDS actions contain an action type that indicates the type of policy being defined, namely Attack, TR, Scan Global, or Scan Event. Only one IDS action can be specified for each rule. QoS and IDS actions (or conditions) can't be mixed within a single policy rule.

Considerations for defining LDAP objects

LDAP objects can refer to other objects, using the DN of the referenced object. For example, a policy rule can be separated from its conditions and time periods, with those objects being referenced by the rule object.

Each LDAP object is composed of a number of attributes. Some of the attributes are generic LDAP attributes that apply to all LDAP objects. Other attributes are used only for Version 1 policy definitions. All other Version 2 and later policy attributes must begin with a unique prefix:

```
ibm-
```

When defining complex policy rules (those with more than one condition or action), two mutually exclusive methods can be used to associate the conditions or actions with the rule:

- The ibm-policyConditionListDN and ibm-policyActionListDN attributes can be omitted from the rule. In this case, the condition and action association objects MUST be created as subordinate objects to the policy rule, in other words, *under* the rule in the directory subtree. This is known as Directory Information Tree (DIT)-containment.
- The ibm-policyConditionListDN and ibm-policyActionListDN attributes can be specified in the rule. In this case, the condition and action association objects SHOULD be created as subordinate objects to the policy rule, in other words, *under* the rule in the directory subtree. However, this is not a requirement, only a recommendation. The objects can actually exist anywhere in the DIT.

Policy Agent retrieval of LDAP objects

The design of the LDAP object tree should be carefully thought out. The Policy Agent uses a variety of mechanisms to search for and retrieve objects from an LDAP server:

- An initial search is done for a subtree of objects based on the SearchBaseDN parameter on the ReadFromDirectory statement.
- If any objects retrieved by this initial search contain subtree pointer references (using the ibm-policySubtreesAuxContainedSet attribute) then a search is done for all such subtrees. This is a recursive search: additional objects retrieved might also contain subtree pointer references.
- The above searches use a filter to only retrieve certain object classes. For LDAP protocol version 3, the default is to only scan for the ibm-policy object class. This is an abstract object class from which all other policy object classes are derived. Most LDAPv3 servers implement abstract and auxiliary classes such that this search will properly retrieve policy, and only policy, object classes. However, some LDAPv3 servers do not honor abstract/auxiliary object classes as a search filter. For these servers, specify LDAP_AbstractPolicy NO on the ReadFromDirectory statement. This causes the searches to use a filter that retrieves ALL object classes.
- All of the above searches may be scoped, or filtered, using keywords specified on the ReadFromDirectory statement parameters SearchPolicyKeyword, SearchPolicyGroupKeyword, or SearchPolicyRuleKeyword. The LDAP server only returns objects with any matching keywords.
- Some objects retrieved using the above searches may contain DN pointer references to additional objects. These objects are individually retrieved. If the object to be retrieved is a policy rule, then a subtree search is performed, using the keywords specified on the ReadFromDirectory statement. All other objects are retrieved as single objects, using the DN pointers (no keywords are used on the search).
- All policy rule objects retrieved using the above searches are further filtered using the PolicyRole parameter on the ReadFromDirectory statement. Any rules that do not match policy roles specified on the ReadFromDirectory statement are discarded.

Therefore, it is possible to design an LDAP tree such that a minimal set of objects is initially retrieved, followed by many additional individual LDAP retrievals. If the total set of objects is large, there is a performance impact to retrieving objects in this manner. If possible, try to design the tree and the ReadFromDirectory parameters to retrieve the largest set of objects initially, to achieve the best performance, or to use subtree pointer references to retrieve larger sets of objects in one operation.

LDAP sample files

The following set of sample files provides an example of policy definitions in LDAP. For more information on using these sample files, see "Using the sample LDAP objects" on page 1532.

/usr/lpp/tcpip/samples/pagent.ldif
: This file contains the top level directory structure for the set of sample quality of service (QoS) and intrusion detection services (IDS) policies.

/usr/lpp/tcpip/samples/pagent_starter_QOS.ldif
: This file contains the starter set sample of LDAP definitions of QoS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_starter_IDS.ldif
This file contains the starter set sample of LDAP definitions of IDS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_QOS.ldif
This file contains the advanced set sample of LDAP definitions of QoS objects. This file requires the objects defined in the QoS starter set sample file pagent_starter_QOS.ldif and the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_IDS.ldif
This file contains the advanced set sample of LDAP definitions of IDS objects. This file requires the objects defined in the IDS starter set sample file pagent_starter_IDS.ldif and the directory structure defined in sample file pagent.ldif.

The next set of samples is the definition of the schemas in LDAP protocol version 3 format. They must be installed on the LDAPv3 server in the proper order as an object in the server's database, rather than as configuration information. This process is known as schema publication. See RFCs 1804 and 2251. The files need to be specified on ldapmodify commands to modify the cn:schema entry in the server's database. See "Installing the schema definition on the LDAP server" for more information.

/usr/lpp/tcpip/samples/pagent_r8qosschema.ldif
This file contains the schema version 3 QoS schema definitions.

/usr/lpp/tcpip/samples/pagent_r5idsschema.ldif
This file contains the schema version 3 IDS schema definitions.

The next set of samples contain the text of draft documents used to develop the Version 3 schema.

/usr/lpp/tcpip/samples/pagent_pcim.txt
This file contains the draft version of the proposed Policy Core Information Model (PCIM) used as the basis for the support in this release. PCIM is described by RFC 3060 but this file is an earlier draft level.

/usr/lpp/tcpip/samples/pagent_core.txt
This file contains the draft version of the proposed Policy Core LDAP Schema Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

/usr/lpp/tcpip/samples/pagent_cond.txt
This file contains the draft version of the proposed Policy Conditions Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

Installing the schema definition on the LDAP server

The files that define the schema supported by the Policy Agent are shipped as a set of sample files. You need to modify the configuration of the LDAP server to include these schema definition files.

For LDAP protocol version 3, the schema definition is shipped in *ldif* format and installed on the LDAP server as a modification to the generic schema entry, known as a subschema. You must modify the existing schema entry to include the supported schema as a subschema by using the **ldapmodify** command. The schema definition files that you must install are located in the /usr/lpp/tcpip/samples directory. You must install the files in the following order:

1. pagent_r8qosschema.ldif
2. pagent_r5idsschema.ldif

This process is supported for the z/OS LDAP server.

To install the schema definitions, use commands like those shown in the following examples:

```
ldapmodify -h <server address> -p <server port> -D <administrator userid>
-w <password> -f /usr/lpp/tcpip/samples/pagent_r8qosschema.ldif
```

```
ldapmodify -h <server address> -p <server port> -D <administrator userid>
-w <password> -f /usr/lpp/tcpip/samples/pagent_r5idsschema.ldif
```

See the TDBM backend information in *z/OS Integrated Security Services LDAP Server Administration and Use* for more details.

Using the sample LDAP objects

There are 5 sample files that provide examples of policy definitions in LDAP:

- pagent.ldif
- pagent_starter_IDS.ldif
- pagent_starter_QOS.ldif
- pagent_advanced_IDS.ldif
- pagent_advanced_QOS.ldif

For brief descriptions of these files, see "Policy sample files" on page 841. You can either use some or all of these predefined policies in the starter and advanced sets, or modify them as needed.

The recommended way to create customized policies is to copy the sample policies you want to change to the custom portion of the pagent.ldif file (under the appropriate cn=custom root, QoS or IDS), modify them as needed, and then point to the custom set as the search base on the ReadFromDirectory statement.

For example, the pagent.ldif file has the following hierarchical structure [this shows the relevant parts of the Distingushed Name (DN) for each object]:

```
o=IBM, c=US (root object)
    cn=repository (root of all reusable policy conditions and actions)
    ou=policy (root of all policy groups and rules)
       cn=groups (root of sample groups)
       cn=starter (root of simple starter set of policies)
           cn=IDS (IDS starter set - actually defined in file pagent_starter_IDS.ldif)
           cn=QoS (QOS starter set - actually defined in file pagent_starter_QOS.ldif)
       cn=advanced (root of advanced set of policies)
           cn=IDS (IDS advanced set - actually defined in file pagent_advanced_IDS.ldif)
           cn=QoS (QOS advanced set - actually defined in file pagent_advanced_QOS.ldif)
       cn=custom (root of customer-defined set of policies)
           cn=IDS (root of customer-defined IDS policies (empty))
           cn=QoS (root of customer-defined QOS policies (empty))
```

To obtain only the customized policies, specify the top custom policy group object as the search base on the ReadFromDirectory statement as follows:

```
ReadFromDirectory {
...
SearchPolicyBaseDN   dn:cn=custom, ou=policy, o=IBM, c=US
...
}
```

Note: If your LDAP server has a root structure other than "o=IBM, c=US", be sure to change the root structure in all the files you want to use by replacing every instance of "o=IBM, c=US" with the appropriate root used on your LDAP server.

Defining QoS policies using LDAP

This topic contains examples for defining QoS policies using LDAP.

Differentiated Services policy example

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the ibm-PolicyScope:DataTraffic attribute in the ibm-PolicyActionInstance object.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11 or 200.50.33.14 or 202::B055:1.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005.
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
- The action establishes a *token bucket* traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as *best effort*, with an accompanying ToS byte of '00000000'.

The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will only match traffic on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".
- Since we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the ibm-PolicyScope:RSVP attribute in the ibm-PolicyActionInstance object.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- One policy action specifies that the ToS byte be set to 01100000 for traffic that conforms to this policy.
- The RSVP policy action limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.
- The action also limits the number of active RSVP flows that map to this policy to 10.

```

Sysplex distributor routing policy example

The goal of this sysplex distributor policy is to limit the number of SD target servers for inbound Telnet traffic. The policies are identified as SD policies by the ibm-policyGroupForLoadDistribution:TRUE attribute in the ibm-PolicyGroup object.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target servers.
- The policy rules select incoming Telnet connection requests.
- The selected target server will be based on WLM information and QoS information if activated at the target servers.
- The rule (disttelnet) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (targtelnet) is coded on the target server to select outbound data from the Telnet server.
- If none of the specified target servers are available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target server.

Note: If the ibm-Interface:1–0.0.0.0 attribute were not present, and none of the defined target servers were available, sysplex distributor would reject the request.

Appendix G. Related protocol specifications

This appendix lists the related protocol specifications (RFCs) for TCP/IP. The Internet Protocol suite is still evolving through requests for comments (RFC). New protocols are being designed and implemented by researchers and are brought to the attention of the Internet community in the form of RFCs. Some of these protocols are so useful that they become recommended protocols. That is, all future implementations for TCP/IP are recommended to implement these particular functions or protocols. These become the *de facto* standards, on which the TCP/IP protocol suite is built.

You can request RFCs through electronic mail, from the automated Network Information Center (NIC) mail server, by sending a message to `service@nic.ddn.mil` with a subject line of `RFC nnnn` for text versions or a subject line of `RFC nnnn.PS` for PostScript versions. To request a copy of the RFC index, send a message with a subject line of `RFC INDEX`.

For more information, contact `nic@nic.ddn.mil` or at:

Government Systems, Inc.
Attn: Network Information Center
14200 Park Meadow Drive
Suite 200
Chantilly, VA 22021

Hard copies of all RFCs are available from the NIC, either individually or by subscription. Online copies are available at the following Web address: http://www.rfc-editor.org/rfc.html.

See “Internet drafts” on page 1571 for draft RFCs implemented in this and previous Communications Server releases.

Many features of TCP/IP Services are based on the following RFCs:

RFC	Title and Author
RFC 652	*Telnet output carriage-return disposition option* D. Crocker
RFC 653	*Telnet output horizontal tabstops option* D. Crocker
RFC 654	*Telnet output horizontal tab disposition option* D. Crocker
RFC 655	*Telnet output formfeed disposition option* D. Crocker
RFC 657	*Telnet output vertical tab disposition option* D. Crocker
RFC 658	*Telnet output linefeed disposition* D. Crocker
RFC 698	*Telnet extended ASCII option* T. Mock
RFC 726	*Remote Controlled Transmission and Echoing Telnet option* J. Postel, D. Crocker
RFC 727	*Telnet logout option* M.R. Crispin
RFC 732	*Telnet Data Entry Terminal option* J.D. Day
RFC 733	*Standard for the format of ARPA network text messages* D. Crocker, J. Vittal, K.T. Pogran, D.A. Henderson

RFC 734 *SUPDUP Protocol* M.R. Crispin

RFC 735 *Revised Telnet byte macro option* D. Crocker, R.H. Gumpertz

RFC 736 *Telnet SUPDUP option* M.R. Crispin

RFC 749 *Telnet SUPDUP—Output option* B. Greenberg

RFC 765 *File Transfer Protocol specification* J. Postel

RFC 768 *User Datagram Protocol* J. Postel

RFC 779 *Telnet send-location option* E. Killian

RFC 783 *TFTP Protocol (revision 2)* K.R. Sollins

RFC 791 *Internet Protocol* J. Postel

RFC 792 *Internet Control Message Protocol* J. Postel

RFC 793 *Transmission Control Protocol* J. Postel

RFC 820 *Assigned numbers* J. Postel

RFC 821 *Simple Mail Transfer Protocol* J. Postel

RFC 822 *Standard for the format of ARPA Internet text messages* D. Crocker

RFC 823 *DARPA Internet gateway* R. Hinden, A. Sheltzer

RFC 826 *Ethernet Address Resolution Protocol: Or converting network protocol addresses to 48.bit Ethernet address for transmission on Ethernet hardware* D. Plummer

RFC 854 *Telnet Protocol Specification* J. Postel, J. Reynolds

RFC 855 *Telnet Option Specification* J. Postel, J. Reynolds

RFC 856 *Telnet Binary Transmission* J. Postel, J. Reynolds

RFC 857 *Telnet Echo Option* J. Postel, J. Reynolds

RFC 858 *Telnet Suppress Go Ahead Option* J. Postel, J. Reynolds

RFC 859 *Telnet Status Option* J. Postel, J. Reynolds

RFC 860 *Telnet Timing Mark Option* J. Postel, J. Reynolds

RFC 861 *Telnet Extended Options: List Option* J. Postel, J. Reynolds

RFC 862 *Echo Protocol* J. Postel

RFC 863 *Discard Protocol* J. Postel

RFC 864 *Character Generator Protocol* J. Postel

RFC 865 *Quote of the Day Protocol* J. Postel

RFC 868 *Time Protocol* J. Postel, K. Harrenstien

RFC 877 *Standard for the transmission of IP datagrams over public data networks* J.T. Korb

RFC 883 *Domain names: Implementation specification* P.V. Mockapetris

RFC 884 *Telnet terminal type option* M. Solomon, E. Wimmers

RFC 885 *Telnet end of record option* J. Postel

RFC 894 *Standard for the transmission of IP datagrams over Ethernet networks* C. Hornig

RFC 896 *Congestion control in IP/TCP internetworks* J. Nagle

RFC 903 *Reverse Address Resolution Protocol* R. Finlayson, T. Mann, J. Mogul, M. Theimer

RFC 904 *Exterior Gateway Protocol formal specification* D. Mills

RFC 919 *Broadcasting Internet Datagrams* J. Mogul

RFC 922 *Broadcasting Internet datagrams in the presence of subnets* J. Mogul

RFC 927 *TACACS user identification Telnet option* B.A. Anderson

RFC 933 *Output marking Telnet option* S. Silverman

RFC 946 *Telnet terminal location number option* R. Nedved

RFC 950 *Internet Standard Subnetting Procedure* J. Mogul, J. Postel

RFC 952 *DoD Internet host table specification* K. Harrenstien, M. Stahl, E. Feinler

RFC 959 *File Transfer Protocol* J. Postel, J.K. Reynolds

RFC 961 *Official ARPA-Internet protocols* J.K. Reynolds, J. Postel

RFC 974 *Mail routing and the domain system* C. Partridge

RFC 1001 *Protocol standard for a NetBIOS service on a TCP/UDP transport: Concepts and methods* NetBios Working Group in the Defense Advanced Research Projects Agency, Internet Activities Board, End-to-End Services Task Force

RFC 1002 *Protocol Standard for a NetBIOS service on a TCP/UDP transport: Detailed specifications* NetBios Working Group in the Defense Advanced Research Projects Agency, Internet Activities Board, End-to-End Services Task Force

RFC 1006 *ISO transport services on top of the TCP: Version 3* M.T. Rose, D.E. Cass

RFC 1009 *Requirements for Internet gateways* R. Braden, J. Postel

RFC 1011 *Official Internet protocols* J. Reynolds, J. Postel

RFC 1013 *X Window System Protocol, version 11: Alpha update April 1987* R. Scheifler

RFC 1014 *XDR: External Data Representation standard* Sun Microsystems

RFC 1027 *Using ARP to implement transparent subnet gateways* S. Carl-Mitchell, J. Quarterman

RFC 1032 *Domain administrators guide* M. Stahl

RFC 1033 *Domain administrators operations guide* M. Lottor

RFC 1034 *Domain names—concepts and facilities* P.V. Mockapetris

RFC 1035 *Domain names—implementation and specification* P.V. Mockapetris

RFC 1038 *Draft revised IP security option* M. St. Johns

RFC 1041 *Telnet 3270 regime option* Y. Rekhter

RFC 1042 *Standard for the transmission of IP datagrams over IEEE 802 networks* J. Postel, J. Reynolds

RFC 1043 *Telnet Data Entry Terminal option: DODIIS implementation* A. Yasuda, T. Thompson

RFC 1044 *Internet Protocol on Network System's HYPERchannel: Protocol specification* K. Hardwick, J. Lekashman

RFC 1053 *Telnet X.3 PAD option* S. Levy, T. Jacobson

RFC 1055 *Nonstandard for transmission of IP datagrams over serial lines: SLIP* J. Romkey

RFC 1057 *RPC: Remote Procedure Call Protocol Specification: Version 2* Sun Microsystems

RFC 1058 *Routing Information Protocol* C. Hedrick

RFC 1060 *Assigned numbers* J. Reynolds, J. Postel

RFC 1067 *Simple Network Management Protocol* J.D. Case, M. Fedor, M.L. Schoffstall, J. Davin

RFC 1071 *Computing the Internet checksum* R.T. Braden, D.A. Borman, C. Partridge

RFC 1072 *TCP extensions for long-delay paths* V. Jacobson, R.T. Braden

RFC 1073 *Telnet window size option* D. Waitzman

RFC 1079 *Telnet terminal speed option* C. Hedrick

RFC 1085 *ISO presentation services on top of TCP/IP based internets* M.T. Rose

RFC 1091 *Telnet terminal-type option* J. VanBokkelen

RFC 1094 *NFS: Network File System Protocol specification* Sun Microsystems

RFC 1096 *Telnet X display location option* G. Marcy

RFC 1101 *DNS encoding of network names and other types* P. Mockapetris

RFC 1112 *Host extensions for IP multicasting* S.E. Deering

RFC 1113 *Privacy enhancement for Internet electronic mail: Part I — message encipherment and authentication procedures* J. Linn

RFC 1118 *Hitchhikers Guide to the Internet* E. Krol

RFC 1122 *Requirements for Internet Hosts—Communication Layers* R. Braden, Ed.

RFC 1123 *Requirements for Internet Hosts—Application and Support* R. Braden, Ed.

RFC 1146 *TCP alternate checksum options* J. Zweig, C. Partridge

RFC 1155 *Structure and identification of management information for TCP/IP-based internets* M. Rose, K. McCloghrie

RFC 1156 *Management Information Base for network management of TCP/IP-based internets* K. McCloghrie, M. Rose

RFC 1157 *Simple Network Management Protocol (SNMP)* J. Case, M. Fedor, M. Schoffstall, J. Davin

RFC 1158 *Management Information Base for network management of TCP/IP-based internets: MIB-II* M. Rose

RFC 1166 *Internet numbers* S. Kirkpatrick, M.K. Stahl, M. Recker

RFC 1179 *Line printer daemon protocol* L. McLaughlin

RFC 1180 *TCP/IP tutorial* T. Socolofsky, C. Kale

RFC 1183 *New DNS RR Definitions* C.F. Everhart, L.A. Mamakos, R. Ullmann, P.V. Mockapetris

RFC 1184 *Telnet Linemode Option* D. Borman

RFC 1186 *MD4 Message Digest Algorithm* R.L. Rivest

RFC 1187 *Bulk Table Retrieval with the SNMP* M. Rose, K. McCloghrie, J. Davin

RFC 1188 *Proposed Standard for the Transmission of IP Datagrams over FDDI Networks* D. Katz

RFC 1190 *Experimental Internet Stream Protocol: Version 2 (ST-II)* C. Topolcic

RFC 1191 *Path MTU discovery* J. Mogul, S. Deering

RFC 1198 *FYI on the X window system* R. Scheifler

RFC 1207 *FYI on Questions and Answers: Answers to commonly asked "experienced Internet user" questions* G. Malkin, A. Marine, J. Reynolds

RFC 1208 *Glossary of networking terms* O. Jacobsen, D. Lynch

RFC 1213 *Management Information Base for Network Management of TCP/IP-based internets: MIB-II* K. McCloghrie, M.T. Rose

RFC 1215 *Convention for defining traps for use with the SNMP* M. Rose

RFC 1227 *SNMP MUX protocol and MIB* M.T. Rose

RFC 1228 *SNMP-DPI: Simple Network Management Protocol Distributed Program Interface* G. Carpenter, B. Wijnen

RFC 1229 *Extensions to the generic-interface MIB* K. McCloghrie

RFC 1230 *IEEE 802.4 Token Bus MIB* K. McCloghrie, R. Fox

RFC 1231 *IEEE 802.5 Token Ring MIB* K. McCloghrie, R. Fox, E. Decker

RFC 1236 *IP to X.121 address mapping for DDN* L. Morales, P. Hasse

RFC 1256 *ICMP Router Discovery Messages* S. Deering, Ed.

RFC 1267 *Border Gateway Protocol 3 (BGP-3)* K. Lougheed, Y. Rekhter

RFC 1268 *Application of the Border Gateway Protocol in the Internet* Y. Rekhter, P. Gross

RFC 1269 *Definitions of Managed Objects for the Border Gateway Protocol: Version 3* S. Willis, J. Burruss

RFC 1270 *SNMP Communications Services* F. Kastenholz, ed.

RFC 1285 *FDDI Management Information Base* J. Case

RFC 1315 *Management Information Base for Frame Relay DTEs* C. Brown, F. Baker, C. Carvalho

RFC 1321 *The MD5 Message-Digest Algorithm* R. Rivest

RFC 1323 *TCP Extensions for High Performance* V. Jacobson, R. Braden, D. Borman

RFC 1325 *FYI on Questions and Answers: Answers to Commonly Asked "New Internet User" Questions* G. Malkin, A. Marine

RFC 1327 *Mapping between X.400 (1988)/ISO 10021 and RFC 822* S. Hardcastle-Kille

RFC 1340 *Assigned Numbers* J. Reynolds, J. Postel

RFC 1344 *Implications of MIME for Internet Mail Gateways* N. Bornstein

RFC 1349 *Type of Service in the Internet Protocol Suite* P. Almquist

RFC 1350 *The TFTP Protocol (Revision 2)* K.R. Sollins

RFC 1351 *SNMP Administrative Model* J. Davin, J. Galvin, K. McCloghrie

RFC 1352 *SNMP Security Protocols* J. Galvin, K. McCloghrie, J. Davin

RFC 1353 *Definitions of Managed Objects for Administration of SNMP Parties* K. McCloghrie, J. Davin, J. Galvin

RFC 1354 *IP Forwarding Table MIB* F. Baker

RFC 1356 *Multiprotocol Interconnect on X.25 and ISDN in the Packet Mode* A. Malis, D. Robinson, R. Ullmann

RFC 1358 *Charter of the Internet Architecture Board (IAB)* L. Chapin

RFC 1363 *A Proposed Flow Specification* C. Partridge

RFC 1368 *Definition of Managed Objects for IEEE 802.3 Repeater Devices* D. McMaster, K. McCloghrie

RFC 1372 *Telnet Remote Flow Control Option* C. L. Hedrick, D. Borman

RFC 1374 *IP and ARP on HIPPI* J. Renwick, A. Nicholson

RFC 1381 *SNMP MIB Extension for X.25 LAPB* D. Throop, F. Baker

RFC 1382 *SNMP MIB Extension for the X.25 Packet Layer* D. Throop

RFC 1387 *RIP Version 2 Protocol Analysis* G. Malkin

RFC 1388 *RIP Version 2 Carrying Additional Information* G. Malkin

RFC 1389 *RIP Version 2 MIB Extensions* G. Malkin, F. Baker

RFC 1390 *Transmission of IP and ARP over FDDI Networks* D. Katz

RFC 1393 *Traceroute Using an IP Option* G. Malkin

RFC 1398 *Definitions of Managed Objects for the Ethernet-Like Interface Types* F. Kastenholz

RFC 1408 *Telnet Environment Option* D. Borman, Ed.

RFC 1413 *Identification Protocol* M. St. Johns

RFC 1416 *Telnet Authentication Option* D. Borman, ed.

RFC 1420 *SNMP over IPX* S. Bostock

RFC 1428 *Transition of Internet Mail from Just-Send-8 to 8bit-SMTP/MIME* G. Vaudreuil

RFC 1442 *Structure of Management Information for version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1443 *Textual Conventions for version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1445 *Administrative Model for version 2 of the Simple Network Management Protocol (SNMPv2)* J. Galvin, K. McCloghrie

RFC 1447 *Party MIB for version 2 of the Simple Network Management Protocol (SNMPv2)* K. McCloghrie, J. Galvin

RFC 1448 *Protocol Operations for version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1464 *Using the Domain Name System to Store Arbitrary String Attributes* R. Rosenbaum

RFC 1469 *IP Multicast over Token-Ring Local Area Networks* T. Pusateri

RFC 1483 *Multiprotocol Encapsulation over ATM Adaptation Layer 5* Juha Heinanen

RFC 1514 *Host Resources MIB* P. Grillo, S. Waldbusser

RFC 1516 *Definitions of Managed Objects for IEEE 802.3 Repeater Devices* D. McMaster, K. McCloghrie

RFC 1521 *MIME (Multipurpose Internet Mail Extensions) Part One: Mechanisms for Specifying and Describing the Format of Internet Message Bodies* N. Borenstein, N. Freed

RFC 1535 *A Security Problem and Proposed Correction With Widely Deployed DNS Software* E. Gavron

RFC 1536 *Common DNS Implementation Errors and Suggested Fixes* A. Kumar, J. Postel, C. Neuman, P. Danzig, S. Miller

RFC 1537 *Common DNS Data File Configuration Errors* P. Beertema

RFC 1540 *Internet Official Protocol Standards* J. Postel

RFC 1571 *Telnet Environment Option Interoperability Issues* D. Borman

RFC 1572 *Telnet Environment Option* S. Alexander

RFC 1573 *Evolution of the Interfaces Group of MIB-II* K. McCloghrie, F. Kastenholz

RFC 1577 *Classical IP and ARP over ATM* M. Laubach

RFC 1583 *OSPF Version 2* J. Moy

RFC 1591 *Domain Name System Structure and Delegation* J. Postel

RFC 1592 *Simple Network Management Protocol Distributed Protocol Interface Version 2.0* B. Wijnen, G. Carpenter, K. Curran, A. Sehgal, G. Waters

RFC 1594 *FYI on Questions and Answers— Answers to Commonly Asked "New Internet User" Questions* A. Marine, J. Reynolds, G. Malkin

RFC 1644 *T/TCP — TCP Extensions for Transactions Functional Specification* R. Braden

RFC 1646 *TN3270 Extensions for LUname and Printer Selection* C. Graves, T. Butts, M. Angel

RFC 1647 *TN3270 Enhancements* B. Kelly

RFC 1652 *SMTP Service Extension for 8bit-MIMEtransport* J. Klensin, N. Freed, M. Rose, E. Stefferud, D. Crocker

RFC 1664 *Using the Internet DNS to Distribute RFC1327 Mail Address Mapping Tables* C. Allochio, A. Bonito, B. Cole, S. Giordano, R. Hagens

RFC 1693 *An Extension to TCP: Partial Order Service* T. Connolly, P. Amer, P. Conrad

RFC 1695 *Definitions of Managed Objects for ATM Management Version 8.0 using SMIv2* M. Ahmed, K. Tesink

RFC 1701 *Generic Routing Encapsulation (GRE)* S. Hanks, T. Li, D. Farinacci, P. Traina

RFC 1702 *Generic Routing Encapsulation over IPv4 networks* S. Hanks, T. Li, D. Farinacci, P. Traina

RFC 1706 *DNS NSAP Resource Records* B. Manning, R. Colella

RFC 1712 *DNS Encoding of Geographical Location* C. Farrell, M. Schulze, S. Pleitner D. Baldoni

RFC 1713 *Tools for DNS debugging* A. Romao

RFC 1723 *RIP Version 2—Carrying Additional Information* G. Malkin

RFC 1752 *The Recommendation for the IP Next Generation Protocol* S. Bradner, A. Mankin

RFC 1766 *Tags for the Identification of Languages* H. Alvestrand

RFC 1771 *A Border Gateway Protocol 4 (BGP-4)* Y. Rekhter, T. Li

RFC 1794 *DNS Support for Load Balancing* T. Brisco

RFC 1819 *Internet Stream Protocol Version 2 (ST2) Protocol Specification—Version ST2+* L. Delgrossi, L. Berger Eds.

RFC 1826 *IP Authentication Header* R. Atkinson

RFC 1828 *IP Authentication using Keyed MD5* P. Metzger, W. Simpson

RFC 1829 *The ESP DES-CBC Transform* P. Karn, P. Metzger, W. Simpson

RFC 1830 *SMTP Service Extensions for Transmission of Large and Binary MIME Messages* G. Vaudreuil

RFC 1831 *RPC: Remote Procedure Call Protocol Specification Version 2* R. Srinivasan

RFC 1832 *XDR: External Data Representation Standard* R. Srinivasan

RFC 1833 *Binding Protocols for ONC RPC Version 2* R. Srinivasan

RFC 1850 *OSPF Version 2 Management Information Base* F. Baker, R. Coltun

RFC 1854 *SMTP Service Extension for Command Pipelining* N. Freed

RFC 1869 *SMTP Service Extensions* J. Klensin, N. Freed, M. Rose, E. Stefferud, D. Crocker

RFC 1870 *SMTP Service Extension for Message Size Declaration* J. Klensin, N. Freed, K. Moore

RFC 1876 *A Means for Expressing Location Information in the Domain Name System* C. Davis, P. Vixie, T. Goodwin, I. Dickinson

RFC 1883 *Internet Protocol, Version 6 (IPv6) Specification* S. Deering, R. Hinden

RFC 1884 *IP Version 6 Addressing Architecture* R. Hinden, S. Deering, Eds.

RFC 1886 *DNS Extensions to support IP version 6* S. Thomson, C. Huitema

RFC 1888 *OSI NSAPs and IPv6* J. Bound, B. Carpenter, D. Harrington, J. Houldsworth, A. Lloyd

RFC 1891 *SMTP Service Extension for Delivery Status Notifications* K. Moore

RFC 1892 *The Multipart/Report Content Type for the Reporting of Mail System Administrative Messages* G. Vaudreuil

RFC 1894 *An Extensible Message Format for Delivery Status Notifications*K. Moore, G. Vaudreuil

RFC 1901 *Introduction to Community-based SNMPv2* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1902 *Structure of Management Information for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1903 *Textual Conventions for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1904 *Conformance Statements for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1905 *Protocol Operations for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1906 *Transport Mappings for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1907 *Management Information Base for Version 2 of the Simple Network Management Protocol (SNMPv2)* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1908 *Coexistence between Version 1 and Version 2 of the Internet-standard Network Management Framework* J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1912 *Common DNS Operational and Configuration Errors* D. Barr

RFC 1918 *Address Allocation for Private Internets* Y. Rekhter, B. Moskowitz, D. Karrenberg, G.J. de Groot, E. Lear

RFC 1928 *SOCKS Protocol Version 5* M. Leech, M. Ganis, Y. Lee, R. Kuris, D. Koblas, L. Jones

RFC 1930 *Guidelines for creation, selection, and registration of an Autonomous System (AS)* J. Hawkinson, T. Bates

RFC 1939 *Post Office Protocol-Version 3* J. Myers, M. Rose

RFC 1981 *Path MTU Discovery for IP version 6* J. McCann, S. Deering, J. Mogul

RFC 1982 *Serial Number Arithmetic* R. Elz, R. Bush

RFC 1985 *SMTP Service Extension for Remote Message Queue Starting* J. De Winter

RFC 1995 *Incremental Zone Transfer in DNS* M. Ohta

RFC 1996 *A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)* P. Vixie

RFC 2010 *Operational Criteria for Root Name Servers* B. Manning, P. Vixie

RFC 2011 *SNMPv2 Management Information Base for the Internet Protocol using SMIv2* K. McCloghrie, Ed.

RFC 2012 *SNMPv2 Management Information Base for the Transmission Control Protocol using SMIv2* K. McCloghrie, Ed.

RFC 2013 *SNMPv2 Management Information Base for the User Datagram Protocol using SMIv2* K. McCloghrie, Ed.

RFC 2018 *TCP Selective Acknowledgement Options* M. Mathis, J. Mahdavi, S. Floyd, A. Romanow

RFC 2026 *The Internet Standards Process — Revision 3* S. Bradner

RFC 2030 *Simple Network Time Protocol (SNTP) Version 4 for IPv4, IPv6 and OSI* D. Mills

RFC 2033 *Local Mail Transfer Protocol* J. Myers

RFC 2034 *SMTP Service Extension for Returning Enhanced Error Codes*N. Freed

RFC 2040 *The RC5, RC5–CBC, RC-5–CBC-Pad, and RC5–CTS Algorithms*R. Baldwin, R. Rivest

RFC 2045 *Multipurpose Internet Mail Extensions (MIME) Part One: Format of Internet Message Bodies* N. Freed, N. Borenstein

RFC 2052 *A DNS RR for specifying the location of services (DNS SRV)* A. Gulbrandsen, P. Vixie

RFC 2065 *Domain Name System Security Extensions* D. Eastlake 3rd, C. Kaufman

RFC 2066 *TELNET CHARSET Option* R. Gellens

RFC 2080 *RIPng for IPv6* G. Malkin, R. Minnear

RFC 2096 *IP Forwarding Table MIB* F. Baker

RFC 2104 *HMAC: Keyed-Hashing for Message Authentication* H. Krawczyk, M. Bellare, R. Canetti

RFC 2119 *Keywords for use in RFCs to Indicate Requirement Levels* S. Bradner

RFC 2133 *Basic Socket Interface Extensions for IPv6* R. Gilligan, S. Thomson, J. Bound, W. Stevens

RFC 2136 *Dynamic Updates in the Domain Name System (DNS UPDATE)* P. Vixie, Ed., S. Thomson, Y. Rekhter, J. Bound

RFC 2137 *Secure Domain Name System Dynamic Update* D. Eastlake 3rd

RFC 2163 *Using the Internet DNS to Distribute MIXER Conformant Global Address Mapping (MCGAM)* C. Allocchio

RFC 2168 *Resolution of Uniform Resource Identifiers using the Domain Name System* R. Daniel, M. Mealling

RFC 2178 *OSPF Version 2* J. Moy

RFC 2181 *Clarifications to the DNS Specification* R. Elz, R. Bush

RFC 2205 *Resource ReSerVation Protocol (RSVP)—Version 1 Functional Specification* R. Braden, Ed., L. Zhang, S. Berson, S. Herzog, S. Jamin

RFC 2210 *The Use of RSVP with IETF Integrated Services* J. Wroclawski

RFC 2211 *Specification of the Controlled-Load Network Element Service* J. Wroclawski

RFC 2212 *Specification of Guaranteed Quality of Service* S. Shenker, C. Partridge, R. Guerin

RFC 2215 *General Characterization Parameters for Integrated Service Network Elements* S. Shenker, J. Wroclawski

RFC 2217 *Telnet Com Port Control Option* G. Clarke

RFC 2219 *Use of DNS Aliases for Network Services* M. Hamilton, R. Wright

RFC 2228 *FTP Security Extensions* M. Horowitz, S. Lunt

RFC 2230 *Key Exchange Delegation Record for the DNS* R. Atkinson

RFC 2233 *The Interfaces Group MIB using SMIv2* K. McCloghrie, F. Kastenholz

RFC 2240 *A Legal Basis for Domain Name Allocation* O. Vaughn

RFC 2246 *The TLS Protocol Version 1.0* T. Dierks, C. Allen

RFC 2251 *Lightweight Directory Access Protocol (v3)* M. Wahl, T. Howes, S. Kille

RFC 2253 *Lightweight Directory Access Protocol (v3): UTF-8 String Representation of Distinguished Names* M. Wahl, S. Kille, T. Howes

RFC 2254 *The String Representation of LDAP Search Filters* T. Howes

RFC 2261 *An Architecture for Describing SNMP Management Frameworks* D. Harrington, R. Presuhn, B. Wijnen

RFC 2262 *Message Processing and Dispatching for the Simple Network Management Protocol (SNMP)* J. Case, D. Harrington, R. Presuhn, B. Wijnen

RFC 2271 *An Architecture for Describing SNMP Management Frameworks* D. Harrington, R. Presuhn, B. Wijnen

RFC 2273 *SNMPv3 Applications* D. Levi, P. Meyer, B. Stewartz

RFC 2274 *User-based Security Model (USM) for version 3 of the Simple Network Management Protocol (SNMPv3)* U. Blumenthal, B. Wijnen

RFC 2275 *View-based Access Control Model (VACM) for the Simple Network Management Protocol (SNMP)* B. Wijnen, R. Presuhn, K. McCloghrie

RFC 2279 *UTF-8, a transformation format of ISO 10646* F. Yergeau

RFC 2292 *Advanced Sockets API for IPv6* W. Stevens, M. Thomas

RFC 2308 *Negative Caching of DNS Queries (DNS NCACHE)* M. Andrews

RFC 2317 *Classless IN-ADDR.ARPA delegation* H. Eidnes, G. de Groot, P. Vixie

RFC 2320 *Definitions of Managed Objects for Classical IP and ARP Over ATM Using SMIv2 (IPOA-MIB)* M. Greene, J. Luciani, K. White, T. Kuo

RFC 2328 *OSPF Version 2* J. Moy

RFC 2345 *Domain Names and Company Name Retrieval* J. Klensin, T. Wolf, G. Oglesby

RFC 2352 *A Convention for Using Legal Names as Domain Names* O. Vaughn

RFC 2355 *TN3270 Enhancements* B. Kelly

RFC 2358 *Definitions of Managed Objects for the Ethernet-like Interface Types* J. Flick, J. Johnson

RFC 2373 *IP Version 6 Addressing Architecture* R. Hinden, S. Deering

RFC 2374 *An IPv6 Aggregatable Global Unicast Address Format* R. Hinden, M. O'Dell, S. Deering

RFC 2375 *IPv6 Multicast Address Assignments* R. Hinden, S. Deering

RFC 2385 *Protection of BGP Sessions via the TCP MD5 Signature Option*A. Hefferman

RFC 2389 *Feature negotiation mechanism for the File Transfer Protocol* P. Hethmon, R. Elz

RFC 2401 *Security Architecture for Internet Protocol* S. Kent, R. Atkinson

RFC 2402 *IP Authentication Header* S. Kent, R. Atkinson

RFC 2403 *The Use of HMAC-MD5–96 within ESP and AH* C. Madson, R. Glenn

RFC 2404 *The Use of HMAC-SHA–1–96 within ESP and AH* C. Madson, R. Glenn

RFC 2405 *The ESP DES-CBC Cipher Algorithm With Explicit IV* C. Madson, N. Doraswamy

RFC 2406 *IP Encapsulating Security Payload (ESP)* S. Kent, R. Atkinson

RFC 2407 *The Internet IP Security Domain of Interpretation for ISAKMP*D. Piper

RFC 2408 *Internet Security Association and Key Management Protocol (ISAKMP)* D. Maughan, M. Schertler, M. Schneider, J. Turner

RFC 2409 *The Internet Key Exchange (IKE)* D. Harkins, D. Carrel

RFC 2410 *The NULL Encryption Algorithm and Its Use With IPsec* R. Glenn, S. Kent,

RFC 2428 *FTP Extensions for IPv6 and NATs* M. Allman, S. Ostermann, C. Metz

RFC 2445 *Internet Calendaring and Scheduling Core Object Specification (iCalendar)* F. Dawson, D. Stenerson

RFC 2459 *Internet X.509 Public Key Infrastructure Certificate and CRL Profile* R. Housley, W. Ford, W. Polk, D. Solo

RFC 2460 *Internet Protocol, Version 6 (IPv6) Specification* S. Deering, R. Hinden

RFC 2461 *Neighbor Discovery for IP Version 6 (IPv6)* T. Narten, E. Nordmark, W. Simpson

RFC 2462 *IPv6 Stateless Address Autoconfiguration* S. Thomson, T. Narten

RFC 2463 *Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) Specification* A. Conta, S. Deering

RFC 2464 *Transmission of IPv6 Packets over Ethernet Networks* M. Crawford

RFC 2466 *Management Information Base for IP Version 6: ICMPv6 Group* D. Haskin, S. Onishi

RFC 2476 *Message Submission* R. Gellens, J. Klensin

RFC 2487 *SMTP Service Extension for Secure SMTP over TLS* P. Hoffman

RFC 2505 *Anti-Spam Recommendations for SMTP MTAs* G. Lindberg

RFC 2523 *Photuris: Extended Schemes and Attributes* P. Karn, W. Simpson

RFC 2535 *Domain Name System Security Extensions* D. Eastlake 3rd

RFC 2538 *Storing Certificates in the Domain Name System (DNS)* D. Eastlake 3rd, O. Gudmundsson

RFC 2539 *Storage of Diffie-Hellman Keys in the Domain Name System (DNS)* D. Eastlake 3rd

RFC 2540 *Detached Domain Name System (DNS) Information* D. Eastlake 3rd

RFC 2554 *SMTP Service Extension for Authentication* J. Myers

RFC 2570 *Introduction to Version 3 of the Internet-standard Network Management Framework* J. Case, R. Mundy, D. Partain, B. Stewart

RFC 2571 *An Architecture for Describing SNMP Management Frameworks* B. Wijnen, D. Harrington, R. Presuhn

RFC 2572 *Message Processing and Dispatching for the Simple Network Management Protocol (SNMP)* J. Case, D. Harrington, R. Presuhn, B. Wijnen

RFC 2573 *SNMP Applications* D. Levi, P. Meyer, B. Stewart

RFC 2574 *User-based Security Model (USM) for version 3 of the Simple Network Management Protocol (SNMPv3)* U. Blumenthal, B. Wijnen

RFC 2575 *View-based Access Control Model (VACM) for the Simple Network Management Protocol (SNMP)* B. Wijnen, R. Presuhn, K. McCloghrie

RFC 2576 *Co-Existence between Version 1, Version 2, and Version 3 of the Internet-standard Network Management Framework* R. Frye, D. Levi, S. Routhier, B. Wijnen

RFC 2578 *Structure of Management Information Version 2 (SMIv2)* K. McCloghrie, D. Perkins, J. Schoenwaelder

RFC 2579 *Textual Conventions for SMIv2* K. McCloghrie, D. Perkins, J. Schoenwaelder

RFC 2580 *Conformance Statements for SMIv2* K. McCloghrie, D. Perkins, J. Schoenwaelder

RFC 2581 *TCP Congestion Control* M. Allman, V. Paxson, W. Stevens

RFC 2583 *Guidelines for Next Hop Client (NHC) Developers* R. Carlson, L. Winkler

RFC 2591 *Definitions of Managed Objects for Scheduling Management Operations* D. Levi, J. Schoenwaelder

RFC 2625 *IP and ARP over Fibre Channel* M. Rajagopal, R. Bhagwat, W. Rickard

RFC 2635 *Don't SPEW A Set of Guidelines for Mass Unsolicited Mailings and Postings (spam*)* S. Hambridge, A. Lunde

RFC 2637 *Point-to-Point Tunneling Protocol* K. Hamzeh, G. Pall, W. Verthein, J. Taarud, W. Little, G. Zorn

RFC 2640 *Internationalization of the File Transfer Protocol* B. Curtin

RFC 2665 *Definitions of Managed Objects for the Ethernet-like Interface Types* J. Flick, J. Johnson

RFC 2671 *Extension Mechanisms for DNS (EDNS0)* P. Vixie

RFC 2672 *Non-Terminal DNS Name Redirection* M. Crawford

RFC 2675 *IPv6 Jumbograms* D. Borman, S. Deering, R. Hinden

RFC 2710 *Multicast Listener Discovery (MLD) for IPv6* S. Deering, W. Fenner, B. Haberman

RFC 2711 *IPv6 Router Alert Option* C. Partridge, A. Jackson

RFC 2740 *OSPF for IPv6* R. Coltun, D. Ferguson, J. Moy

RFC 2753 *A Framework for Policy-based Admission Control* R. Yavatkar, D. Pendarakis, R. Guerin

RFC 2782 *A DNS RR for specifying the location of services (DNS SRV)* A. Gubrandsen, P. Vixix, L. Esibov

RFC 2821 *Simple Mail Transfer Protocol* J. Klensin, Ed.

RFC 2822 *Internet Message Format* P. Resnick, Ed.

RFC 2840 *TELNET KERMIT OPTION* J. Altman, F. da Cruz

RFC 2845 *Secret Key Transaction Authentication for DNS (TSIG)* P. Vixie, O. Gudmundsson, D. Eastlake 3rd, B. Wellington

RFC 2851 *Textual Conventions for Internet Network Addresses* M. Daniele, B. Haberman, S. Routhier, J. Schoenwaelder

RFC 2852 *Deliver By SMTP Service Extension* D. Newman

RFC 2874 *DNS Extensions to Support IPv6 Address Aggregation and Renumbering* M. Crawford, C. Huitema

RFC 2915 *The Naming Authority Pointer (NAPTR) DNS Resource Record* M. Mealling, R. Daniel

RFC 2920 *SMTP Service Extension for Command Pipelining* N. Freed

RFC 2930 *Secret Key Establishment for DNS (TKEY RR)* D. Eastlake, 3rd

RFC 2941 *Telnet Authentication Option* T. Ts'o, ed., J. Altman

RFC 2942 *Telnet Authentication: Kerberos Version 5* T. Ts'o

RFC 2946 *Telnet Data Encryption Option* T. Ts'o

RFC 2952 *Telnet Encryption: DES 64 bit Cipher Feedback* T. Ts'o

RFC 2953 *Telnet Encryption: DES 64 bit Output Feedback* T. Ts'o

RFC 2992 *Analysis of an Equal-Cost Multi-Path Algorithm* C. Hopps

RFC 3019 *IP Version 6 Management Information Base for The Multicast Listener Discovery Protocol* B. Haberman, R. Worzella

RFC 3060 *Policy Core Information Model—Version 1 Specification* B. Moore, E. Ellesson, J. Strassner, A. Westerinen

RFC 3152 *Delegation of IP6.ARPA* R. Bush

RFC 3164 *The BSD Syslog Protocol* C. Lonvick

RFC 3207 *SMTP Service Extension for Secure SMTP over Transport Layer Security* P. Hoffman

RFC 3226 *DNSSEC and IPv6 A6 aware server/resolver message size requirements* O. Gudmundsson

RFC 3291 *Textual Conventions for Internet Network Addresses* M. Daniele, B. Haberman, S. Routhier, J. Schoenwaelder

RFC 3363 *Representing Internet Protocol version 6 (IPv6) Addresses in the Domain Name System* R. Bush, A. Durand, B. Fink, O. Gudmundsson, T. Hain

RFC 3376 *Internet Group Management Protocol, Version 3* B. Cain, S. Deering, I. Kouvelas, B. Fenner, A. Thyagarajan

RFC 3390 *Increasing TCP's Initial Window* M. Allman, S. Floyd, C. Partridge

RFC 3410 *Introduction and Applicability Statements for Internet-Standard Management Framework* J. Case, R. Mundy, D. Partain, B. Stewart

RFC 3411 *An Architecture for Describing Simple Network Management Protocol (SNMP) Management Frameworks* D. Harrington, R. Presuhn, B. Wijnen

RFC 3412 *Message Processing and Dispatching for the Simple Network Management Protocol (SNMP)* J. Case, D. Harrington, R. Presuhn, B. Wijnen

RFC 3413 *Simple Network Management Protocol (SNMP) Applications* D. Levi, P. Meyer, B. Stewart

RFC 3414 *User-based Security Model (USM) for version 3 of the Simple Network Management Protocol (SNMPv3)* U. Blumenthal, B. Wijnen

RFC 3415 *View-based Access Control Model (VACM) for the Simple Network Management Protocol (SNMP)* B. Wijnen, R. Presuhn, K. McCloghrie

RFC 3416 *Version 2 of the Protocol Operations for the Simple Network Management Protocol (SNMP)* R. Presuhn, J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 3417 *Transport Mappings for the Simple Network Management Protocol (SNMP)* R. Presuhn, J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 3418 *Management Information Base (MIB) for the Simple Network Management Protocol (SNMP)* R. Presuhn, J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 3419 *Textual Conventions for Transport Addresses* M. Daniele, J. Schoenwaelder

RFC 3484 *Default Address Selection for Internet Protocol version 6 (IPv6)* R. Draves

RFC 3493 *Basic Socket Interface Extensions for IPv6* R. Gilligan, S. Thomson, J. Bound, J. McCann, W. Stevens

RFC 3513 *Internet Protocol Version 6 (IPv6) Addressing Architecture* R. Hinden, S. Deering

RFC 3526 *More Modular Exponential (MODP) Diffie-Hellman groups for Internet Key Exchange (IKE)* T. Kivinen, M. Kojo

RFC 3542 *Advanced Sockets Application Programming Interface (API) for IPv6* W. Richard Stevens, M. Thomas, E. Nordmark, T. Jinmei

RFC 3566 *The AES-XCBC-MAC-96 Algorithm and Its Use With IPsec* S. Frankel, H. Herbert

RFC 3569 *An Overview of Source-Specific Multicast (SSM)* S. Bhattacharyya, Ed.

RFC 3584 *Coexistence between Version 1, Version 2, and Version 3 of the Internet-standard Network Management Framework* R. Frye, D. Levi, S. Routhier, B. Wijnen

RFC 3602 *The AES-CBC Cipher Algorithm and Its Use with IPsec* S. Frankel, R. Glenn, S. Kelly

RFC 3629 *UTF-8, a transformation format of ISO 10646* R. Kermode, C. Vicisano

RFC 3658 *Delegation Signer (DS) Resource Record (RR)* O. Gudmundsson

RFC 3678 *Socket Interface Extensions for Multicast Source Filters* D. Thaler, B. Fenner, B. Quinn

RFC 3715 *IPsec-Network Address Translation (NAT) Compatibility Requirements* B. Aboba, W. Dixon

RFC 3810 *Multicast Listener Discovery Version 2 (MLDv2) for IPv6* R. Vida, Ed., L. Costa, Ed.

RFC 3947 *Negotiation of NAT-Traversal in the IKE* T. Kivinen, B. Swander, A. Huttunen, V. Volpe

RFC 3948 *UDP Encapsulation of IPsec ESP Packets* A. Huttunen, B. Swander, V. Volpe, L. DiBurro, M. Stenberg

RFC 4001 *Textual Conventions for Internet Network Addresses* M. Daniele, B. Haberman, S. Routhier, J. Schoenwaelder

RFC 4007 *IPv6 Scoped Address Architecture* S. Deering, B. Haberman, T. Jinmei, E. Nordmark, B. Zill

RFC 4022 *Management Information Base for the Transmission Control Protocol (TCP)* R. Raghunarayan

RFC 4106 *The Use of Galois/Counter Mode (GCM) in IPsec Encapsulating Security Payload (ESP)* J. Viega, D. McGrew

RFC 4109 *Algorithms for Internet Key Exchange version 1 (IKEv1)* P. Hoffman

RFC 4113 *Management Information Base for the User Datagram Protocol (UDP)* B. Fenner, J. Flick

RFC 4191 *Default Router Preferences and More-Specific Routes* R. Draves, D. Thaler

RFC 4217 *Securing FTP with TLS* P. Ford-Hutchinson

RFC 4292 *IP Forwarding Table MIB* B. Haberman

RFC 4293 *Management Information Base for the Internet Protocol (IP)* S. Routhier

RFC 4301 *Security Architecture for the Internet Protocol* S. Kent, K. Seo

RFC 4302 *IP Authentication Header* S. Kent

RFC 4303 *IP Encapsulating Security Payload (ESP)* S. Kent

RFC 4304 *Extended Sequence Number (ESN) Addendum to IPsec Domain of Interpretation (DOI) for Internet Security Association and Key Management Protocol (ISAKMP)* S. Kent

RFC 4306 *Internet Key Exchange (IKEv2) Protocol* C. Kaufman, Ed.

RFC 4307 *Cryptographic Algorithms for Use in the Internet Key Exchange Version 2 (IKEv2)* J. Schiller

RFC 4308 *Cryptographic Suites for IPsec* P. Hoffman

RFC 4434 *The AES-XCBC-PRF-128 Algorithm for the Internet Key Exchange Protocol* P. Hoffman

RFC 4552 *Authentication/Confidentiality for OSPFv3* M. Gupta, N. Melam

RFC 4678 *Server/Application State Protocol v1* A. Bivens

RFC 4718 *IKEv2 Clarifications and Implementation Guidelines* P. Eronen, P. Hoffman

RFC 4753 *ECP Groups for IKE and IKEv2* D. Fu, J. Solinas

RFC 4754 *IKE and IKEv2 Authentication Using the Elliptic Curve Digital Signature Algorithm (ECDSA)* D. Fu, J. Solinas

RFC 4809	*Requirements for an IPsec Certificate Management Profile* C. Bonatti, Ed., S. Turner, Ed., G. Lebovitz, Ed.
RFC 4835	*Cryptographic Algorithm Implementation Requirements for Encapsulating Security Payload (ESP) and Authentication Header* V. Manral
RFC 4862	*IPv6 Stateless Address Autoconfiguration* S. Thomson, T. Narten, T. Jinmei
RFC 4868	*Using HMAC-SHA-256, HMAC-SHA-384, and HMAC-SHA-512 with IPsec* S. Kelly, S. Frankel
RFC 4869	*Suite B Cryptographic Suites for IPsec* L. Law, J. Solinas
RFC 4941	*Privacy Extensions for Stateless Address Autoconfiguration in IPv6* T. Narten, R. Draves, S. Krishnan
RFC 4945	*The Internet IP Security PKI Profile of IKEv1/ISAKMP, IKEv2, and PKIX* B. Korver
RFC 5014	*IPv6 Socket API for Source Address Selection* E. Nordmark, S. Chakrabarti, J. Laganier
RFC 5095	*Deprecation of Type 0 Routing Headers in IPv6* J. Abley, P. Savola, G. Neville-Neil
RFC 5175	*IPv6 Router Advertisement Flags Option* B. Haberman, Ed., R. Hinden
RFC 5282	*Using Authenticated Encryption Algorithms with the Encrypted Payload of the Internet Key Exchange version 2 (IKEv2) Protocol* D. Black, D. McGrew

Internet drafts

Internet drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Other groups may also distribute working documents as Internet drafts. You can see Internet drafts at http://www.ietf.org/ID.html.

Several areas of IPv6 implementation include elements of the following Internet drafts and are subject to change during the RFC review process.

Draft Title and Author

draft-ietf-ipngwg-icmp-v3-07
Internet Control Message Protocol (ICMPv6) for the Internet Protocol Version 6 (IPv6) Specification A. Conta, S. Deering

Appendix H. Accessibility

Publications for this product are offered in Adobe Portable Document Format (PDF) and should be compliant with accessibility standards. If you experience difficulties when using PDF files, you may view the information through the z/OS Internet Library Web site or the z/OS Information Center. If you continue to experience problems, send an e-mail to mhvrcfs@us.ibm.com or write to:

IBM Corporation
Attention: MHVRCFS Reader Comments
Department H6MA, Mail Station P181
2455 South Road
Poughkeepsie, NY 12601-5400
U.S.A.

Accessibility features help a user who has a physical disability, such as restricted mobility or limited vision, to use software products successfully. The major accessibility features in z/OS enable users to:

- Use assistive technologies such as screen readers and screen magnifier software
- Operate specific or equivalent features using only the keyboard
- Customize display attributes such as color, contrast, and font size

Using assistive technologies

Assistive technology products, such as screen readers, function with the user interfaces found in z/OS. Consult the assistive technology documentation for specific information when using such products to access z/OS interfaces.

Keyboard navigation of the user interface

Users can access z/OS user interfaces using TSO/E or ISPF. Refer to *z/OS TSO/E Primer*, *z/OS TSO/E User's Guide*, and *z/OS ISPF User's Guide Vol I* for information about accessing TSO/E and ISPF interfaces. These guides describe how to use TSO/E and ISPF, including the use of keyboard shortcuts or function keys (PF keys). Each guide includes the default settings for the PF keys and explains how to modify their functions.

z/OS information

z/OS information is accessible using screen readers with the BookServer/Library Server versions of z/OS books in the Internet library at www.ibm.com/systems/z/os/zos/bkserv/.

Notices

This information was developed for products and services offered in the USA.

IBM may not offer all of the products, services, or features discussed in this document in other countries. Consult your local IBM representative for information on the products and services currently available in your area. Any reference to an IBM product, program, or service is not intended to state or imply that only that IBM product, program, or service may be used. Any functionally equivalent product, program, or service that does not infringe any IBM intellectual property right may be used instead. However, it is the user's responsibility to evaluate and verify the operation of any non-IBM product, program, or service.

IBM may have patents or pending patent applications covering subject matter described in this document. The furnishing of this document does not give you any license to these patents. You can send license inquiries, in writing, to:

IBM Director of Licensing
IBM Corporation
North Castle Drive
Armonk, NY 10504-1785
U.S.A.

For license inquiries regarding double-byte (DBCS) information, contact the IBM Intellectual Property Department in your country or send inquiries, in writing, to:

Intellectual Property Licensing
Legal and Intellectual Property Law
IBM Japan Ltd.
1623-14 Shimotsuruma,, Yamato-Shi
Kanagawa 242-8502 Japan

The following paragraph does not apply to the United Kingdom or any other country where such provisions are inconsistent with local law:
INTERNATIONAL BUSINESS MACHINES CORPORATION PROVIDES THIS PUBLICATION "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESS OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF NON-INFRINGEMENT, MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. Some states do not allow disclaimer of express or implied warranties in certain transactions, therefore, this statement may not apply to you.

This information could include technical inaccuracies or typographical errors. Changes are periodically made to the information herein; these changes will be incorporated in new editions of the publication. IBM may make improvements and/or changes in the product(s) and/or the program(s) described in this publication at any time without notice.

Any references in this information to non-IBM Web sites are provided for convenience only and do not in any manner serve as an endorsement of those Web sites. The materials at those Web sites are not part of the materials for this IBM product and use of those Web sites is at your own risk.

IBM may use or distribute any of the information you supply in any way it believes appropriate without incurring any obligation to you.

Licensees of this program who wish to have information about it for the purpose of enabling: (i) the exchange of information between independently created programs and other programs (including this one) and (ii) the mutual use of the information which has been exchanged, should contact:

Site Counsel
IBM Corporation
P.O. Box 12195
3039 Cornwallis Road
Research Triangle Park, North Carolina 27709-2195
U.S.A

Such information may be available, subject to appropriate terms and conditions, including in some cases, payment of a fee.

The licensed program described in this information and all licensed material available for it are provided by IBM under terms of the IBM Customer Agreement, IBM International Program License Agreement, or any equivalent agreement between us.

Any performance data contained herein was determined in a controlled environment. Therefore, the results obtained in other operating environments may vary significantly. Some measurements may have been made on development-level systems and there is no guarantee that these measurements will be the same on generally available systems. Furthermore, some measurement may have been estimated through extrapolation. Actual results may vary. Users of this document should verify the applicable data for their specific environment.

Information concerning non-IBM products was obtained from the suppliers of those products, their published announcements or other publicly available sources. IBM has not tested those products and cannot confirm the accuracy of performance, compatibility or any other claims related to non-IBM products. Questions on the capabilities of non-IBM products should be addressed to the suppliers of those products.

All statements regarding IBM's future direction or intent are subject to change or withdrawal without notice, and represent goals and objectives only.

This information contains examples of data and reports used in daily business operations. To illustrate them as completely as possible, the examples include the names of individuals, companies, brands, and products. All of these names are fictitious and any similarity to the names and addresses used by an actual business enterprise is entirely coincidental.

COPYRIGHT LICENSE:

This information contains sample application programs in source language, which illustrates programming techniques on various operating platforms. You may copy, modify, and distribute these sample programs in any form without payment to IBM, for the purposes of developing, using, marketing or distributing application programs conforming to the application programming interface for the operating platform for which the sample programs are written. These examples have not been thoroughly tested under all conditions. IBM, therefore, cannot guarantee or

imply reliability, serviceability, or function of these programs. The sample programs are provided "AS IS", without warranty of any kind. IBM shall not be liable for any damages arising out of your use of the sample programs.

Each copy or any portion of these sample programs or any derivative work must include a copyright notice as follows:

© (your company name) (year). Portions of this code are derived from IBM Corp. Sample Programs. © Copyright IBM Corp. _enter the year or years_.

IBM is required to include the following statements in order to distribute portions of this document and the software described herein to which contributions have been made by The University of California. If you are viewing this information softcopy, the photographs and color illustrations may not appear.

You can obtain softcopy from the z/OS Collection (SK3T-4269), which contains BookManager and PDF formats.

Policy for unsupported hardware

Various z/OS elements, such as DFSMS, HCD, JES2, JES3, and MVS, contain code that supports specific hardware servers or devices. In some cases, this device-related element support remains in the product even after the hardware devices pass their announced End of Service date. z/OS may continue to service element code; however, it will not provide service related to unsupported hardware devices. Software problems related to these devices will not be accepted for service, and current service activity will cease if a problem is determined to be associated with out-of-support devices. In such cases, fixes will not be issued.

Trademarks

IBM, the IBM logo, and ibm.com are trademarks or registered trademarks of International Business Machines Corp., registered in many jurisdictions worldwide. Other product and service names might be trademarks of IBM or other companies. A current list of IBM trademarks is available on the Web at Copyright and trademark information at www.ibm.com/legal/copytrade.shtml.

Adobe and PostScript are registered trademarks of Adobe Systems Incorporated in the United States, and/or other countries.

Intel is a registered trademark of Intel Corporation or its subsidiaries in the United States and other countries.

Java and all Java-based trademarks and logos are trademarks of Sun Microsystems, Inc. in the United States, other countries, or both.

Linux is a registered trademark of Linus Torvalds in the United States, other countries, or both.

Microsoft and Windows are trademarks of Microsoft Corporation in the United States, other countries, or both.

UNIX is a registered trademark of The Open Group in the United States and other countries.

Other product and service names might be trademarks of IBM or other companies.

Bibliography

This bibliography contains descriptions of the documents in the z/OS Communications Server library.

z/OS Communications Server documentation is available in the following forms:

- Online at the z/OS Internet Library web page at www.ibm.com/systems/z/os/zos/bkserv/
- In softcopy on CD-ROM collections. See "Softcopy information" on page xxxv.

z/OS Communications Server library updates

An index to z/OS Communications Server book updates is at http://www.ibm.com/support/docview.wss?uid=swg21178966. Updates to documents are also available on RETAIN® and in information APARs (info APARs). Go to http://www.ibm.com/software/network/commserver/zos/support to view information APARs. In addition, Info APARs for z/OS documents are in *z/OS and z/OS.e DOC APAR and PTF ++HOLD Documentation*, which can be found at http://publibz.boulder.ibm.com/cgi-bin/bookmgr_OS390/ BOOKS/ZIDOCMST/CCONTENTS.

z/OS Communications Server information

z/OS Communications Server product information is grouped by task in the following tables.

Planning

Title	Number	Description
z/OS Communications Server: New Function Summary	GC31-8771	This document is intended to help you plan for new IP for SNA function, whether you are migrating from a previous version or installing z/OS for the first time. It summarizes what is new in the release and identifies the suggested and required modifications needed to use the enhanced functions.
z/OS Communications Server: IPv6 Network and Application Design Guide	SC31-8885	This document is a high-level introduction to IPv6. It describes concepts of z/OS Communications Server's support of IPv6, coexistence with IPv4, and migration issues.

Resource definition, configuration, and tuning

Title	Number	Description
z/OS Communications Server: IP Configuration Guide	SC31-8775	This document describes the major concepts involved in understanding and configuring an IP network. Familiarity with the z/OS operating system, IP protocols, z/OS UNIX System Services, and IBM Time Sharing Option (TSO) is recommended. Use this document in conjunction with the *z/OS Communications Server: IP Configuration Reference*.

Title	Number	Description
z/OS Communications Server: IP Configuration Reference	SC31-8776	This document presents information for people who want to administer and maintain IP. Use this document in conjunction with the *z/OS Communications Server: IP Configuration Guide*. The information in this document includes: • TCP/IP configuration data sets • Configuration statements • Translation tables • Protocol number and port assignments
z/OS Communications Server: SNA Network Implementation Guide	SC31-8777	This document presents the major concepts involved in implementing an SNA network. Use this document in conjunction with the *z/OS Communications Server: SNA Resource Definition Reference*.
z/OS Communications Server: SNA Resource Definition Reference	SC31-8778	This document describes each SNA definition statement, start option, and macroinstruction for user tables. It also describes NCP definition statements that affect SNA. Use this document in conjunction with the *z/OS Communications Server: SNA Network Implementation Guide*.
z/OS Communications Server: SNA Resource Definition Samples	SC31-8836	This document contains sample definitions to help you implement SNA functions in your networks, and includes sample major node definitions.
z/OS Communications Server: IP Network Print Facility	SC31-8833	This document is for system programmers and network administrators who need to prepare their network to route SNA, JES2, or JES3 printer output to remote printers using TCP/IP Services.

Operation

Title	Number	Description
z/OS Communications Server: IP User's Guide and Commands	SC31-8780	This document describes how to use TCP/IP applications. It contains requests that allow a user to log on to a remote host using Telnet, transfer data sets using FTP, send and receive electronic mail, print on remote printers, and authenticate network users.
z/OS Communications Server: IP System Administrator's Commands	SC31-8781	This document describes the functions and commands helpful in configuring or monitoring your system. It contains system administrator's commands, such as TSO NETSTAT, PING, TRACERTE and their UNIX counterparts. It also includes TSO and MVS commands commonly used during the IP configuration process.
z/OS Communications Server: SNA Operation	SC31-8779	This document serves as a reference for programmers and operators requiring detailed information about specific operator commands.
z/OS Communications Server: Quick Reference	SX75-0124	This document contains essential information about SNA and IP commands.

Customization

Title	Number	Description
z/OS Communications Server: SNA Customization	SC31-6854	This document enables you to customize SNA, and includes the following: • Communication network management (CNM) routing table • Logon-interpret routine requirements • Logon manager installation-wide exit routine for the CLU search exit • TSO/SNA installation-wide exit routines • SNA installation-wide exit routines

Writing application programs

Title	Number	Description
z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference	SC31-8788	This document describes the syntax and semantics of program source code necessary to write your own application programming interface (API) into TCP/IP. You can use this interface as the communication base for writing your own client or server application. You can also use this document to adapt your existing applications to communicate with each other using sockets over TCP/IP.
z/OS Communications Server: IP CICS Sockets Guide	SC31-8807	This document is for programmers who want to set up, write application programs for, and diagnose problems with the socket interface for CICS using z/OS TCP/IP.
z/OS Communications Server: IP IMS Sockets Guide	SC31-8830	This document is for programmers who want application programs that use the IMS TCP/IP application development services provided by the TCP/IP Services of IBM.
z/OS Communications Server: IP Programmer's Guide and Reference	SC31-8787	This document describes the syntax and semantics of a set of high-level application functions that you can use to program your own applications in a TCP/IP environment. These functions provide support for application facilities, such as user authentication, distributed databases, distributed processing, network management, and device sharing. Familiarity with the z/OS operating system, TCP/IP protocols, and IBM Time Sharing Option (TSO) is recommended.
z/OS Communications Server: SNA Programming	SC31-8829	This document describes how to use SNA macroinstructions to send data to and receive data from (1) a terminal in either the same or a different domain, or (2) another application program in either the same or a different domain.
z/OS Communications Server: SNA Programmer's LU 6.2 Guide	SC31-8811	This document describes how to use the SNA LU 6.2 application programming interface for host application programs. This document applies to programs that use only LU 6.2 sessions or that use LU 6.2 sessions along with other session types. (Only LU 6.2 sessions are covered in this document.)
z/OS Communications Server: SNA Programmer's LU 6.2 Reference	SC31-8810	This document provides reference material for the SNA LU 6.2 programming interface for host application programs.
z/OS Communications Server: CSM Guide	SC31-8808	This document describes how applications use the communications storage manager.

Title	Number	Description
z/OS Communications Server: CMIP Services and Topology Agent Guide	SC31-8828	This document describes the Common Management Information Protocol (CMIP) programming interface for application programmers to use in coding CMIP application programs. The document provides guide and reference information about CMIP services and the SNA topology agent.

Diagnosis

Title	Number	Description
z/OS Communications Server: IP Diagnosis Guide	GC31-8782	This document explains how to diagnose TCP/IP problems and how to determine whether a specific problem is in the TCP/IP product code. It explains how to gather information for and describe problems to the IBM Software Support Center.
z/OS Communications Server: ACF/TAP Trace Analysis Handbook	GC23-8588-00	This document explains how to gather the trace data that is collected and stored in the host processor. It also explains how to use the Advanced Communications Function/Trace Analysis Program (ACF/TAP) service aid to produce reports for analyzing the trace data information.
z/OS Communications Server: SNA Diagnosis Vol 1, Techniques and Procedures and *z/OS Communications Server: SNA Diagnosis Vol 2, FFST Dumps and the VIT*	GC31-6850 GC31-6851	These documents help you identify an SNA problem, classify it, and collect information about it before you call the IBM Support Center. The information collected includes traces, dumps, and other problem documentation.
z/OS Communications Server: SNA Data Areas Volume 1 and *z/OS Communications Server: SNA Data Areas Volume 2*	GC31-6852 GC31-6853	These documents describe SNA data areas and can be used to read an SNA dump. They are intended for IBM programming service representatives and customer personnel who are diagnosing problems with SNA.

Messages and codes

Title	Number	Description
z/OS Communications Server: SNA Messages	SC31-8790	This document describes the ELM, IKT, IST, IUT, IVT, and USS messages. Other information in this document includes: • Command and RU types in SNA messages • Node and ID types in SNA messages • Supplemental message-related information
z/OS Communications Server: IP Messages Volume 1 (EZA)	SC31-8783	This volume contains TCP/IP messages beginning with EZA.
z/OS Communications Server: IP Messages Volume 2 (EZB, EZD)	SC31-8784	This volume contains TCP/IP messages beginning with EZB or EZD.
z/OS Communications Server: IP Messages Volume 3 (EZY)	SC31-8785	This volume contains TCP/IP messages beginning with EZY.
z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)	SC31-8786	This volume contains TCP/IP messages beginning with EZZ and SNM.
z/OS Communications Server: IP and SNA Codes	SC31-8791	This document describes codes and other information that appear in z/OS Communications Server messages.

Communicating your comments to IBM

If you especially like or dislike anything about this document, please use one of the methods listed below to send your comments to IBM. Whichever method you choose, make sure you send your name, address, and telephone number if you would like a reply.

Feel free to comment on specific errors or omissions, accuracy, organization, subject matter, or completeness of this document. However, the comments you send should pertain to only the information in this manual and the way in which the information is presented. To request additional publications, or to ask questions or make comments about the functions of IBM products or systems, you should talk to your IBM representative or to your IBM authorized remarketer.

When you send comments to IBM, you grant IBM a nonexclusive right to use or distribute your comments in any way it believes appropriate without incurring any obligation to you.

Please send your comments to us in either of the following ways:

- If you prefer to send comments by FAX, use this number: 1+919-254-1258
- If you prefer to send comments electronically, use this address:
  - comsvrcf@us.ibm.com
- If you prefer to send comments by post, use this address:

```
International Business Machines Corporation
Attn: z/OS Communications Server Information Development
P.O. Box 12195, 3039 Cornwallis Road
Department AKCA, Building 501
Research Triangle Park, North Carolina 27709-2195
```

Make sure to include the following in your note:

- Title and publication number of this document
- Page number or topic to which your comment applies.
